With the advent of effective, noninvasive pelvic stabilization techniques and rapid angiography and embolization, external fixators are no longer routinely placed in the ED. External fixators may be used in the operating room in patients requiring laparotomy. When transfer to a regional trauma center is imminent, time should not be wasted waiting for an orthopedic surgeon to apply a fixator. Instead, a temporary device should be applied, and transport should proceed without delay.

Detection of Intraperitoneal Hemorrhage

During the initial assessment of the unstable patient with pelvic trauma, it is essential to quickly identify the predominant site of hemorrhage. Immediate angiography and pelvic stabilization is indicated if pelvic bleeding poses the primary life threat. An exploratory laparotomy should be performed first, however, if there is evidence of intra-abdominal hemorrhage.

Focused abdominal sonography for trauma (FAST) is routinely used in trauma centers for the rapid detection of hemoperitoneum following blunt abdominal injury. However investigators have found that the FAST examination is not sufficiently sensitive in patients with pelvic fractures to rule out intraperitoneal hemorrhage. Friese et al. reported a sensitivity of 26% for hemoperitoneum in patients with a pelvic fracture. Thirty-one of 96 patients had a false-negative study. The authors concluded that a patient with a negative FAST examination still requires a confirmatory test, such as CT or diagnostic peritoneal lavage (DPL) (15). Tayal et al. (16) also

reported a lower sensitivity of the FAST examination in the presence of a pelvic fracture (80.8%) compared to patients with blunt abdominal injury without a pelvic fracture. While not sensitive in these patients, the FAST examination does have sufficient specificity in patients with unstable vital signs and a pelvic fracture to recommend laparotomy for control of intra-abdominal hemorrhage.

The following approach based on the Ultrasound (US) findings and hemodynamic status of the patient is recommended.

1. US (+), patient stable: Perform abdominal CT.
2. US (+), patient unstable: Perform DPL aspirate or laparotomy.
3. US (–), patient stable: Perform abdominal CT or close observation.
4. US (–), patient unstable: Perform DPL aspirate (17).

When using a DPL in patients with pelvic fractures, the supraumbilical technique is preferred and has higher specificity. Classically, it has been recommended that the DPL be performed using a semi-open technique, but some authors are now reporting success using a percutaneous technique. Because the lavage can be falsely positive in patients with a pelvic fracture, the DPL aspirate should be used to guide decision making. An aspirate of 10 mL of gross blood is suggestive of intra-abdominal hemorrhage (17). An algorithm for the detection of intraperitoneal hemorrhage is presented in Figure 42.13.

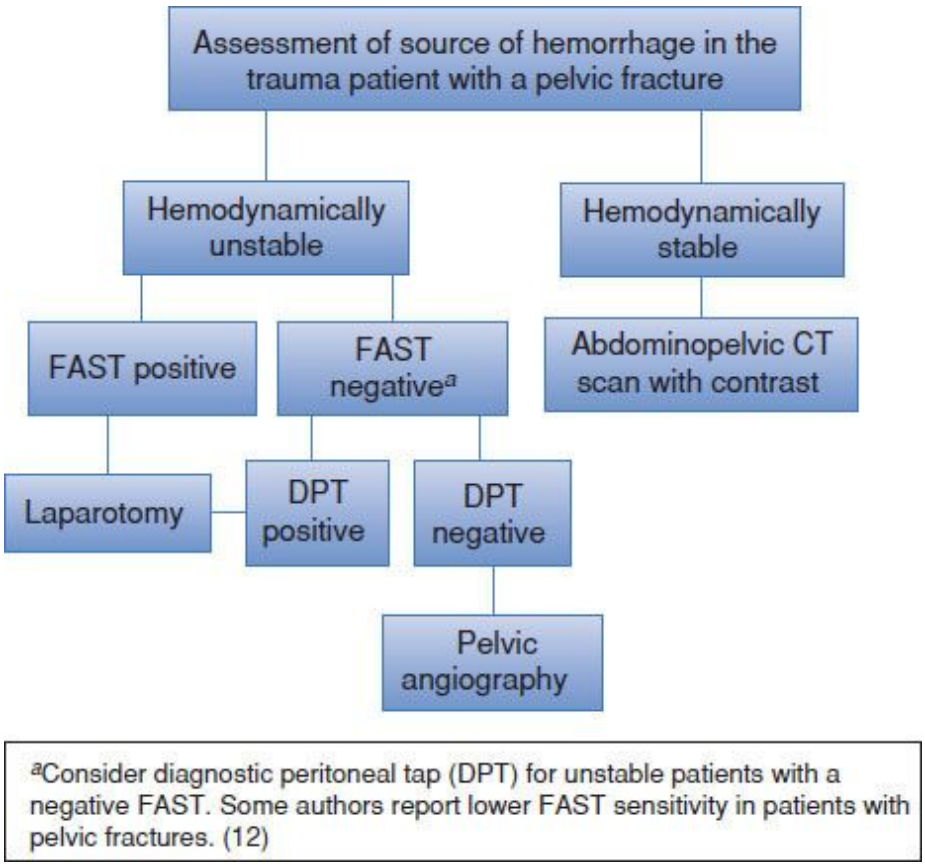

FIGURE 42.13 Evaluation of hemorrhage in patients with pelvic fractures.

CT imaging in the patient with pelvic trauma is straightforward, and the study of choice in the hemodynamically stable patient. Clinicians should be wary of potential delays in the unstable patient in need of immediate laparotomy or pelvic angiography.

KEY TESTING

- Plain films for hemodynamically unstable patients.
- FAST examination to assess for intraperitoneal bleeding.
- Abdominal/pelvic CT for hemodynamically stable patients.

Definitive Management

Although venous bleeding accounts for the majority of bleeding in the pelvis, injury to pelvic arteries results in brisk hemorrhage that is not controlled by pelvic stabilization alone. Arterial injury is found

in up to 20% of patients with AP compression and VS injuries, but it is uncommon in LC injury (18). The most commonly injured vessels include the superior gluteal, internal pudendal, obturator, and lateral sacral arteries. In the presence of arterial injury, vascular embolization is effective in 86% to 100% of cases and improves outcome (19,20). Early mobilization of the angiography team is essential because the length of time before embolization impacts survival.

Recently, investigators have attempted to determine factors that predict which patients would benefit from early angiography and embolization. As mentioned previously, contrast extravasation and increased pelvic hemorrhage volume on CT scan are predictive of associated arterial bleeding. Blackmore et al. (21) reported that a hematocrit <30, a pulse >130, or a displaced obturator ring fracture and pubic symphyseal wide diastasis predict major hemorrhage from a pelvic fracture. Miller et al. (22) found that patients with repeated episodes of hypotension despite adequate fluid resuscitation have a high likelihood of arterial injury. Pelvic fracture patterns may be predictive of the most important source of bleeding in the unstable patient, but should not be used in isolation, but in combination with other clinical signs (18). Eastridge et al. described the injury patterns in 231 hypotensive patients with pelvic trauma. In persistently hypotensive patients with “stable” fractures (i.e., LC and AP compression injuries with minor displacement), abdominal hemorrhage was the culprit in 85% of cases. Conversely, in patients with “unstable” fracture patterns (i.e., LC and AP compression injuries with major displacement and all VS injuries), hemorrhage was predominantly from a pelvic source. Pelvic angiography was positive in 59% of cases (23). Of note, anterior acetabular fractures were recently shown to have similar rates of arterial bleeding as pelvic ring fractures (18).

Intraoperative packing of the pelvis, in an effort to tamponade venous bleeding, has become an important adjunct in the management of these patients in some trauma centers. In general, peritoneal packing is used in the unstable patient also requiring an emergent laparotomy, as a temporizing measure if angiography is

not available, or as first-line procedure, with angiography following evidence of ongoing hemorrhage. Evidence suggests this technique reduces the need for transfusions and subsequent angiography (24,25).

CRITICAL INTERVENTIONS

- Aggressively resuscitate with crystalloid and early blood transfusion
- Activate a multidisciplinary team including emergency medicine, trauma surgery, interventional radiology, and orthopedics
- Rapidly detect or exclude hemoperitoneum at the bedside using US, CT scan, or diagnostic peritoneal aspirate
- Evaluate for associated visceral injuries (torso, genitourinary, and neurologic)
- Immobilize fractures that open the pelvic ring using a pelvic binder or wrapped sheet
- Initiate timely transfer to a level I trauma center

DISPOSITION

Patients with complex pelvic fractures require the resources of a level I trauma center. Rapid transport to a hospital capable of handling such injuries is essential, for these patients may deteriorate quickly. Preparation of the pelvic fracture patient for interfacility transport includes appropriate clinical stabilization, temporary pelvic stabilization, and communication with the accepting physician.

A small minority of patients with pelvic fractures can be discharged from the ED and managed as outpatients. The mechanism of injury, the age, and social supports of the patient should be factored into this decision. An example might be an isolated pubic ramus fracture in an otherwise healthy person. Consulting with an orthopedic surgeon, careful discharge instructions, and close outpatient follow-up are essential.

Common Pitfalls

- Failure to order pelvic imaging in all unconscious blunt trauma patients.
- Delays in immobilizing interventional radiology for definitive arterial embolization.
- Underresuscitation of a patient with an unstable pelvic fracture.
- Failure to diagnose associated intraperitoneal, retroperitoneal, and neurovascular injuries.
- Delaying transfer to a level 1 trauma center.

CHAPTER 43 Hip and Femur Injuries

Carl A. Germann and Megan L. Fix

Hip injuries are common and associated with notable morbidity and mortality, especially in older patient populations. It is predicted that by the year 2050, 6.3 million hip fractures will occur yearly worldwide (1). Causes of hip fracture are primarily pathologic (from osteopenia) and falls, whereas motor vehicle collisions account for the majority of hip dislocations.

Anatomically, the hip is an articulation between the femoral head and the acetabulum. The femoral head is firmly seated in the acetabulum, which is reinforced by labral cartilage, capsule, overlying ligaments, and proximal musculature of the lower extremity (Fig. 43.1). It is a very stable articulation, requiring violent injury to fracture or dislocate. The femur is the longest and strongest bone in the human body and is often subjected to substantial forces produced during powerful muscle contraction, weight transmission, or trauma. The length, angle, and narrow circumference of the femoral neck allow substantial range of motion at the hip, but these same characteristics subject the neck to incredible shearing forces.

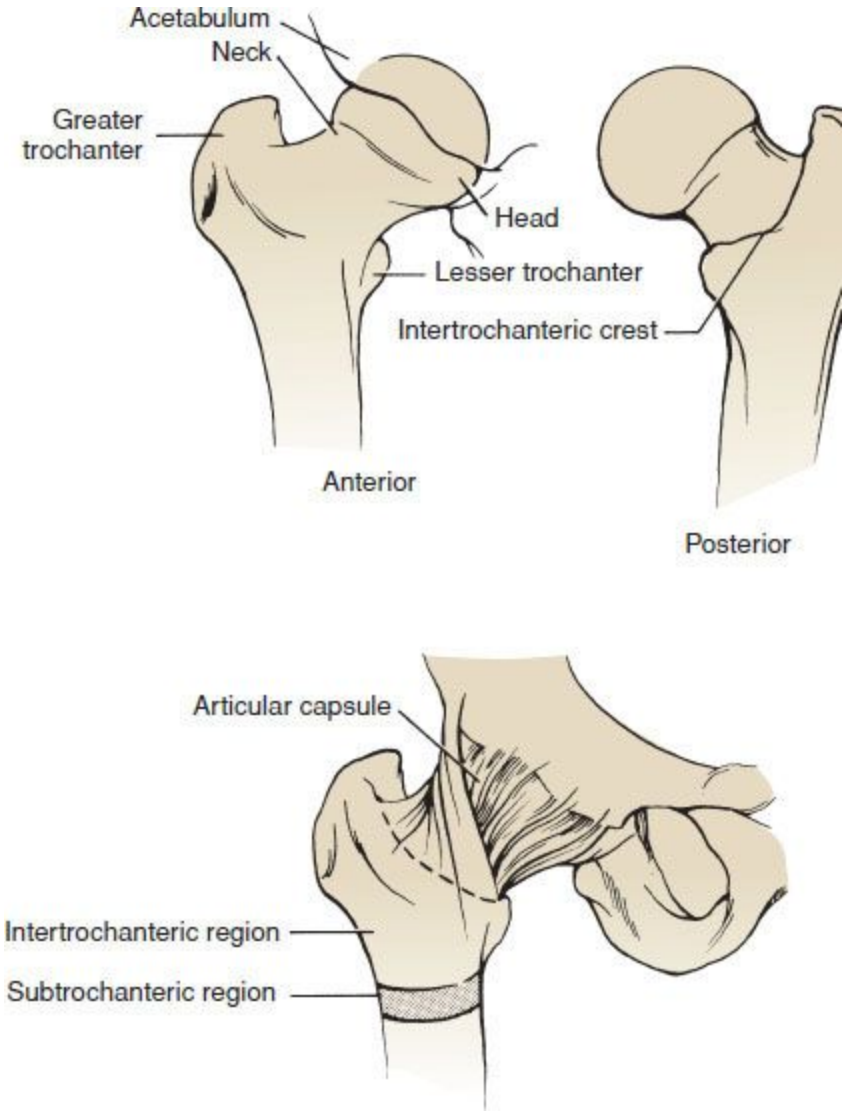

FIGURE 43.1 Anatomy of the hip. Anterior and posterior views of the femur (top) and division of the proximal femur (bottom).

Primary sources of blood flow for the femoral head are the retinacular branches of the circumflex femoral artery. These arteries enter the femur in the region of the femoral neck; fractures proximal to their entry can result in disruption of blood flow and cause avascular necrosis (AVN) of the femoral head.

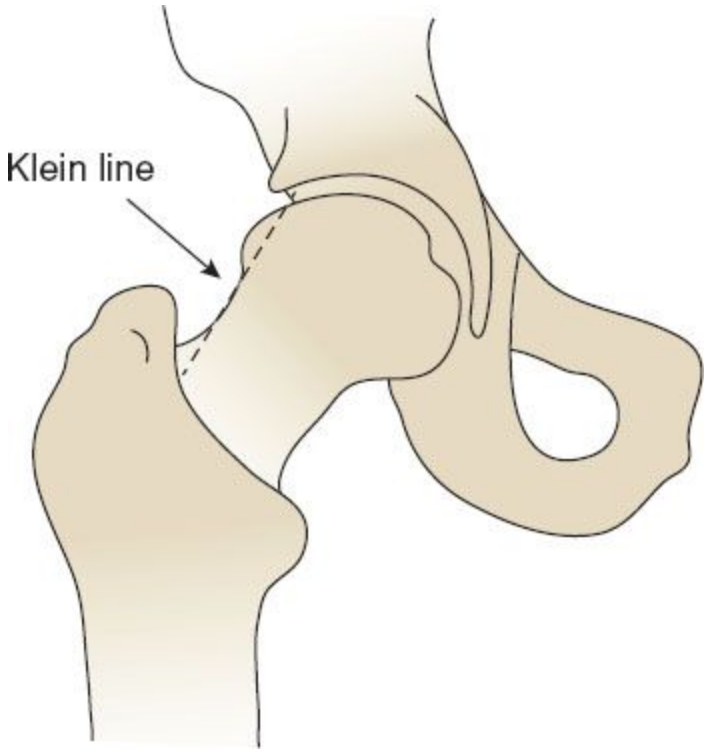
ED EVALUATION

During the initial evaluation, details of the mechanism of injury as well as a thorough physical examination and search for associated

neurovascular injuries are imperative. The initial radiographic studies in patients with suspected hip and femur injuries are the anteroposterior (AP) and lateral views. When analyzing the AP view of the hip, there are two important radiographic lines that help identify femur fractures and slipped capital femoral epiphysis (SCFE): Shenton and Klein lines. The Shenton line is a gentle arc seen on the AP view that runs along the inferior border of the femoral neck and extends to the inferior border of the superior pubic ramus (eFig. 43.1). The Shenton line will have a step or discontinuity in subtle cases of femoral neck and head fractures. The line may also appear disrupted in the radiograph of a normal hip, if it is not a true AP view. Klein line runs along the superior border of the femoral neck and intersects the superior portion of the femoral head (eFig. 43.2). The Klein line will project superior to a subtle fracture of the femoral head. The Klein line will also project superior to the epiphysis in a subtle case of SCFE.

FIGURE 43.2 Posterior hip dislocation.

eFIGURE 43.1 The Shenton line. (From Gruber JE, Gibbs MA, Ferrera PC, et al. Trauma Management: An Emergency Medicine Approach. St. Louis, MO: Mosby; 2001:398 (Figure 26–2), with permission.)



eFIGURE 43.2 The Klein line. (From Gruber JE, Gibbs MA, Ferrara PC, et al. Trauma Management: An Emergency Medicine Approach. St. Louis, MO: Mosby; 2001:398 (Figure 26–3), with permission.)

Approximately 2% to 10% of all hip fractures are radiographically "occult" on plain films (2). Therefore, if clinical suspicion remains and plain radiographs are negative, magnetic resonance imaging (MRI) is indicated. Although computed tomography (CT) scan can be used, small studies suggest that it is inferior to MRI (2,3). CT does seem to have merit when the patient does not have significant osteoporosis or in the setting of significant trauma (3). MRI is the imaging modality of choice with a sensitivity and specificity approaching 100%. In studies of patients with suspicion of hip fracture and normal plain radiographs, MRI showed occult fracture in 37% to 55% of patients (4).

KEY TESTING

- The initial radiographic studies in patients with suspected hip and femur injuries are the AP and lateral views.

- If clinical suspicion remains high and plain radiographs are negative, MRI is recommended to evaluate for occult fracture.
- Failure to detect these injuries results in increased mortality, risk of subsequent displacement, and a higher incidence of complications such as AVN.

ED MANAGEMENT

Hip Dislocations

The relationship of the femoral head to the acetabulum is used to classify dislocations into posterior, anterior, inferior, and central. Posterior dislocations account for 80% to 90% of cases. Anterior dislocations are seen in 10% to 15% of patients. Inferior dislocation (luxatio erecta) of the hip is very rare and occurs almost exclusively in children younger than 7 years of age. Central dislocation is often used to describe the translocation of the hip joint causing a comminuted fracture of the acetabulum.

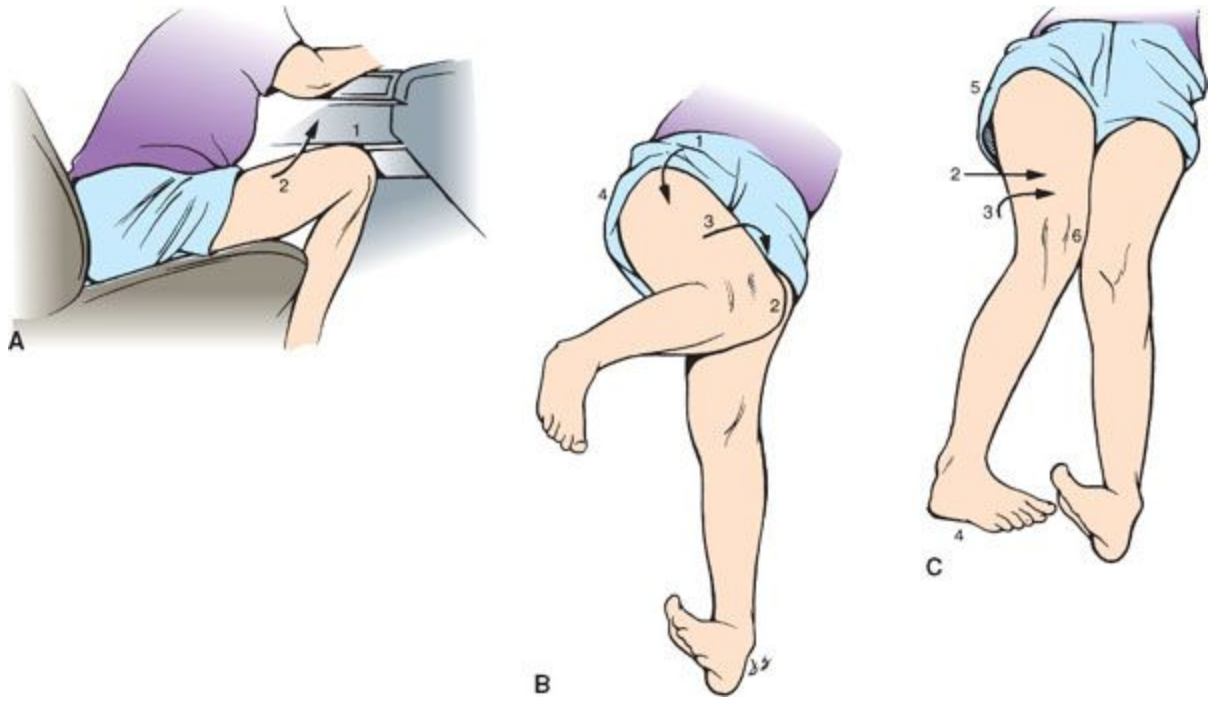
The neurovascular examination after a hip dislocation should focus on the sciatic nerve and femoral nerve and vessels. Sciatic nerve palsy is more likely to occur in conditions such as traumatic dislocation of a nonprosthetic hip or during the total hip arthroplasty (THA) procedure itself. Sciatic palsies may be present in approximately 10% of patients who experience traumatic hip dislocation. The sciatic neuropathy may produce paralysis of the peroneal muscles. The femoral artery and its branches are the most likely vessels to be injured, particularly after an anterior dislocation. The development of AVN of the femoral head caused by arterial injury has been reported in 1% to 17% of dislocations (5). Risk factors for the development of AVN include the total dislocation time, severity of the injury, number of reduction attempts, and presence of comorbid conditions. The incidence of AVN, traumatic arthritis, permanent sciatic nerve palsy, and joint instability logarithmically increases with the length of time for which the hip remains dislocated (6). Of course, prosthetic femoral heads are not at risk for developing AVN.

Posterior Hip Dislocations

Posterior hip dislocations are the most common type of hip dislocation and result from force applied to a flexed knee and hip. These injuries usually occur as a result of motor vehicle crashes where a seated occupant typically has the hip adducted, flexed, and internally rotated at the time of impact. This injury may be prevented by the use of a lap belt.

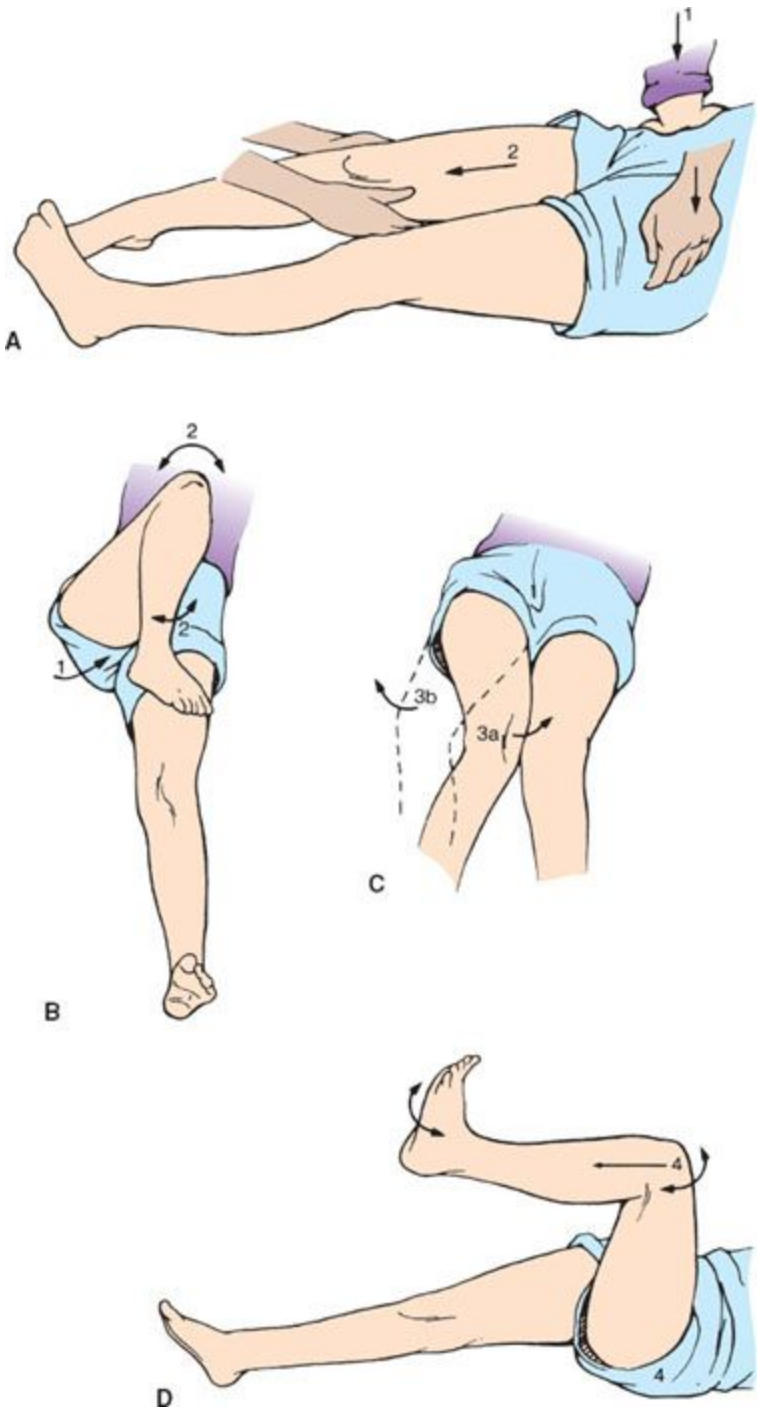
In posterior hip dislocations, the limb is often found flexed, adducted, internally rotated, and shortened. The knee of the affected extremity often rests on the opposite thigh. The greater trochanter may be unusually prominent. Likewise, the femoral head can often be palpated in the buttocks region (Fig. 43.2 and eFig. 43.3). Examination of the leg should ensure vascular function (rarely compromised) and include neurologic evaluation for possible sciatic nerve injury. Up to 50% of dislocations are associated with acetabular or femoral head fractures.

FIGURE 43.3 Slipped capital femoral epiphysis. A 13-year-old boy with a severe left-sided SCFE. (From Swiontkowski MF, Stovitz SD. Manual of Orthopaedics. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)



eFIGURE 43.3 Posterior dislocation of the hip. A: Mechanism of injury: The knee (1) strikes the dashboard. The thigh (2) is forced into flexion and adduction, and the femoral head is driven backward out of the acetabulum. B: Ischial dislocation: The hip (1) is flexed. The hip is markedly adducted, so that the knee (2) of the affected limb lies on the opposite thigh. The limb (3) is in extreme internal rotation. The greater trochanter and buttock (4) on the affected side are unusually prominent. C: Iliac dislocation: As in (B), the hip is flexed and is adducted (2).

Optimally, posterior dislocations should be reduced within 6 hours to minimize the risk for AVN (7). Therefore, this procedure should be attempted in the emergency department (ED) (eFig. 43.4). Adequate analgesia and muscle relaxation must be obtained using appropriate agents (e.g., a short-acting opioid and a short-acting benzodiazepine or propofol) and monitoring.



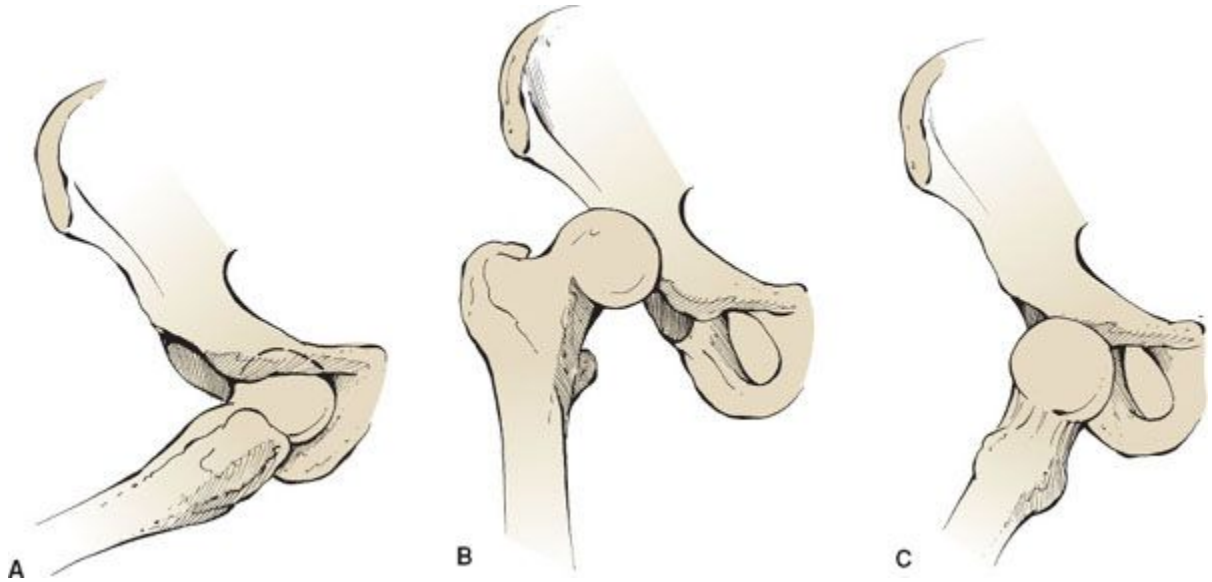
eFIGURE 43.4 Posterior dislocation of the hip: method of manipulative reduction. A: The assistant holds downward pressure (1) on the anterior superior iliac spine. With the knee flexed (2), the operator pulls on the limb in the line of deformity. B: The assistant slowly brings the thigh (1) to 90 degrees of flexion. The assistant gently rotates the thigh internally and externally and rocks the thigh

(2) backward and forward to disengage the head from the external rotator muscles and the posterior capsule. C: The assistant relocates the femoral head by further internal rotation and extension of the thigh (3a) or external rotation and extension of the thigh (3b). D: The assistant pushes firmly on the trochanter to direct the femoral head into the acetabulum while the limb is rotated and extended (4). Forceful rotation should be avoided, because it can fracture the femoral neck. If the reduction is not accomplished with two adequate attempts, open reduction is indicated.

Among the several techniques described in the literature, the Allis technique is commonly used to relocate posterior hip dislocations. After the patient is adequately sedated, the hip is flexed and an upward traction is applied to the supine patient. An assistant may apply pressure to the iliac crests, stabilizing the pelvis from lifting off the bed. To apply constant traction to the leg, it is often necessary to stand on the bed and straddle the patient. Upward traction and continued longitudinal force is applied with gentle internal and external rotation. Successful reduction is often felt by a dull click. After reduction, the extremity should be placed in extension and neurovascular function of the extremity should be reassessed. Postreduction radiographs should be obtained to identify the proper location of the femoral head. General anesthesia is occasionally necessary if procedural sedation is unsuccessful.

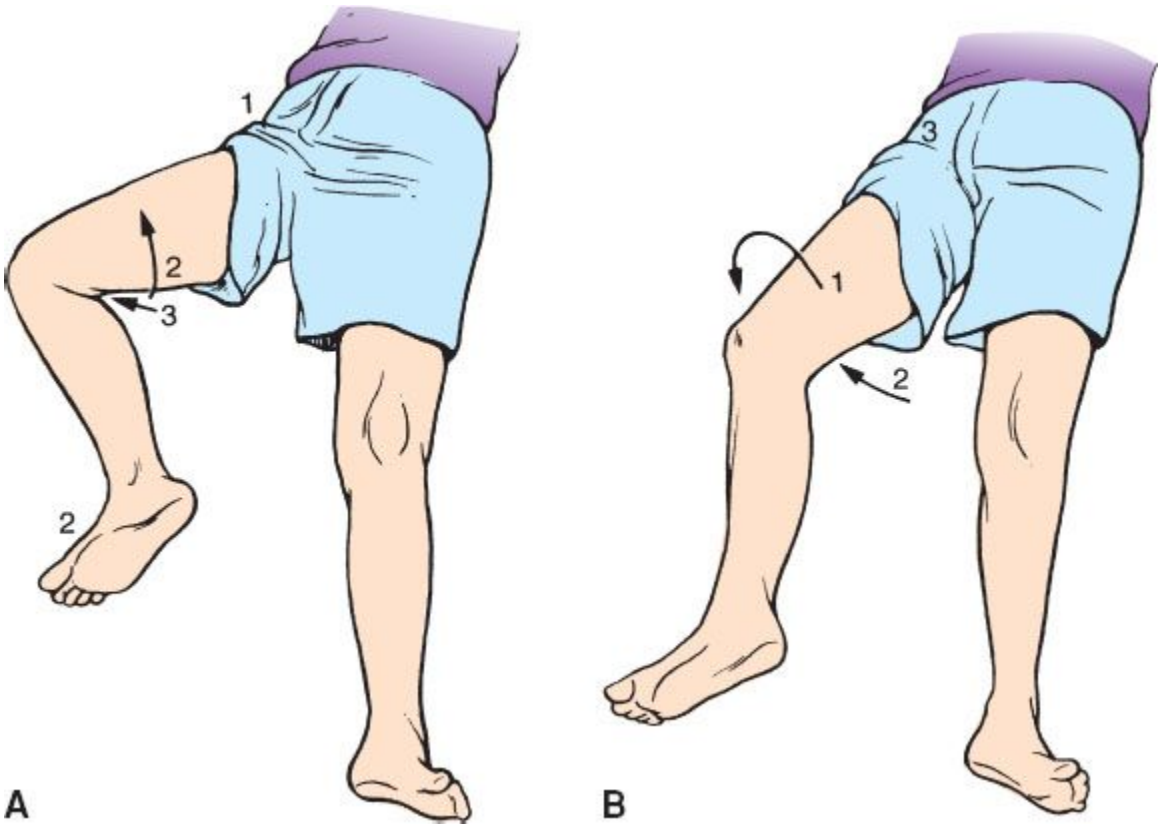
Anterior Hip Dislocations

Anterior hip dislocations occur most commonly from a direct blow to the abducted hip. A distally applied force causes the femoral head to tear through the anterior capsule and lever out of the acetabular cup. The mechanism of injury is most often an MVC during which the occupant has the hip abducted and externally rotated at the time of impact or a fall or sports injury causing forced hyperextension. Anterior dislocations are classified as obturator, iliac, and pubic (eFig. 43.5).



eFIGURE 43.5 Anterior hip dislocations. Anterior obturator hip dislocation (A), anterior iliac hip dislocation (B), and anterior pubic hip dislocation (C).

On physical examination, patients with anterior obturator dislocations present with abduction, external rotation, and flexion of the involved extremity. Patients with anterior iliac and pubic dislocations present with slight abduction, external rotation, and extension of the involved extremity (eFig. 43.6). Following anterior dislocation, a careful neurovascular examination is mandatory as the femoral artery, vein, or nerve are prone to injury.



eFIGURE 43.6 Anterior dislocations of the hip. A: Obturator dislocation. The hip (1) is slightly flexed. The limb (2) is externally rotated. The thigh (3) is abducted. B: Pubic dislocation. The extremity (1) is in severe external rotation (90 degrees). The extremity (2) is abducted only slightly (15 to 20 degrees), and it is slightly flexed. The femoral head (3) can readily be palpated in the inguinal region.

Early reduction is recommended to minimize neurovascular complications, such as AVN. A modified Allis maneuver is a commonly used reduction technique for anterior dislocations. Like the Allis technique, the patient is placed supine and an assistant stabilizes the pelvis. Traction is applied along the long axis of the femur with slight hip flexion. Gentle adduction and internal rotation may encourage reduction. If reduction is unsuccessful using common procedural sedation techniques, closed reduction under general anesthesia may be required.

Prosthetic Hip Dislocations

More than one million hip arthroplasties are done every year worldwide, and the number is projected to double within the next two decades given the ageing population and obesity epidemic (8). After THA, instability in the form of dislocation is second in frequency to joint loosening as a major complication of this procedure. Dislocation of the prosthesis occurs in 1% to 3% of patients with primary THA and in 5% to 20% of patients with a revised THA (9). Dislocations after THA can occur in a posterior or anterior direction. Posterior dislocation is the most common and accounts for 75% to 90% of THA dislocations (10). Dislocations often occur in the first 3 months postoperatively and are generally caused by relaxed soft tissues and immature scar formation (11). Over time, stretching of the pseudocapsule caused by extremes of motion may lessen soft tissue constraints and allow for dislocation.

Reduction techniques for prosthetic hip dislocations are identical to those described earlier. While a dislocated prosthetic hip carries no risk of AVN, injury to the sciatic nerve can occur.

Hip Fractures

Given the increasing elderly population and number of patients with osteoarthritis of the hip, the number of hip fractures may double over the next 20 years, reaching half a million a year by 2050 (12). A third of those over age 65 who live at home and half of institutionalized individuals are estimated to fall yearly. Morbidity in this age group is staggering, with a third dying within 1 year (13). Thirty percent of those who were independently ambulatory prefracture require permanent postinjury crutches or a walker, and 7% of them become permanently bedridden (14).

The term hip fracture refers to a fracture of the femur proximal to the subtrochanteric region. Hip fractures are generally classified into six anatomic groups: femoral head and neck fractures, intertrochanteric fractures, subtrochanteric fractures, and isolated fractures of greater or lesser trochanters. The terms intracapsular (femoral head and neck) and extracapsular (intertrochanteric,

subtrochanteric, and greater and lesser trochanter) are also commonly used.

Currently, treatment of these fractures is hemiarthroplasty or open reduction and internal fixation (ORIF) for femoral neck fractures.

Femoral Head Fractures

Isolated fractures of the femoral head are relatively uncommon and most often due to motor vehicle collisions. They are more common in younger patients as the force required often causes femoral *neck* fractures in older patients. As with dislocations of the hip, acetabular fractures may also be seen. These fractures usually occur in conjunction with hip dislocations caused by severe shearing forces. Femoral head fractures occur in 6% to 16% of hip dislocations (15).

Femoral head fractures may not be visualized on routine radiographs and CT or MRI may be required to confirm the diagnosis. Early recognition and reduction is important to maximize future joint function and minimize complications such as arthritis, AVN of the femoral head, or myositis ossificans. Urgent orthopedic consultation is mandatory. In most cases, satisfactory results can be obtained with closed reduction. However, if the hip cannot be reduced by manipulation or if reduction of the femoral head fragment is unsatisfactory, open reduction will be required. Unfortunately, complications may occur regardless of proper intervention and result in the need for prosthetic replacement.

Femoral Neck Fractures

It is estimated that 5% to 10% of people reaching their 80s will have a femoral neck fracture. These fractures occur below the femoral head and above the greater trochanter and are much more common than femoral head fractures. In the elderly, these fractures may be pathologic, occurring with a fall or minimal trauma. In younger patients, they are usually associated with high-energy mechanisms such as motor vehicle trauma. Osteoporosis is a major

risk factor, making the injury four times more common in women than in men.

Several classifications systems have been described but are not consistently used because of poor interrater reliability and limited clinical utility. More commonly, femoral neck fractures are classified as either nondisplaced or displaced. Most femoral neck fractures are displaced and present with the limb externally rotated, abducted, and slightly shortened. Fifteen percent to 20% of all femoral neck fractures are nondisplaced. The prognosis for nondisplaced fractures is excellent; functional outcome is favorable and the majority of patients heal without complication. However, a nondisplaced femoral neck fracture possesses no inherent stability and may become displaced without surgical fixation.

Stress fractures represent a unique type of femoral neck fracture. These fractures most commonly occur in young, athletic individuals, but they also occur in those with pathologic bones, (rheumatoid arthritis, renal osteodystrophy, and chronic steroid use). Stress fractures may be bilateral and are usually the result of repetitive abnormal stress on normal bone or repetitive normal stress on abnormal bone. The pain is often gradual in onset. Ambulation is common, and patients complain of pain with weight bearing. The usual signs of fracture are missing, both clinically and radiographically. Bone scan or MRI is indicated in any high-risk individual who cannot bear weight. Treatment is based upon the degree of injury and the state of the underlying bone. Treatment ranges from resting the affected hip to prosthetic hip replacement.

AVN and nonunion are the two major complications of femoral neck fractures. AVN of the femoral head is most common and may occur despite optimal treatment. It is identified on x-ray as an increase in density in the region of the femoral head thought to be new bone deposition.

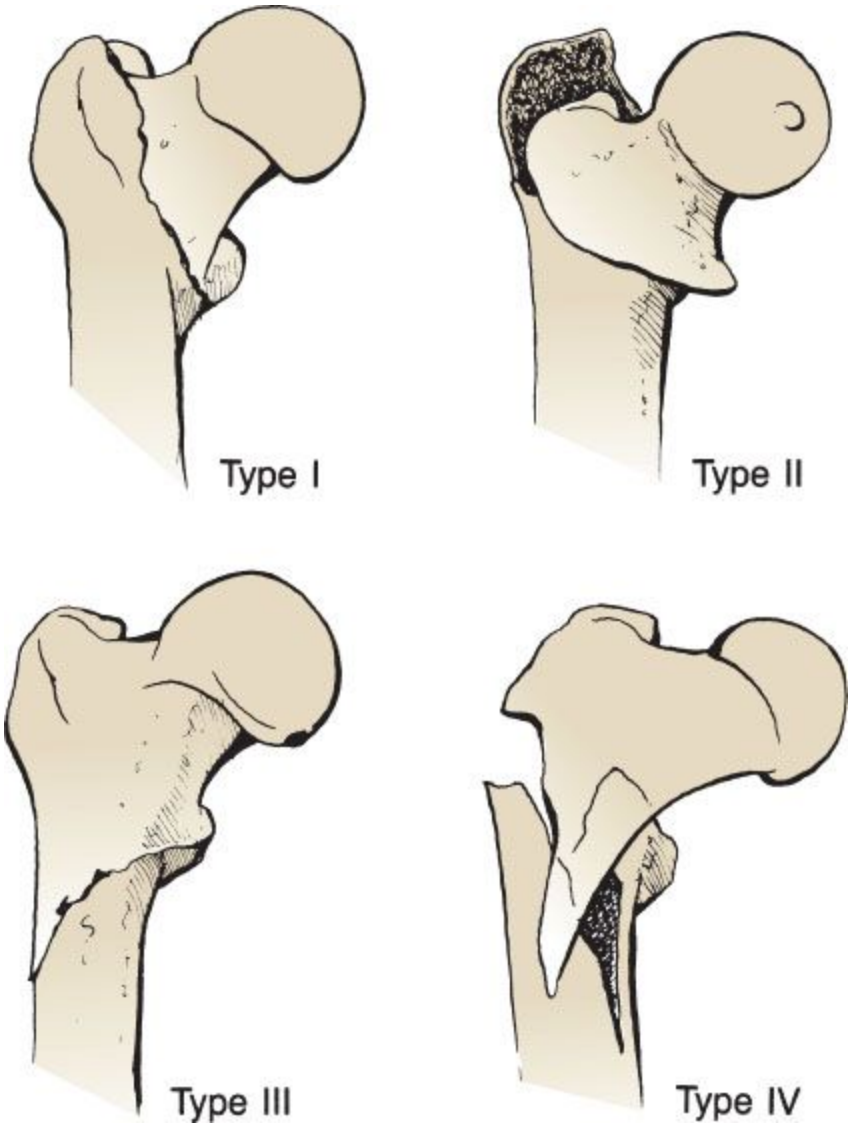
Early and precise anatomic reduction reduces the risk of AVN. Prompt recognition and orthopedic consultation in the ED may help minimize AVN and other sequelae. Treatment of displaced fractures often consists of ORIF, hemiarthroplasty, or THA.

Intertrochanteric Fractures

These are the most common types of hip fractures with the majority being caused by falls in the elderly. Intertrochanteric fractures are often considered pathologic, most commonly secondary to osteoporosis. Other causes include cancer and, less commonly, Paget disease. X-ray findings usually show comminution, the majority with three, four, or more fragments (16).

Emergency diagnosis is usually straightforward. Any movement causes extreme pain, and the hip may be tender to palpation. The affected leg is shortened and externally rotated, and weight bearing is not possible. The diagnosis is usually confirmed with a single AP view of the hip. A lateral or groin view may be necessary to evaluate the degree of comminution.

The intertrochanteric fracture is extra-articular and typically extends in a relatively straight line between the greater and lesser trochanters (eFig. 43.7). A variety of classifications are used to describe these fractures with no universal agreement. The Boyd and Griffin classification uses four categories (eFig. 43.7). When obtaining orthopedic consultation, precise anatomic description may be more useful than a specific classification type.



eFIGURE 43.7 Boyd and Griffin classification of intertrochanteric hip fractures. (Adapted from Rockwood CA Jr, Green DP, Bucholz RW. Rockwood and Green's Fractures in Adults. 3rd ed. Philadelphia, PA: Lippincott Co.; 1991.)

Initial management consists of immobilization with sandbags or Buck traction (2 to 4 kg) which helps decrease blood loss. Intravenous volume replacement, with crystalloid or blood, may be necessary because patients can lose 1 to 2 L of blood with these fractures. Many of these patients have chronic medical problems that should be addressed (including the cause of the fall), and this history will help to establish whether the patient is an operative

candidate. Laboratory evaluation should include the standard preoperative labs, as well as analysis necessary to ascertain cause of the fall (may include neurologic and cardiovascular evaluations).

Operative repair has historically been considered safer than conservative therapy. This opinion is a result of the morbidity and mortality associated with extended immobilization. Surgical reduction and fixation should be considered urgently rather than emergently, and all patients should have a thorough preoperative evaluation. Selected fractures may be managed by splinting, traction, or spica immobilization as determined by the consulting orthopedist and the patient's underlying medical conditions. Complications are common and reflect the frail status of most of these patients. Mortality rates are up to 15% (17).

Greater and Lesser Trochanteric Fractures

Greater trochanteric fractures are rare and occur as a result of direct trauma in adults or secondary to apophyseal avulsion as a result of forceful muscular contraction in young patients (ages 7 to 17). Tenderness to palpation is usually present over the greater trochanter. Patients are usually ambulatory with a limp. When caused by direct trauma, these fractures are rarely displaced and can be difficult to see on routine radiographs, so comparison views of the other leg are recommended. The direct blow (adult) fracture is usually comminuted without significant displacement whereas the epiphyseal avulsion (youth) type is usually displaced but not comminuted. Management varies from adduction splint and bed rest, to ORIF. In most instances, the prognosis is good, regardless of the method used.

Lesser trochanteric fractures usually occur in the young: 85% occur before age 20. These fractures usually occur from forceful contraction of the iliopsoas muscle during strenuous activities. The lesser trochanter can be displaced up to 1 cm. This injury in an adult mandates a search for pathologic bone. Patients have pain and tenderness in the femoral triangle. In a complete avulsion, they are unable to lift the affected extremity in the sitting position (Ludloff

sign). Radiographic imaging frequently requires comparison views. Treatment is usually conservative, unless there is significant displacement and outcomes are uniformly good (18).

Subtrochanteric Fractures

Subtrochanteric fractures are defined as fractures occurring between the lesser trochanter and a point 5 cm distally. These fractures account for 10% of hip fractures and are associated with more severe trauma or pathologic bone (such as osteoporosis, Paget disease, or bony metastasis).

Clinical presentation is similar to that of intertrochanteric fractures. The forces of the muscles extending across this region frequently result in abduction, flexion, and external rotation. Young patients with these fractures are subject to violent forces, and associated injuries or other associated hip fractures are common. Blood loss can be substantial in fractures of the midshaft femur. Classification is varied and complex. Anatomic description is best used when describing these fractures.

Treatment involves immobilization, analgesia, volume replacement (if indicated), and timely orthopedic intervention. Examination for associated neurovascular injury should be performed. The presence of a tense, swollen upper thigh should be evaluated with angiography or Doppler for an acute vascular injury. Prompt vascular surgery consultation should be obtained if this is suspected. Operative reduction and fixation (usually intramedullary nail) is used based on specific patient and fracture characteristics.

Acetabular Fractures

Acetabular fractures should be considered in patients with femoral head dislocations and, more commonly, pelvic fractures. The force of injury applied to the femur from impact onto the dashboard is transmitted to the acetabulum.

There are four types of acetabular fractures: posterior lip fracture (most commonly associated with posterior hip dislocations), transverse acetabulum fracture, anterior fracture, and ilioischial (or

posterior) fracture. In the ilioischial fracture, the entire posterior column (the bone extending from the ilium to the ischium) becomes separated from the pelvis. An occult acetabular fracture should be suspected when the patient gives a history of a recent fall, but the pelvic radiograph is normal. Oblique views, CT scan, MRI, and bone scan are often necessary for diagnosis, as initial films generally do not visualize the injury. MRI is the gold standard for diagnosis of clinically suspected occult injury (3).

Acetabular fractures are managed in consultation with an orthopedic surgeon. ED management involves immobilization, analgesia, volume replacement (if necessary), and identification of associated injuries.

Slipped Capital Femoral Epiphysis

SCFE is the most common hip disorder in adolescents. If this injury is untreated, it can result in profound lifelong morbidity due to AVN. The diagnosis is initially frequently missed. SCFE is a Salter–Harris type 1 fracture of the femoral capital epiphysis where the head of the femur slips posteriorly and inferiorly. This fracture occurs in boys twice as often as in girls. SCFE prior to age 8 mandates a metabolic workup for endocrine disorders, although ED treatment remains the same. Most affected children are obese, suggesting a primary mechanical problem. However, the disease is considered multifactorial. Up to half of SCFEs present bilaterally and hips are usually affected within 18 months of each other (19).

The most common presentation is a limping obese adolescent, complaining of hip pain. Because of referred pain from the hip, a common presentation is knee pain (15%). The average onset is 13.5 years for boys and 12 years for girls. The hip is externally rotated with an antalgic gait. Bilateral hip radiographs are mandatory and need to include AP and frog-leg lateral views. Klein line will not project through the femoral head if SCFE is present (Fig. 43.3).

All patients with SCFE should be nonweight bearing, and need operative percutaneous fixation of the femoral head. There is controversy as to specifics including timing or surgery and value of

reduction, thus immediate consultation with orthopedics is indicated. The most common complication of SCFE is AVN, which ultimately requires hip replacement. Chondrolysis is another potential complication that has decreased with improved surgical techniques, and now occurs in about 1% to 2% of SCFE cases (19).

CRITICAL INTERVENTIONS

- Evaluate patients with hip dislocations for associated acetabular, femur, or knee injuries.
- Perform early closed reduction of hip dislocations (<6 hours is ideal). This treatment lowers the risk of AVN and posttraumatic osteoarthritis.
- Perform a CT or MRI in patients with persistent hip pain in the absence of radiographic findings to identify an occult hip fracture.

DISPOSITION

Orthopedic consultation is recommended for all hip dislocations and fractures. Hip dislocations require careful observation with frequent neurovascular checks. Young healthy patients with nondisplaced femoral neck fractures are typically managed by keeping weight off the joint. Occasionally they will require surgical fixation. Both elderly and young patients with intertrochanteric and subtrochanteric fractures require surgical fixation. Hospital admission for all elderly patients with acute hip fractures is recommended. These patients generally require evaluation and consultation for preoperative medical clearance, as well as frequent neurovascular checks. If there is a strong clinical suspicion of occult disease, then further imaging (bone scanning or MRI) is appropriate, either in the ED or as an inpatient.

Common Pitfalls

- Failure to consider SCFE in adolescent patients with knee or hip pain.

- Failure to image the hip in an elderly patient with a history of a recent fall and a complaint of knee pain.
- Failure to realize that hip pain and inability to walk, even in the absence of trauma, may be due to a hip fracture and advanced imaging should be considered (MRI).
- Failure to look for acetabular fractures in patients with hip dislocations and inferior pubic ramus fractures.

CHAPTER 44
Knee Injuries

Christine B. Irish and Christopher T. Bowe

Knee trauma accounts for more than one million emergency department (ED) visits each year (1). The knee joint is made up of bones, ligaments, muscles, and cartilage (Fig. 44.1). The three bones that make up the knee are the distal femur, patella, and proximal tibia. The femoral condyles articulate with the proximal tibia (tibial plateau) to form the weight-bearing portion of the knee joint. The patella does not function in weight bearing, but rather provides protection to the distal femur, in addition to improving stability and strength of the extensor mechanism.

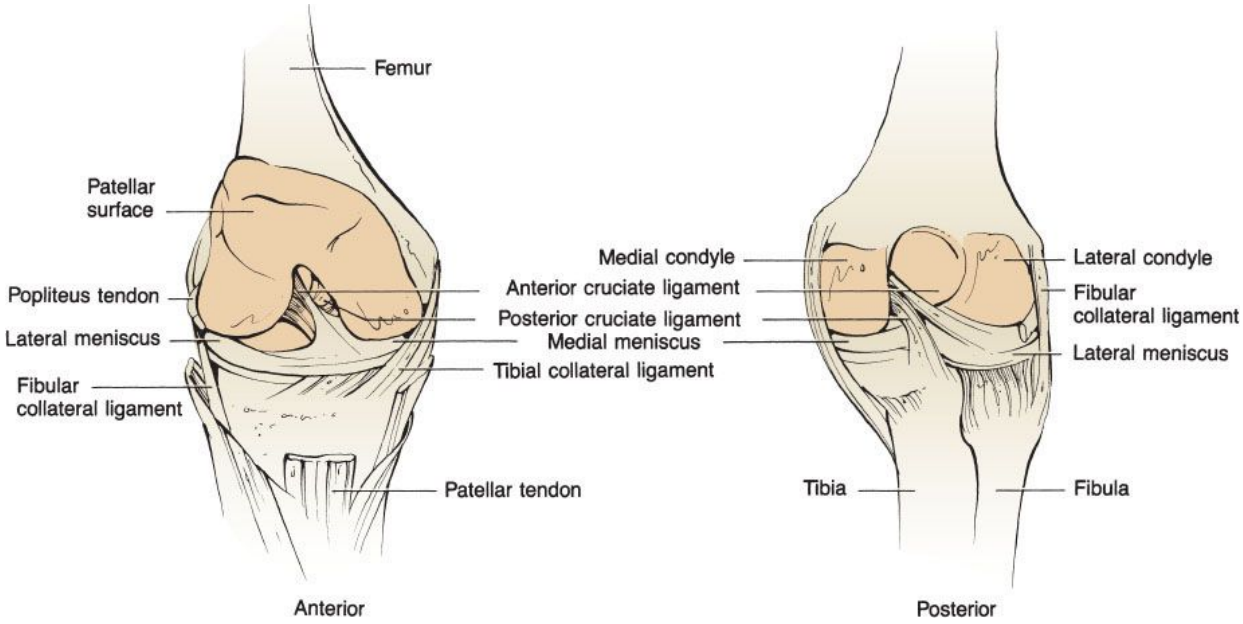

FIGURE 44.1 Anatomy of the knee.

The knee relies on four major ligaments: the medial collateral ligament (MCL), the lateral collateral ligament (LCL), the anterior cruciate ligament (ACL), and the posterior cruciate ligament (PCL) for stability and proper function (2). The MCL provides most of the resistance to valgus stress, while the LCL protects from varus stress. The cruciate ligaments are located within the intercondylar notch. The ACL prevents anterior displacement of the tibia relative to the femur while the PCL prevents posterior displacement (2). The anatomy of the posterior lateral corner of the knee is complex; its major structures consist of the LCL, the arcuate complex, the popliteal tendon, and the popliteal-fibular ligament (3). The posterolateral corner primarily resists posterior lateral rotation of the tibia relative to the femur but also contributes to resisting posterior tibial translation. The posteromedial corner of the knee consists primarily of the posterior oblique portion of the MCL and the associated joint capsule. These structures provide resistance to valgus stress and posterior medial tibial translation. The menisci are cartilage positioned on the articulating surface of the tibia. The menisci function to provide a contact surface between the tibia and femur and distribute and dissipate forces within the knee (4).

The muscles involved with normal knee function are divided into extensors and flexors. Extension is primarily provided by the quadriceps muscles, composed of the vastus medialis, vastus intermedius, vastus lateralis, and rectus femoris. The tendons of these muscles combine to form the quadriceps tendon, which inserts into the superior patella and the medial and lateral retinaculum of the joint capsule. This tendon then becomes the patellar tendon, which connects to the tibial tubercle (5). The primary flexors of the knee are the hamstring muscles, consisting of the semimembranosus, semitendinosus, and the two heads of the biceps femoris of the posterior thigh.

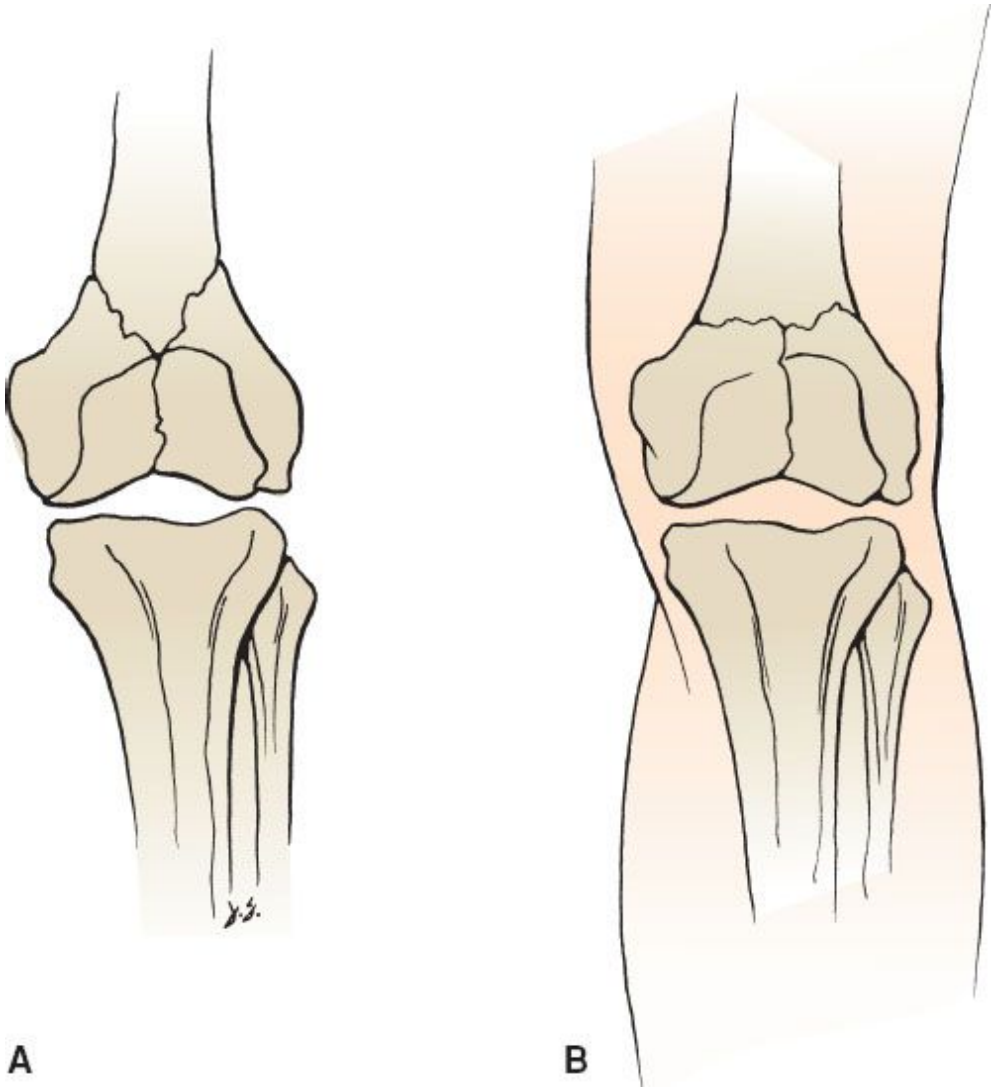
The major vascular structures around the knee are located posteriorly. The popliteal artery is fixed proximally. This tethering makes the popliteal artery susceptible to injury by traction forces, as seen with dislocations. The popliteal artery is also at risk of disruption by fractures or penetrating wounds (6). There is limited

collateral circulation, so damage to the popliteal artery places the viability of the lower limb in jeopardy. The sciatic nerve separates into the tibial and peroneal nerves proximal to the knee. The tibial nerve passes posteriorly and is therefore susceptible to the same mechanisms of injury as the popliteal artery, while the peroneal nerve courses superficially around the lateral aspect of the knee to the proximal fibula (6).

CLINICAL PRESENTATION

Fractures

Distal femoral fractures are typically described relative to the femoral condyles and are separated into supracondylar or intercondylar **(eFig. 44.1)** (7). The proximity of the femoral artery and peroneal nerves to the bone requires that the neurovascular status of the extremity be evaluated and documented in the setting of a fracture.



eFIGURE 44.1 Distal femur fractures. A: Y-shaped intercondylar and B: T-shaped intercondylar.

Tibial plateau fractures occur as a result of varus–valgus forces, axial loads, or both. Fractures of the tibial plateau may cause a major impairment in stability and function of the knee (8). The potential for neurovascular injuries is much higher in patients with proximal tibial fractures than in distal femoral fractures. The potential for the development of a compartment syndrome is also significant. Paresthesias and paralysis from compartment syndromes may be mistaken for a primary nerve injury. Injuries to the menisci, as well as to the collateral and cruciate ligaments, should be suspected as well.

A fracture of the tibial tuberosity often represents an avulsion injury caused by the patellar tendon. This is an uncommon fracture. It occurs with either strong flexion or extension against resistance. Fractures of the tibial tuberosity most commonly occur before closure of the epiphysis. The differential diagnosis of pain over the tibial tuberosity should also include Osgood–Schlatter disease, which is a traction injury to the apophysis of the tibial tuberosity. Although it is most common in boys aged 10 to 13 years, it may be seen in girls, usually aged 8 to 13 years. It is thought that repetitive trauma to the epiphysis results in incomplete separation of parts of the cartilaginous and osseous portions of the tibial tuberosity. Diagnosis is based on the history and physical examination. The tubercle is painful, tender, and usually enlarged. Pain is exacerbated by extension of the knee, particularly against resistance.

Patellar fractures result most commonly from direct forces. Less common are fractures resulting from severe tension placed on the patella by strong contraction of the quadriceps; the usual result is a transverse fracture, which may disrupt the extensor mechanism (5).

Knee Dislocation

Knee dislocations are orthopedic emergencies and require immediate attention. Knee dislocations are generally associated with high-energy trauma. The dislocation is described as anterior, posterior, medial, lateral, or rotary based on the position of the tibia relative to the femur. For a dislocation to occur, significant trauma to the surrounding soft tissue is generally seen, including the collateral ligaments, cruciate ligaments, menisci, joint capsule, and neurovascular structures. Physical examination may be difficult, and a dislocation may spontaneously reduce before the patient arrives at the ED. The patient may describe a history of abnormal position of the joint before reduction. Because of the concern for peroneal nerve and popliteal artery injury, specific attention should be devoted to this aspect of the physical examination. The absence of distal pulses is highly correlated with significant vascular injury; the presence of pulses, however, does not eliminate the possibility of vascular damage (9). Considering the significant mechanisms of injury and

the potential for vascular damage, compartment syndrome is also a potential complication.

Patellar Dislocation

The patella may be completely dislocated or subluxed from the intercondylar groove as a result of a direct blow or by hyperflexion of the knee joint. The patella almost always displaces laterally. Diagnosis is usually made by careful physical examination. If the patella has spontaneously reduced, plain films will confirm proper placement and identify any bony injury (9).

Ligamentous Injuries

LCL injuries are more commonly seen after falls and motor vehicle collisions (MVCs). MCL and LCL tears are associated with cruciate ligament injuries, with the LCL injury less likely to occur as an isolated event (2). The patient generally presents with tenderness along the distribution of the ligament. There may be a history of "popping" and abnormal bending of the knee. The physical examination should include the diagnostic tests discussed below, with varus and valgus forces applied to the knee at extension and 30 degrees of flexion.

Injuries to the cruciate ligaments are common with low-velocity trauma as well as with high-energy forces. The ACL is weaker than the PCL and is more commonly injured. Tests for ACL injuries include the Lachman, anterior drawer, and pivot shift tests. The Lachman test is the most sensitive. PCL stability is evaluated by the posterior drawer and posterior sag tests (2).

Meniscal Tears

Meniscal injuries generally occur with a twisting force applied to the knee. Patients frequently complain of hearing a "pop," which is common but not specific to meniscal injuries. Often, the patient reports locking of the knee, usually a result of a "bucket-handle" tear, with a free central portion of the cartilage becoming lodged in

the intercondylar notch. The medial meniscus is most commonly affected. The patient usually presents with a joint effusion.

Tendon Injuries

The extensor mechanism includes the quadriceps tendon, the patella, and the patellar tendon. Injuries to these structures, or avulsion of the tibial tubercle, can disrupt the extension of the knee. Disruption may result from high-energy or penetrating trauma but is also seen with low-energy forces (9). The quadriceps tendon is more commonly ruptured and usually ruptures just proximal to the patella (10). The patellar tendon frequently ruptures at the insertion into the patella. The physical examination generally reveals a swollen, tender knee, and a palpable deficit may be present. Tenderness is usually identified at the site of injury. To evaluate the tendons properly, the patient's ability to extend the knee fully against resistance must be tested. The diagnosis is usually suspected clinically. Partial injuries may be difficult, if not impossible, to detect in the ED.

DIFFERENTIAL DIAGNOSIS

Common important bony injuries to the knee include fractures, dislocations, and subluxations. Of further concern are tendon and cartilage injuries, as well as injury to the vasculature and nerves surrounding the knee.

ED EVALUATION

The history is extremely useful in guiding the evaluation of the injured knee. The chief complaint, mechanism of injury, and the exact nature and timing of symptoms will help to differentiate acute trauma from chronic injuries. The traumatic mechanism should be fully explored, as well as the position of the knee at the time of injury. The history should also assess for additional injuries, particularly to the hip and ankle.

The physical examination begins with visual inspection of the knee, followed by the remainder of the lower extremity. The examiner should note any obvious deformity, ecchymosis, erythema,

edema, or cutaneous lesions. Often, comparison with the uninjured knee will be helpful in assessing for joint effusion and local edema. Following gross inspection, palpation will elicit specific areas of tenderness, crepitus, abnormal skin temperature, or the presence of an effusion. Finally, the examiner should assess active and passive range of motion, alignment, and neurovascular status (2). The comprehensive examination will include evaluation of the knee in the standing, sitting, and supine positions, when not limited by pain or swelling.

After completion of a thorough physical examination, appropriate radiographic studies may be ordered when clinically indicated. Several clinical decision rules regarding the use of radiographs in the acutely injured knee have been proposed (Table 44.1). Prospective validation has shown excellent sensitivity of these rules (1). Adherence to these clinical decision rules can substantially reduce the incidence of unnecessary radiographs (11). Standard imaging includes the anteroposterior and lateral views and can be supplemented with sunrise (skyline) and tunnel views to evaluate the patellofemoral joint and intercondylar notch.

TABLE 44.1
Decision Rules for the Use of Radiographs in the Acutely Injured Knee

Pittsburgh	Ottawa
Mechanism of injury (blunt trauma, falls)	Age (>55 yrs)
Age (<12, >55 yrs)	Tenderness at fibula head
Inability to walk (four weight-bearing steps)	Isolated tenderness of the patella
	Inability to flex to 90 degrees
	Inability to transfer weight for four steps (either immediately following injury or in the emergency department)

If radiographs are not indicated or are negative, the assessment of potential injuries should continue with a systematic examination of the soft tissues, as well as testing of weight bearing and gait. As

previously noted, the unaffected knee should also be examined for comparison. Any obvious discrepancies between the patient's joints should be noted and are more important than absolute laxity. During examination of the uninjured knee, the physician should demonstrate the specific maneuvers that will be performed on the affected joint. This can diminish the patient's fears and improve cooperation during examination of the affected knee. Often, the presence of excessive tenderness or large joint effusions will make the examination difficult. In these cases, tensing of the musculature secondary to pain may give the impression of more joint stability than is actually present (2). To facilitate a more accurate examination and appropriate treatment recommendations, it is often necessary to immobilize the injured knee in the ED and arrange for a follow-up examination within 5 to 7 days (12).

Specific Tests for Soft Tissue Injuries

Collateral Ligaments

To assess for integrity of the LCLs and MCLs, the knee should be examined in both full extension (0 degree) and at 30 degrees of flexion. The tibia and femur should be stabilized by the examiner's hands while applying varus and valgus force across the joint line. Varus force tests for LCL laxity and is noted by lateral joint line opening, whereas valgus force assesses MCL stability and is noted by medial joint line opening. In both tests, the endpoint should be compared to the uninjured knee (Fig. 44.2A,B) (2).

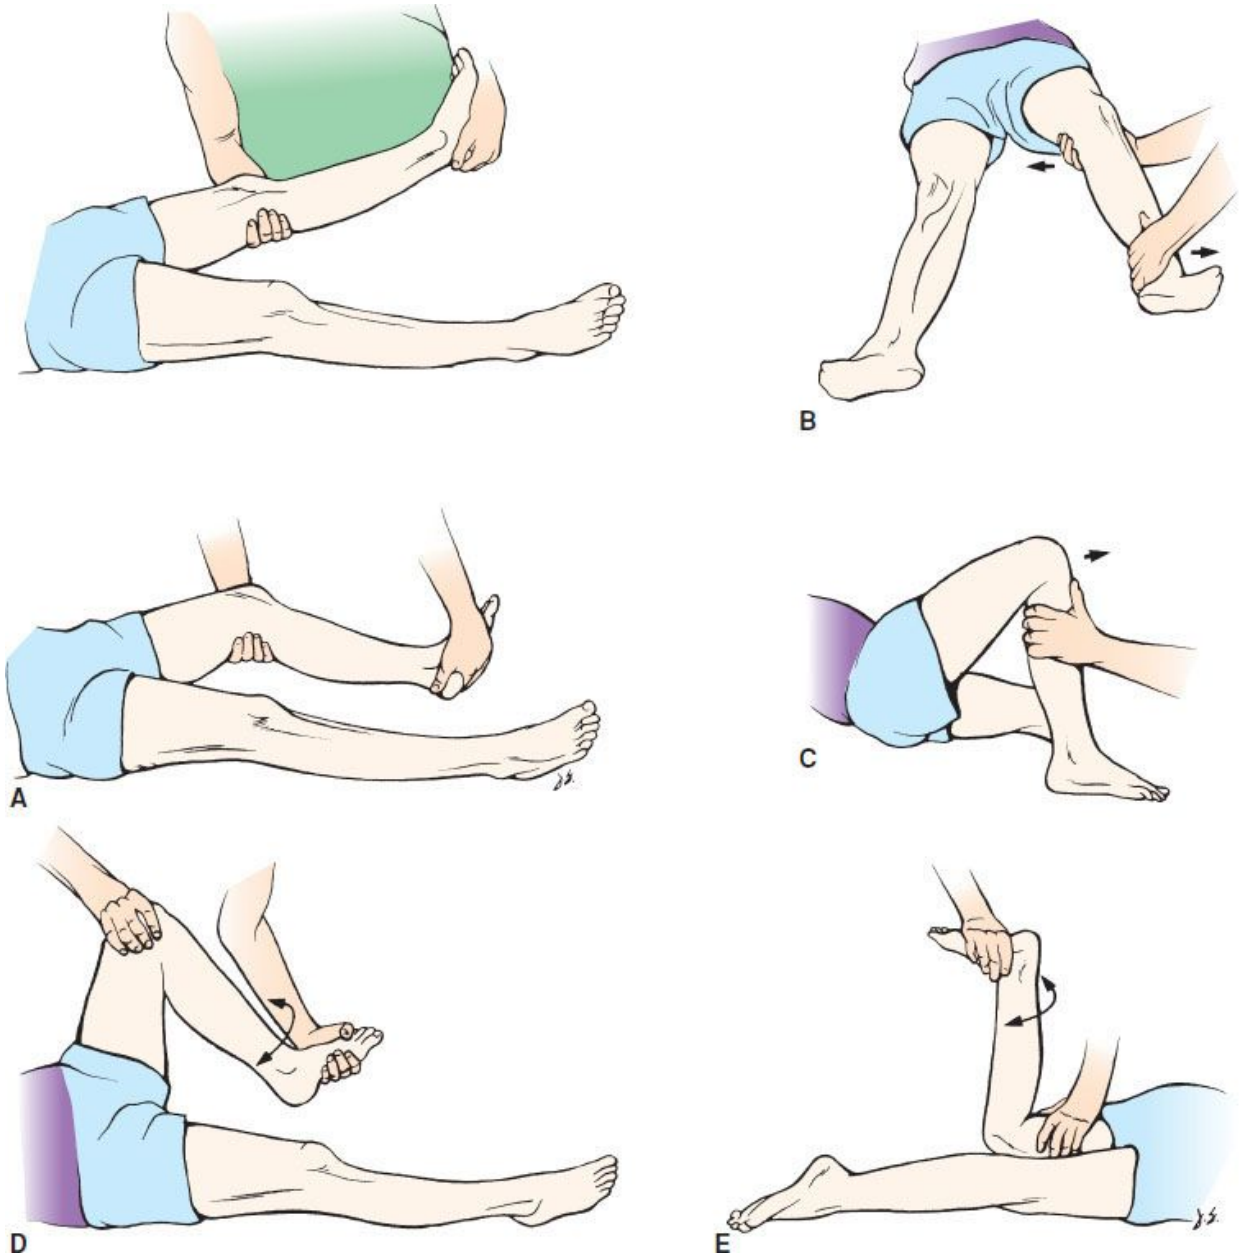


FIGURE 44.2 Examination of the knee. A: valgus stress at 0- and 30-degree flexion, as viewed from the side; B: valgus stress at 0-degree flexion, as viewed from above; C: anterior drawer test; D: McMurray test; and E: Apley test.

Cruciate Ligaments

Given that the primary function of the ACL is to prevent excessive anterior movement of the tibia relative to the femur, the focused physical examination should assess for abnormal anterior tibial

translation. The Lachman test is the test of choice to detect ACL injury (2). The patient should be supine with the knee flexed at 30 degrees. The examiner's hands are placed on the anterolateral femur and posterior proximal tibia. Anterior force is then directed on the posterior tibia, with a positive result noted when there is excessive anterior displacement of the tibia relative to the femur and lack of a distinct endpoint. A positive result indicates an ACL laxity or rupture (13). The Lachman test has a high sensitivity and specificity for ACL injury (approaching 85% and 95%, respectively) (12); False negatives most often result from surrounding muscular contraction in the presence of hemarthrosis, pain, and guarding. False positives may be noted in cases of PCL rupture where the knee is initially subluxed posteriorly (2).

The anterior drawer test may also be utilized to evaluate for ACL injury but it is noted that the accuracy is limited due to hamstring spasm and difficulty achieving appropriate positioning in the acutely injured patient. The knee should be flexed to 90 degrees and stabilized, with the foot flat on the stretcher in a neutral position (Fig. 44.2C). The examiner holds the proximal tibia with both hands and exerts anterior force. Significant displacement of the tibia anteriorly (compared with the unaffected knee) suggests rupture (2).

A third test for ACL injury is the pivot shift, which has a good positive predictive value but poor specificity (12). The examiner should lift the leg by the distal tibia with the knee fully extended. With an ACL rupture, the tibia is subluxed anteriorly in this position. The examiner then applies a mild valgus force while the knee is carefully flexed through 20 to 40 degrees. At this point, the tibia jumps into a reduced position and the examiner and the patient may appreciate a sudden clunk (2). Pain may hinder the performance of this test in the acutely injured knee.

The posterior drawer test is the reverse of the anterior drawer test and is the most accurate test of isolated PCL injury, with sensitivity and specificity of 90% and 99% respectively (2). The posterior Lachman test may be selected as an alternative to the posterior drawer test if flexion to 90 degrees is limited, as the posterior Lachman test is performed in only 30 degrees of flexion. A third

technique for detection of PCL injury is the posterior sag test. The examiner holds the knee in 90 degrees of flexion with the thigh supported by a pillow and the foot secured. In this position, the tibia will displace posteriorly or “sag” if the PCL is ruptured (2).

Meniscus

The McMurray test is commonly used to identify meniscal injury (Fig. 44.2D). While the patient is supine, the examiner holds the knee (flexed at 90 degrees) with one hand and holds the lower leg or foot in the other hand. Then the examiner applies internal and external rotation to the lower leg while flexing and extending the knee which is palpated for catching or clicking sensations. A medial meniscal tear should be suspected if clicking occurs as the leg is extended and externally rotated after being completely flexed. Clicking with internal rotation during extension is used to help identify a lateral meniscal injury. A positive test does not guarantee a meniscal injury but indicates the need for further evaluation (14).

Another test used to identify meniscal injury is the Apley test (Fig. 44.2E). The patient is placed in the prone position, and the knee is flexed to 90 degrees. The examiner applies upward force to the tibia while it is rotated, and the knee is extended (14). A positive test is noted with pain and clicking in the joint and suggests a meniscal injury.

Patellar Subluxation

The apprehension sign is seen with patellar subluxation during manual translation maneuvers. The knee is positioned in extension and the examiner exerts lateral force on the patella. In patients with patellar subluxation, this manipulation is painful and induces apprehension. A positive test is noted when the patient contracts the quadriceps and attempts to flex the knee to resist subluxation (2).

Extensor Mechanism

The extensor mechanism of the knee includes the quadriceps muscle, quadriceps tendon, patella, patellar tendon, and surrounding retinacula. As expected, injuries to the extensor mechanism may lead to the inability to extend the leg. Physical examination of the knee

should include an evaluation of active leg extension; decreased ability to extend indicates an injury to the extensor mechanism (15).

Diagnostic Studies

As previously mentioned, several excellent clinical decision rules exist to help in the decision to order plain films (Table 44.1). Radiographs help diagnose fractures, effusions, dislocations, foreign bodies, and calcified loose bodies. Additional findings include fluid–fluid levels that may represent lipohemarthrosis (fat floating on synovial fluid and an indication of an occult fracture) in the appropriate clinical setting. The presence of such a finding warrants further evaluation utilizing computed tomography (CT) scanning, or magnetic resonance imaging (MRI).

CT scanning may be used to better define bony injuries, particularly tibial plateau fractures. Ultrasound and MRI are indicated to evaluate the soft tissues of the knee. Angiography can be used after knee dislocation to rule out an occult injury to the popliteal artery, and should be considered even in the presence of symmetric pedal pulses (1). Angiography is also indicated in the presence of penetrating trauma in proximity to vascular structures and (16).

Occasionally, it may be difficult to clinically distinguish hemarthrosis from an infective or inflammatory joint effusion. Arthrocentesis and joint-fluid analysis may be helpful in these cases to determine the etiology of an effusion, particularly when the traumatic mechanism is unclear. An acute hemarthrosis may suggest a significant injury, such as an ACL or PCL tear, and the presence of lipid droplets in a bloody effusion can signify an occult fracture. Arthrocentesis of acute hemarthrosis can be quite therapeutic in providing pain relief, however this practice is controversial given the rate of reaccumulation and the small risk of introducing infection associated with the procedure.

For patients with deep lacerations of the knee, it is important to evaluate the integrity of the joint capsule. Methylene blue should be injected into the joint, and simultaneous inspection of the wound will reveal dye extravasation in cases of joint capsule disruption.

KEY TESTING

- Use of the Ottawa Knee Rules is recommended to reduce unnecessary radiographs in acute trauma setting.
- Remember to examine the ipsilateral hip and ankle for associated injury.
- CT scanning may be particularly useful in patients with tibial plateau fractures.
- Methylene blue injection is useful to assess joint space involvement in deep lacerations.

ED MANAGEMENT

Fractures

The initial management of patients with distal femur fractures includes immobilization, pain management, and evaluation for associated injuries. Early orthopedic consultation is indicated for development of definitive care plans (skeletal traction or surgical repair).

For tibial plateau fractures, diagnostic tests include plain radiographs and CT scans. CT scanning has demonstrated improved accuracy over plain radiography as it is more sensitive for detecting subtle nondisplaced fractures as well as occult lesions. With severely comminuted fractures, CT scanning can quantify the extent of the articular surface involved and the amount of displacement or depression of the fracture line. The additional information gained by CT scanning is useful for planning operative repair, and will often modify the surgical plan (1).

Complications of tibial plateau fractures include vascular injury, deep venous thrombosis (DVT), and compartment syndrome. Any indication of distal ischemia, including paresthesias, diminished distal pulses, or a diminished ankle-brachial index should immediately alert the physician to the possibility of a vascular injury, and an arteriogram should be promptly obtained. Although not generally a concern in the acute setting, DVT is a recognized sequelae of this injury and is most easily diagnosed by lower extremity ultrasound. If significant swelling and tenderness are

present, the physician should suspect a developing compartment syndrome. The diagnosis of compartment syndrome is suggested by the presence of the five Ps (pain, pallor, paresthesias, paralysis, pulselessness); however, these findings are not universally present initially and early diagnosis is critical. Compartment pressures should be measured to definitively rule out the diagnosis.

Standard management of tibial plateau fractures includes immobilization, evaluation for other injuries, and timely orthopedic consultation. Depressed fractures require surgical reduction. Because of the risk of compartment syndrome and the possibility of delayed onset, patients with tibial plateau fractures are often admitted for observation.

Tibial tuberosity fractures are generally diagnosed on plain radiographs. In cases of suspected Osgood–Schlatter disease, plain radiographs may be difficult to interpret, as fragments of the tuberosity may be a normal variant. Tibial tuberosity fractures can require open reduction but are usually treated with immobilization. Osgood–Schlatter disease is treated with rest, occasionally plaster cast immobilization, and rarely surgical excision of loose ossicles to relieve symptoms.

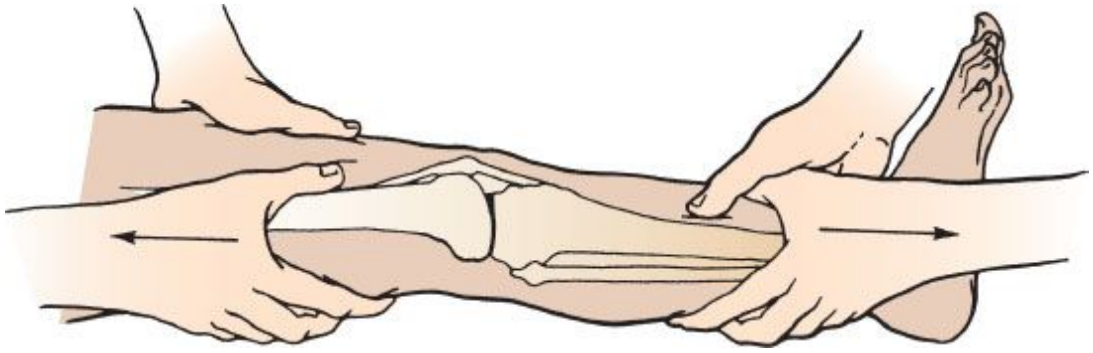
Diagnosis of patellar fractures is generally made with plain radiographs. A bipartite patella may be confused with a fracture. Often, the margins of a bipartite patella are rounded and well corticated but, in the setting of acute trauma, it may be difficult to differentiate from an acute fracture. Management is based on the type of fracture, degree of separation, and integrity of the extensor mechanism. Orthopedic referral is indicated. Simple nondisplaced fractures are treated with immobilization and outpatient orthopedic referral. Fractures that disrupt the extensor mechanism, typically displaced transverse or severely comminuted fractures, will require open reduction and internal fixation for optimal results.

Knee Dislocation

Arteriography has been used in the evaluation of knee dislocations to identify injuries to the popliteal artery. If there are signs of vascular injury (absent/decreased pulses, a diminished ankle-brachial index

[< 0.90], expanding hematoma, hemorrhage, ischemia, or bruit), the patient requires an arteriogram (6). Patients without hard signs may be admitted for serial examinations although some authors have advocated the use of routine arteriography in all patients with posterior knee dislocations, even in patients with intact distal pulses. There is disagreement about mandatory arteriography in patients with intact distal pulses, as the majority of these patients will have nonsurgical lesions, such as intimal tears. Therefore, others advise a more selective approach to arterial imaging, combined with admission and frequent neurovascular examinations (17). CT angiography (CTA) is being used with increasing frequency in place of traditional arteriography to assess for vascular injury, given the reduced radiation dose and less invasive nature of CTA (6).

Emergency management involves rapid reduction of the dislocation, particularly in cases with vascular compromise. Reduction can be accomplished by longitudinal traction (eFig. 44.2). If the clinical status permits, intravenous sedation and analgesia may facilitate the reduction. The limb's neurovascular status must be reassessed periodically, particularly after manipulation. Orthopedic and vascular surgery consultations should be obtained (6).



eFIGURE 44.2 Technique for reduction of knee dislocation.

Patellar Dislocation

Emergency management of patellar subluxations involves acute reduction. Reduction is typically performed by applying medial force to the patella while the knee is passively extended. Once reduced,

the knee is immobilized, and the patient is treated with elevation, ice, crutches, and outpatient orthopedic follow-up.

Ligamentous Injuries

Treatment of patients with collateral ligament injuries is based on the severity of the injury. These patients should be initially treated with immobilization, ice, and crutches. The patient should be referred for timely orthopedic follow-up.

For patients with cruciate ligament injuries, plain radiographs are often nonspecific. Sonography and MRI scanning are used to evaluate the cruciate ligaments and arthroscopy is useful for both diagnosis and treatment (13). Initially, immobilization and orthopedic consultation are necessary.

Meniscal Tears

MRI scanning is very helpful in identifying meniscal injuries. Arthroscopy is generally reserved for treatment, as the accuracy of the MRI is well documented (1). Initial treatment consists of immobilization, analgesia, and outpatient orthopedic referral within 1 week.

Tendon Injuries

X-ray findings may include a high-riding patella (*patella alta*) with a patellar tendon rupture or low-riding patella (*patella baja*) with quadriceps tendon rupture (15). CT or MRI may be necessary but can be deferred to outpatient follow-up. A complete rupture requires surgical repair. Incomplete ruptures usually will heal in 6 to 8 weeks with immobilization. Complete ruptures necessitate outpatient orthopedic referral within 5 to 7 days for further evaluation and definitive management.

Bursitis

If bursitis is suspected, rest, ice, and nonsteroidal anti-inflammatory medications are prescribed. The patient may be referred to an orthopedist for follow-up.

CRITICAL INTERVENTIONS

- Rapidly reduce knee dislocations utilizing longitudinal traction after intravenous sedation and analgesia, especially when vascular compromise is present.
- Perform arteriography in patients with knee dislocations, if there are hard signs of vascular injury (absent pulses, expanding hematoma, hemorrhage, ischemia, or bruit).
- Administer appropriate intravenous antibiotics in patients with open fractures.

DISPOSITION

Many of the knee injuries described may be evaluated in the ED and safely referred for orthopedic follow-up as an outpatient. The emergency physician should ensure that the knee is properly immobilized and provide the patient with appropriate analgesia and clear activity restrictions (weight bearing, crutches, etc). Follow-up appointments should generally take place within 1 week.

More severe injuries often require hospital admission. Significantly displaced fractures, open fractures, fractures with associated vascular or nerve damage, and injuries with the potential to develop compartment syndrome should all be admitted for further evaluation and treatment. Such injuries include distal femur fractures, tibial plateau fractures, patellar fractures (with disruption of the extensor mechanism), and knee dislocations.

Common Pitfalls

- Performing a physical examination while the patient remains in the wheelchair.
- Failure to examine the hip carefully. Knee pain is often referred from the hip, and knee trauma may precipitate hip injuries.
- Misinterpreting a bipartite patella as a patellar fracture on plain films.
- Failure to examine the knee in full extension against resistance when evaluating the extensor mechanism.

• Failure to diagnose a proximal fibula fracture or dislocation resulting from an ankle injury.

CHAPTER 45

Ankle and Foot Injuries

Kaushal Shah and Natasha Desai

Ankle injuries are among the most common sports-related and extremity injuries presenting to the emergency department (ED) accounting for approximately 20 million injuries per year and up to 20% of all sports injuries (1,2,3). Although the vast majority are benign injuries, there are instances when immediate action and emergent consultation are necessary.

The ankle and foot are relatively simple structures. The ankle is formed by (a) the tibia, which forms the medial malleolus, the posterior malleolus, and the plafond (ceiling); (b) the fibula, which forms the lateral malleolus; and (c) the talus (Fig. 45.1). The ankle is held together by (a) the medial ligaments collectively termed *deltoid ligament;* (b) the lateral ligaments–-anterior talofibular ligament (ATFL), calcaneofibular ligament (CFL), and posterior talofibular ligament (PTFL); and (c) the syndesmosis between the distal tibia and fibula (Fig. 45.2). The foot has three general parts: the hindfoot (calcaneus and talus), the midfoot (navicular, cuboid, and cuneiforms), and the forefoot (metatarsals and phalanges) (Fig. 45.1).

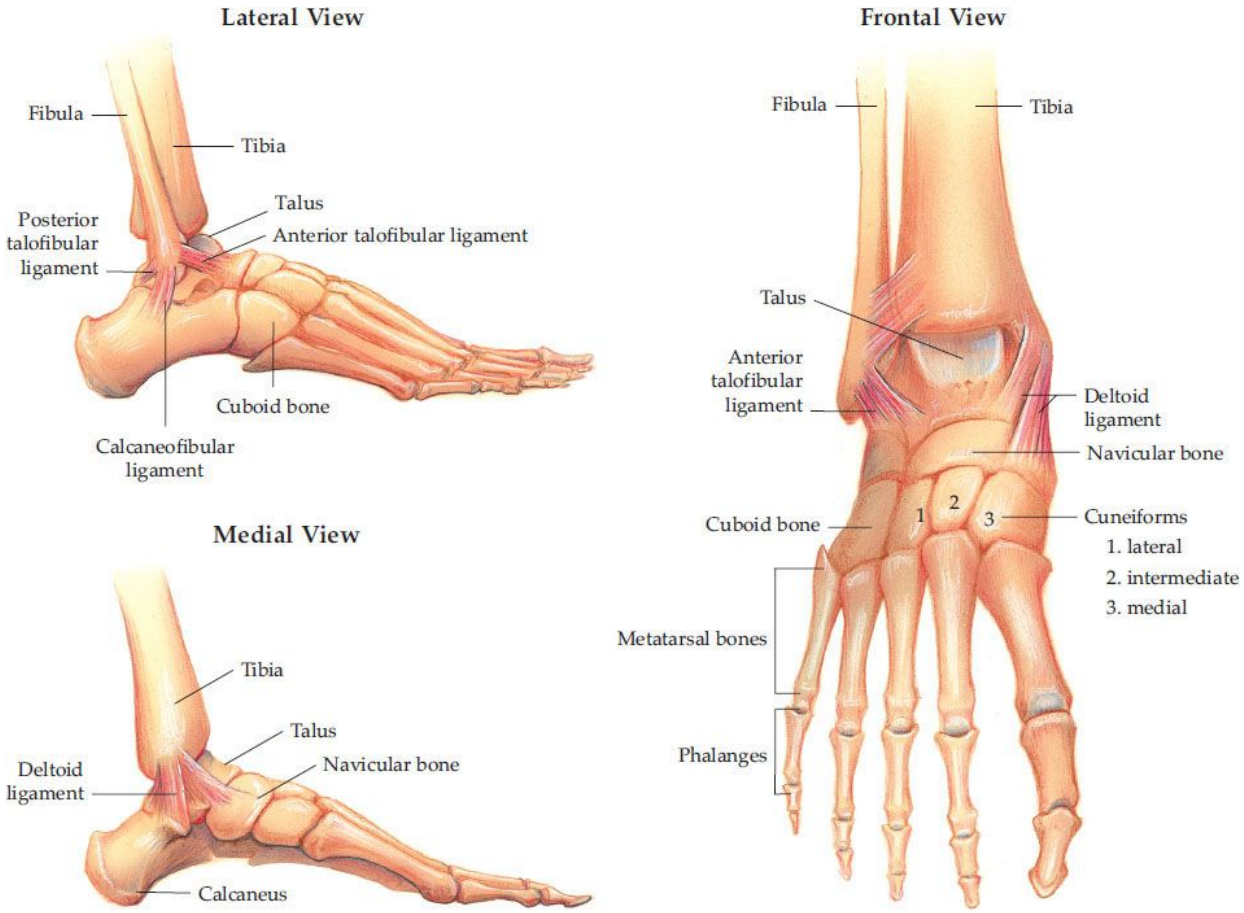

FIGURE 45.1 Anatomy of ankle and foot.

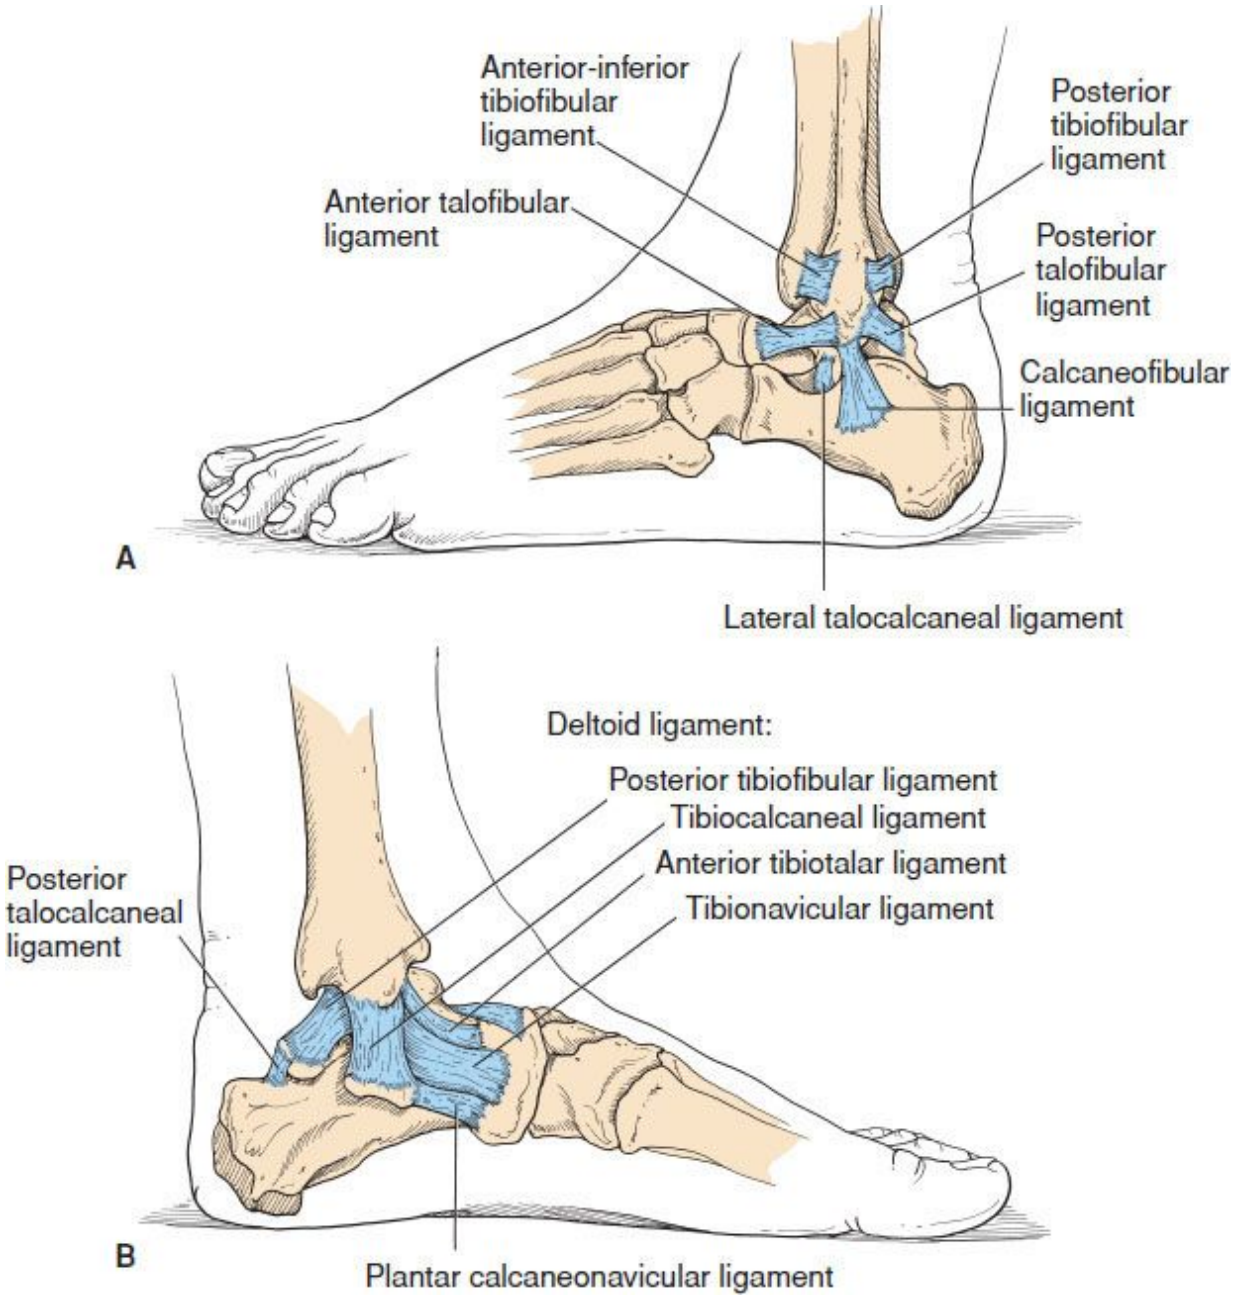

FIGURE 45.2 Ankle and foot – ligaments (A) lateral view; (B) medial view. (From Cipriano J. Photographic Manual of Regional Orthopaedic and Neurological Tests, 2nd ed. Baltimore, MD: Lippincott Williams & Wilkins; 1991.)

CLINICAL PRESENTATION

Ankle injuries can be anticipated by the position of the foot and direction of the force at the time of injury. Other key factors include

the ability to ambulate after injury and a history of previous injuries (1). Most common “red flags” suggestive of a fracture rather than a sprain are inability to bear weight, significant swelling, or tenderness. The ankle should be considered as a closed ring with the tibia, fibula, and talus as the main parts held together by ligaments. A break in two or more places results in instability.

ED EVALUATION AND MANAGEMENT

Ankle Ligamentous Injuries

Approximately 90% of ankle ligamentous injuries are due to inversion of the ankle, resulting in sprain of the lateral ligaments, most commonly the ATFL (1). Significant injuries from an eversion mechanism are far less common because the broad deltoid ligament is strong and resistant to tears. The clinical findings associated with ankle sprains range from mild pain and swelling to severe pain with edema and ecchymosis. Neurovascular status should be checked by palpating the posterior tibial and dorsalis pedis pulses, checking capillary refill, and assessing distal sensation. However, without gross deformity, it is extremely unlikely that the neurovascular status will be compromised. Palpation of the medial and lateral malleoli and the base of the fifth metatarsal for focal tenderness are critical to evaluate for associated fracture. The Ottawa Ankle Rules (OAR) are useful in determining which patients do not need radiographic evaluation for an ankle injury; the sensitivities range from 97% to 100% (Table 45.1) (4–6). In the pediatric population, the OAR have been shown to be 98.5% sensitive for predicting significant ankle and midfoot fractures in a meta-analysis of 12 studies which included 3,130 children older than 5 years (B). If x-rays are obtained, the physician should inspect the AP view for talar shift and malleolar fractures, the mortise view for widening of the tibiotalar joint, and the lateral view for posterior malleolar fracture and general alignment.

TABLE 45.1
Ottawa Criteria for Ankle Radiographs

An ankle radiographic series is required in patients aged 18–55 only if there is any malleolar pain and any of the following findings:

1. Bone tenderness at the posterior edge or tip of the medial malleolus
2. Bone tenderness at the posterior edge or tip of the lateral malleolus
3. Inability to bear weight for four steps both immediately and in the emergency department

From Ankel F. The Ankle. In: Hart RG, Rittenberry TJ, Uehara DT, eds. *Handbook of orthopedic emergencies.* Philadelphia, PA: Lippincott-Raven Publishers; 1999, with permission.

Provocative tests for ankle stability are necessary to determine the grade of injury. eTable 45.1 describes the grading of ankle sprains. The *anterior drawer test* assesses the integrity of the ATFL (Fig. 45.3). The test is positive if greater subluxation is noted on the injured ankle than the opposite one. The *talar tilt test* can be used to assess the lateral and medial ligaments (Fig. 45.3). If there is significant subluxation with inversion, tears of the ATFL or CFL should be suspected. Significant subluxation with eversion raises suspicion for a tear of the deltoid ligament. Integrity of the tibiofibular syndesmosis can be tested via the *squeeze test,* which involves squeezing the proximal tibia and fibula together. If pain is elicited, the test is positive (eFig. 45.1).

eTABLE 45.1
Classification of Ankle Sprains

Severity	Symptoms	Signs	Examination	Treatment
Grade I	Mild pain and swelling, able to bear weight	Slight edema	Negative anterior drawer and talar tilt	RICE[a] and referral to primary care physician in 1 wk
Grade II	Moderate pain and swelling, difficulty bearing weight	Moderate edema and ecchymosis	Positive anterior drawer (4–14 mm) and talar tilt test (5–15 degrees)	Rigid splint and referral to orthopedist in a week
Grade III	Severe pain and swelling, inability to bear weight	Severe edema and ecchymosis	Positive anterior (>15 mm) and tilt test (>15 degrees)	Rigid splint and referral to orthopedist within a week

[a]Rest, ice, compressive dressing, and elevation.

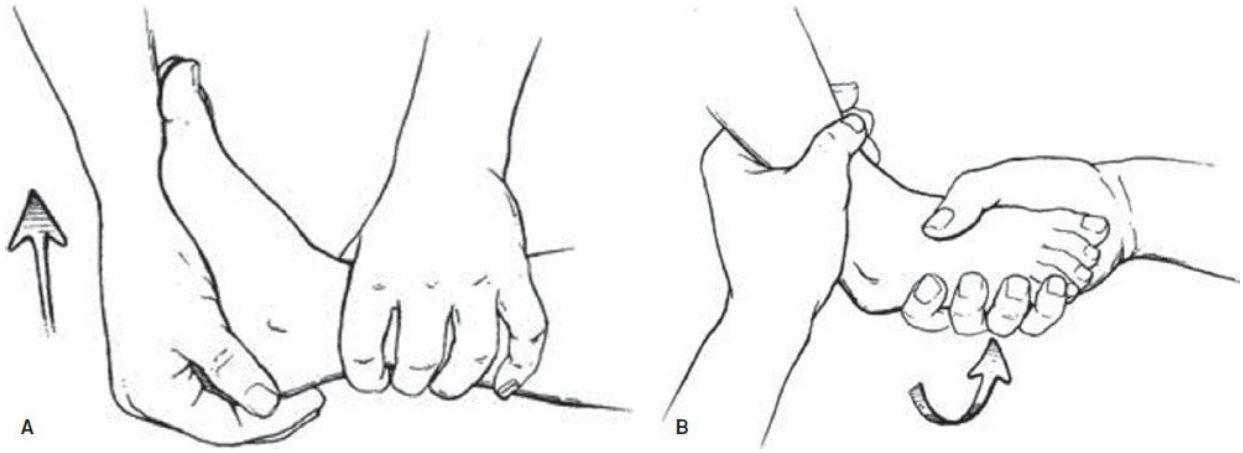

FIGURE 45.3 A: The anterior drawer test is performed by placing the patient's heel in the palm of the examiner's hand with the ankle at a 90-degree angle to the long axis of the leg. The examiner gently, but firmly, moves the heel and foot forward (arrow). B: In the talar tilt maneuver, the heel is firmly adducted (arrow) and assessed for increased laxity or instability compared with the noninjured side. (Adapted from Fleisher GR, Ludwig S, Henretig FM, et al. Textbook of Pediatric Emergency Medicine. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

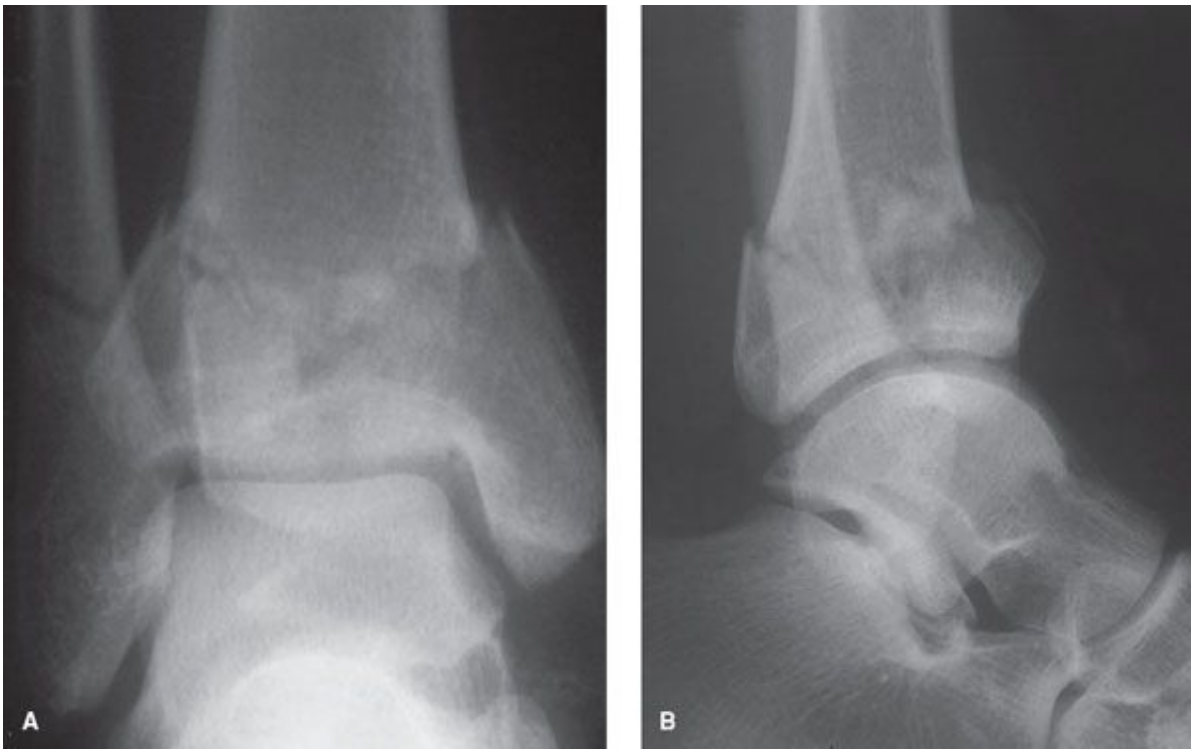
eFIGURE 45.1 The squeeze test—practitioner squeezes the tibia and the fibula together. If pain is elicited, it suggests a tibiofibular syndesmosis injury. (From Dale Berg, Katherine Worzala. Atlas of Adult Physical Diagnosis. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)



eFIGURE 45.2 X-ray of a pilon fracture in a 46-year-old man, resulting from an axial load in a motorcycle accident. A: AP view. B: Lateral view.

Acutely, ibuprofen 10 mg/kg (not to exceed 800 mg) PO or acetaminophen 15 mg/kg (not to exceed 1,000 mg) PO should be administered for pain. Ketorolac 30 to 60 mg IM or IV, in an adult, is also effective. General management guidelines follow the "*RICE*" mnemonic: *r*est ankle and avoid reinjury which may entail use of crutches; *i*ce the ankle for 20 minutes three to four times per day for the first day to reduce swelling; *c*ompress with an elastic ACE wrap or ankle brace to reduce swelling and pain; *e*levate the extremity as often as possible to reduce swelling. eTable 45.1 describes the management based on the grade of the injury. If serious ligamentous injury is suspected, resulting in joint laxity (i.e., grade II and higher sprains), more rigid splinting methods should be considered. An air stirrup splint is moderately effective in preventing inversion and eversion of the ankle and is appropriate for grades I and II ankle sprains. For grade III injuries, a short-leg posterior rigid splint (e.g., plaster) that runs from midcalf to the toes should be used to further

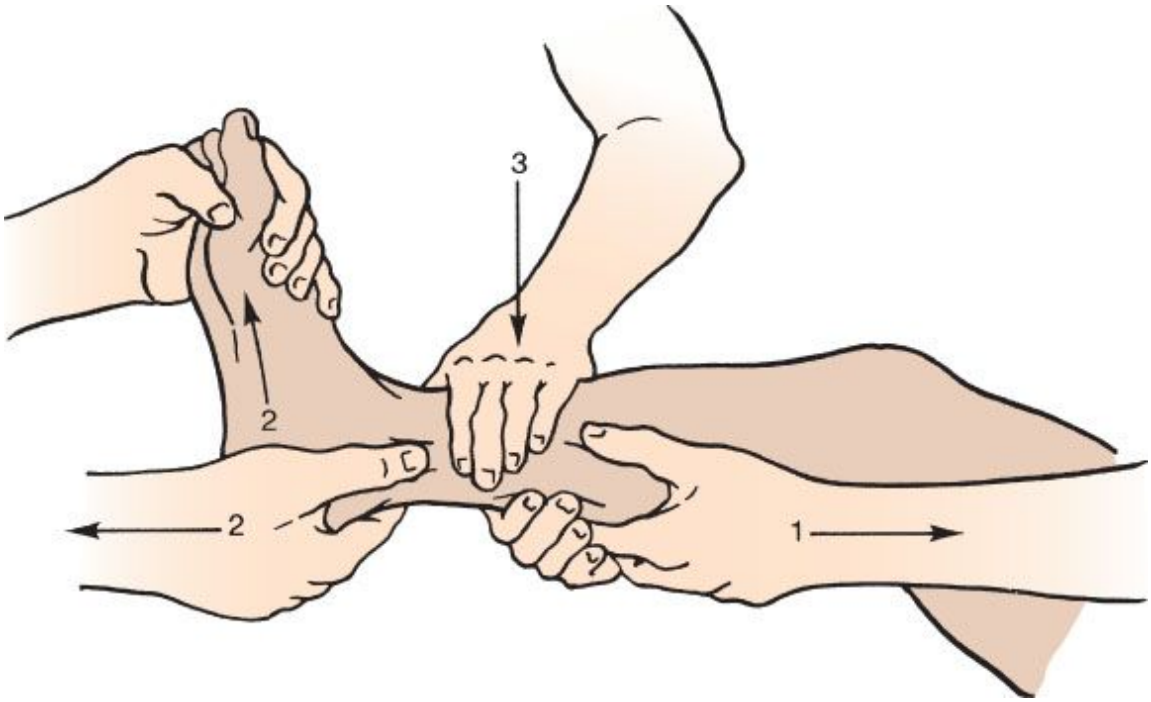
immobilize the ankle to prevent worsening of the injury and promote healing.

All patients with ankle sprains can be discharged home but should have appropriate follow-up within 1 week. Although pain and swelling should abate and the ability to ambulate should improve with time, occult fractures and high-grade sprains may require further orthopedic or sports medicine care. Other indications for orthopedic referral include (a) a "pop" that is heard or felt, (b) a history of several previous injuries, (c) medial ankle tenderness, (d) a positive squeeze test or other stress test, and (e) grade II and higher sprains in children with open growth plates (7). In children, less force is required to sustain a Salter–Harris I fracture than is required to tear a ligament (see Chapter in Pediatric Section, "Extremity fractures"). Thus, any patient who is suspected of having a significant ankle sprain and no clear fracture on x-ray should be splinted and referred to an orthopedic surgeon for follow-up.

Ankle Fractures

Ankle fractures can present after a significant traumatic mechanism or after a simple ankle inversion or eversion twisting injury. There are several types of ankle fractures that should be considered in the differential diagnosis. A *lateral malleolus* fracture is the most common type of ankle fracture resulting from inversion of the ankle. Isolated *medial malleolus* fractures are less common because the injury requires more force than a lateral malleolus fracture. Therefore, other associated fractures and joint instability should be suspected. Patients with *bi-* or *trimalleolar fractures* present with significant pain, swelling, and ecchymosis, and associated dislocations are common. A distal tibial fracture through the articular surface is called a *plafond fracture.* Although commonly used interchangeably with the term plafond fracture, a *pilon fracture* is specifically a comminuted plafond fracture that results from an axial compression force to the tibial plafond (eFig. 45.3). The *Maisonneuve fracture* is an oblique fracture of the proximal fibula associated with a medial malleolus fracture or deltoid ligament tear. It can easily be missed if the proximal fibula is

not routinely palpated in patients with ankle-twisting injuries. These last two fractures require radiographs of the entire tibia and fibula.



eFIGURE 45.3 Technique for posterior dislocation reduction.

As with ankle sprains, neurovascular status should be checked immediately. The history and physical examination are identical to that of ankle sprains. If there is gross deformity, a dislocation should be considered and should be reduced emergently if there is neurovascular compromise. Lacerations and wounds should be examined closely to ensure that an open fracture is not present.

Suspected ankle fractures require x-rays in three views as described above. The two most common classification systems for ankle fractures are the *Lauge-Hansen* and *Danis–Weber*. The Danis–Weber classification system is simpler and is based on the location of the fibular fracture (Fig. 45.4). A fibular avulsion fracture below the tibiotalar joint line is called a *Weber type A* fracture. If the fibular fracture is in the joint line, it is a *Weber type B* fracture. Fractures above the joint line disrupting the syndesmosis ligament are termed *Weber type C* fractures.

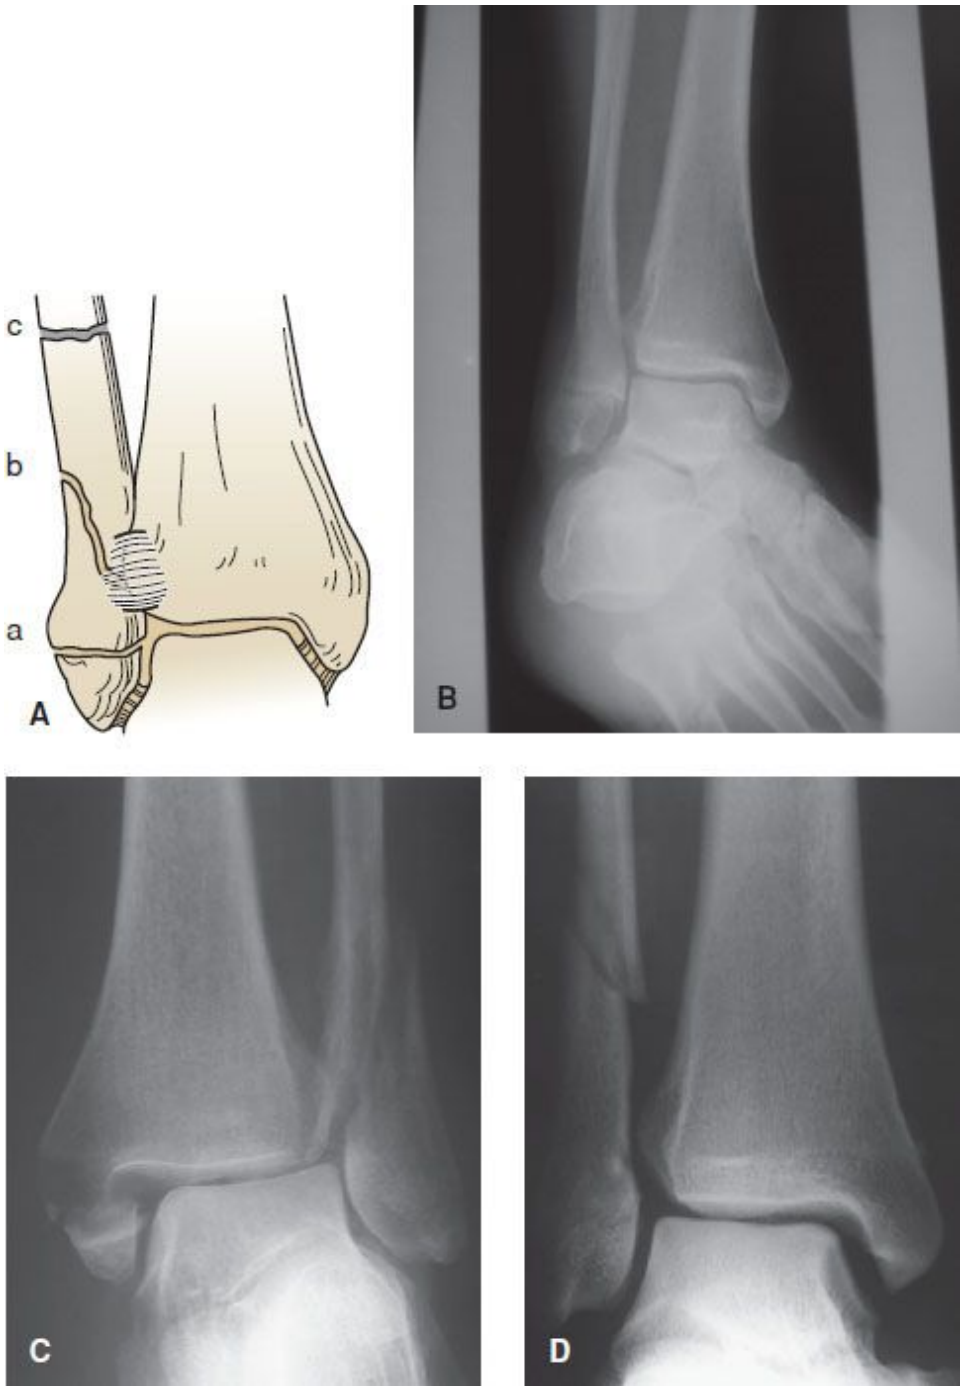


FIGURE 45.4 A: Schematic diagram of the Danis–Weber classification of ankle fractures. B: A type A fracture where the anterior tibiofibular ligament remains intact. C: A type B fracture with the fracture extending through the ligament. D: A type C fracture where the fracture is above the joint line. (From Bucholz RW, Heckman JD, Court-Brown C, et al., eds. Rockwood and Green's

Fractures in Adults. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Patients should receive adequate analgesia. Intravenous, intramuscular, and subcutaneous injections are preferred (rather than oral administration) until it is certain the patient will not require an operative procedure. Isolated lateral or medial malleolar fractures without instability can be safely discharged home without orthopedic consultation in the ED. The emergency physician should first place the ankle in a posterior splint, provide crutches for nonweight bearing, provide adequate analgesia, and ensure close orthopedic follow-up. All other ankle fractures will require orthopedic consultation in the ED.

Isolated fractures of the distal tibia and fibula should be immobilized in a short-leg posterior splint. A *sugar tong* splint (U-splint) can also be used; it wraps along both the medial and lateral sides of the leg with the base of the "U" under the foot (similar to an air stirrup) and is more effective in stabilizing the medial and lateral ligaments. Patients with severe injuries to the ankle, such as bi- and trimalleolar fractures, should be placed in both a posterior splint and a sugar tong splint ("AO" splint). This provides immobilization similar to that of casting but allows for the expected ankle swelling.

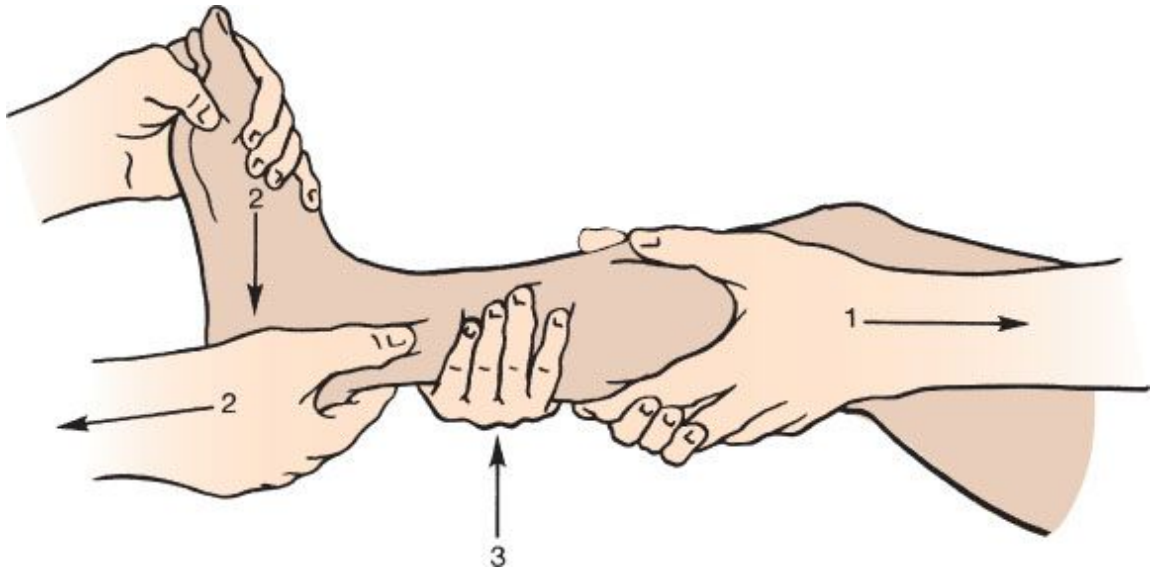
Ankle Dislocations

For the talus to dislocate from the distal tibia, multiple ligaments are torn, and there are often associated malleolar fractures. Significant force is required, and there is always gross deformity and inability to bear weight.

The emergency physician should perform immediate reduction if there is neurovascular compromise or significant skin tenting with concern for conversion into an open fracture–dislocation. In cases of uncomplicated dislocations, x-ray evaluation should precede reduction.

Reduction of the ankle requires conscious sedation and two assistants. For posterior dislocations, the first assistant flexes the

knee to 45 degrees and applies counter-traction over the calf while the second assistant pushes down on the front of the lower leg. The physician applies traction to the heel and forefoot after first plantar flexing the foot and then lifting the heel (eFig. 45.3). For anterior dislocations, the first assistant flexes the knee to 45 degrees and applies counter-traction over the calf while the second assistant lifts up on the lower leg. The physician should dorsiflex the foot initially to disengage the talus and then push downward on the foot (eFig. 45.4). For lateral dislocations, the physician applies longitudinal and medial traction whereas an assistant applies counter-traction.



eFIGURE 45.4 Technique for anterior dislocation reduction.

Orthopedic consultation is necessary for all fracture–dislocations of the ankle. If a patient needs to be transferred, the emergency physician should reduce the ankle and place the ankle in a short-leg posterior splint (with or without a sugar tong splint). For open dislocations, IV antibiotics should be administered prior to transfer. Cefazolin 1 to 2 gm IV in adults is usually adequate, but patients with contaminated wounds should also receive gentamicin 2 mg/kg IV.

Achilles Tendon Rupture

The classic presentation is a middle-aged man complaining of ankle pain and inability to bear weight after hearing a “pop” while playing sports. Risk factors for rupture include steroid injections and tendonitis. The Achilles tendon usually ruptures at the narrowest segment, approximately 5 cm above its attachment to the calcaneus.

Occasionally an obvious defect in the Achilles tendon can be palpated. However, the most useful signs of this injury are weakness of plantar flexion and a positive *Thompson test* (the foot does not plantar flex when the calf is squeezed) (eFig. 45.5). The test is performed with the patient prone and the knee flexed to 90 degrees.

eFIGURE 45.5 The Thompson test for continuity of the gastrocnemius-soleus complex. Without rupture of the Achilles tendon, squeezing the calf causes active plantar flexion of the foot. With rupture, squeezing the superficial posterior compartment of the leg does not induce plantar flexion of the foot. (Adapted from Browner B, Jupiter J, Levine A. Skeletal Trauma: Fractures, Dislocations, and Ligamentous Injuries, 2nd ed. Philadelphia, PA: WB Saunders; 1997.)

Orthopedic consultation should be obtained. Operative versus conservative management is currently under debate; surgical repair has been shown to decrease rate of rerupture; however, complication rates increase (8). It is also appropriate to place a posterior splint

with the foot in plantar flexion and refer to an orthopedist within 48 to 72 hours.

Peroneal Tendon Subluxation

These patients present very similar to those with a simple ankle sprain. However, the mechanism is different. The injury is caused by dorsiflexion and eversion of the ankle resulting in contraction of the peroneal muscle and disruption of the peroneal retinaculum. Because the peroneal tendon subluxes out of its groove along the posterior lateral malleolus, the ankle is swollen, tender, and ecchymotic around the lateral malleolus.

Although x-rays are usually negative for bony disruptions, these patients should be placed in a sugar tong splint with extra lateral malleolar padding. Patients should be referred to an orthopedist within a week for casting and should remain nonweight bearing for 4 to 6 weeks. Occasionally, surgery is recommended for athletes, those who fail nonoperative management, and those with chronic subluxations (9).

Calcaneal Fractures

A vertical compression force, such as jumping or falling from a height and landing directly on the feet, is the most common etiology of calcaneal fractures. They occur more commonly in men who are 30 to 50 years old. Patients complain of heel pain and have difficulty bearing weight.

Three radiographic views (AP, lateral, and axial) of the heel should be obtained. Fractures are often not clearly visible owing to a predominantly compressive force. A helpful measurement to make the diagnosis is determination of *Boehler angle* on the lateral view (Fig. 45.5). A normal angle is 20 to 40 degrees, and an angle less than 20 degrees indicates a calcaneal fracture.

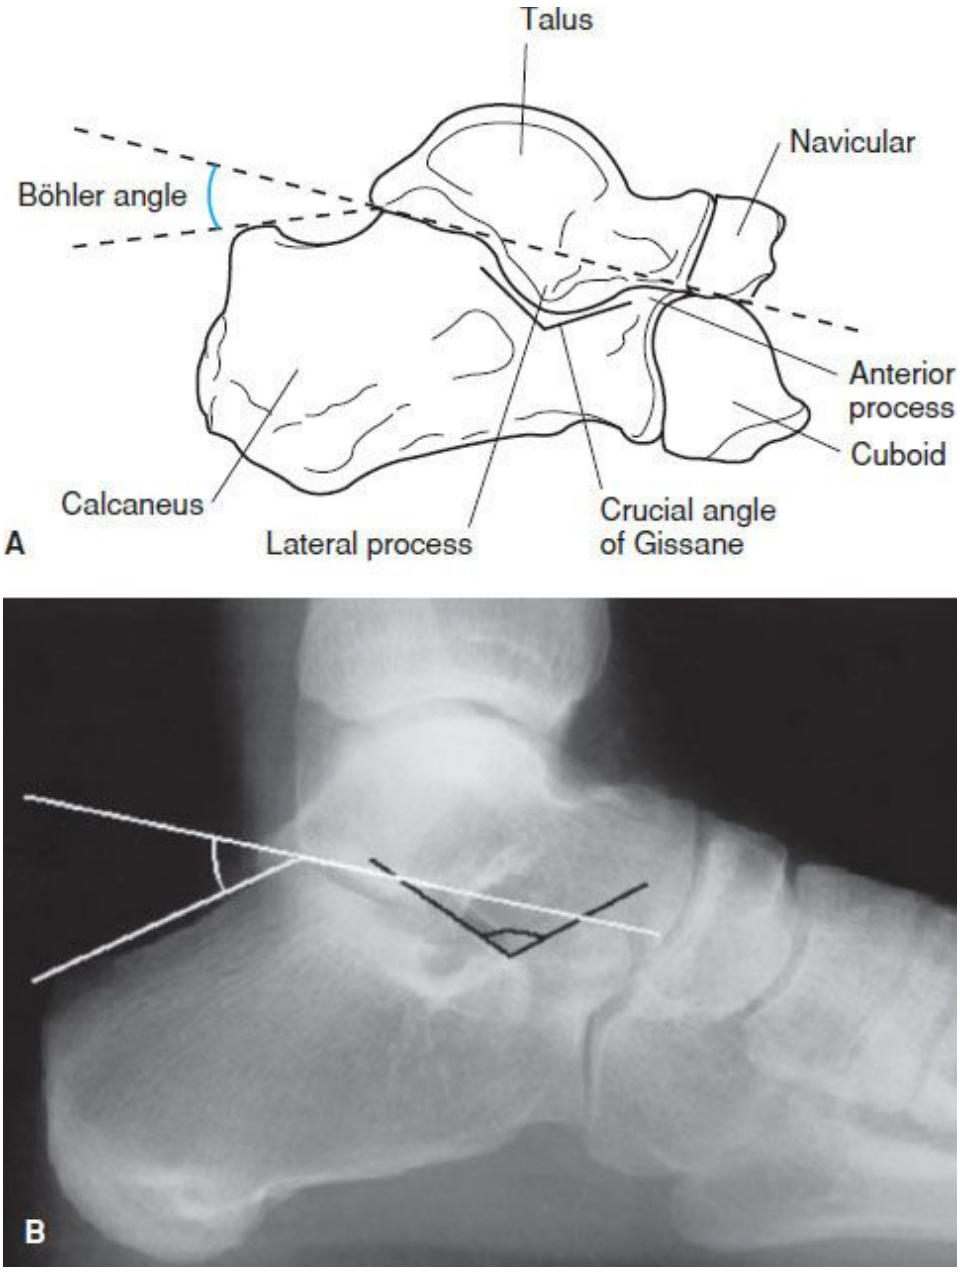


FIGURE 45.5 Lateral view of the calcaneous. A: A schematic outlining Boehler (also known as Böhler) angle and the crucial angle of Gissane. B: Lateral radiograph showing both anatomical angles. (From Bucholz RW, Heckman JD. *Rockwood & Green's Fractures in Adults*. 5th ed. Philadelphia, PA: Lippincott, Williams & Wilkins; 2001.)

Owing to the mechanism and force required, a thorough trauma evaluation is important. Calcaneal fractures are specifically

associated with lumbar spine injuries in 10% of patients.

Patients with calcaneal fractures require emergent orthopedic evaluation. It is likely that the specialist will request a computed tomography (CT) scan or magnetic resonance imaging (MRI) to better delineate the fracture pattern. Operative verses nonoperative management is controversial. However, both are associated with a high incidence of chronic pain and loss of joint mobility and function. If orthopedic consultation is not immediately available and the patient has no associated injuries warranting admission, the physician should provide analgesia and place the patient in a short-leg posterior splint. The patient should be nonweight bearing. Orthopedic follow-up should occur within 24 to 48 hours (10).

Talus Fractures

A high-impact mechanism is required to fracture the talus. A hyperdorsiflexion injury from a motor vehicle collision or fall from a height is necessary to compress the talus between the tibia and calcaneus. Osteochondral fractures of the talar dome (also termed *osteochondritis dessicans*) occur after an inversion mechanism. Patients usually present with chronic pain after the diagnosis is missed on the initial visit because physical findings are nonspecific and plain radiographs may be normal. Suspected talar dome fractures may benefit from bone scan, CT, or MRI for further evaluation and classification.

Unlike talar dome fractures, fractures through the body and neck are usually visible on plain radiographs. It is particularly important to evaluate for the commonly associated *subtalar dislocation.* In addition, the *os trigonum* (accessory bone) can occasionally be mistaken for a posterior process fracture.

Recently, there has been increased attention to fractures of the lateral process of the talus (LPT). This fracture is closely associated with snowboarding and was relatively rare prior to the advent of the sport. It now accounts for less than 1% of all ankle injuries and for 15% of snowboarders' ankle injuries (11,12), leading to the name snowboarder's fracture. The LPT is a wedge-shaped prominence which articulates with the fibula and the calcaneus. Although the

incidence is increasing because of the growing popularity of the sport, this fracture is frequently misdiagnosed as an ATFL sprain, leading to inadequate immobilization and less orthopedic intervention. Misdiagnosis can lead to significant morbidity, such as nonunion and degenerative arthritis (13,14). The mechanism of injury is still under investigation. It is most commonly believed to be a high impact injury on an axially loaded and dorsiflexed ankle, combined with foot inversion (13). Like other talus fractures, it can be difficult to identify an LPT fracture on plain radiographs, with a miss rate of approximately 40%. CT or MRI is often required to make the diagnosis, and thus a high index of suspicion is necessary (15). These fractures often present to the ED as chronic pain after an ankle sprain. All LPT fractures should be immobilized, and require nonweight bearing and close orthopedic evaluation. Operative management is dependent on severity (11,12).

Talus fractures require evaluation and continued care by an orthopedic surgeon because the bone has a tenuous blood supply and, as a result, there is a high rate of avascular necrosis. Most talar fractures require short-leg casting for 6 to 8 weeks, but some require open reduction and internal fixation. Patients should be nonweight bearing. Disposition is based on recommendations by the orthopedist. Patients can be referred for an outpatient CT or MRI for suspected talar dome fractures (10).

Subtalar Dislocation

A subtalar dislocation involves the talocalcaneal and talonavicular joints (without disruption of the tibiotalar joint). This injury results from a significant torsional force usually causing a medial or lateral dislocation. There is usually an obvious deformity of the foot, but swelling can occasionally mask the deformity.

As with any dislocation, assessing the neurovascular status is important. Although uncommon, compromised neurovascular status is an indication for immediate reduction. Plain films of the foot are diagnostic; the AP view is most likely to reveal the subtalar dislocation.

Subtalar dislocations require urgent closed reduction either under conscious sedation or general anesthesia. Reduction is performed by flexing the knee and applying longitudinal traction on the foot with initial reproduction of the injury followed by reversal of the deformity. If closed reduction in the ED is unsuccessful, orthopedic consultation is essential. Successfully reduced subtalar dislocations should be immobilized with a short-leg posterior splint and sugar tongs (U-splint). After reduction, if orthopedic consultation is not available in the ED, follow-up should occur within 24 to 48 hours.

Lisfranc Fracture–Dislocation

The Lisfranc joint is the joint between the midfoot and forefoot (metatarsals and phalanges). Direct trauma or hyperdorsiflexion of the Lisfranc joint (e.g., in a motor vehicle collision) can result in a Lisfranc fracture–dislocation, defined as a fracture at the base of the second metatarsal or second cuneiform with dislocation of the lateral four metatarsals. The occurrence is rare but results in significant morbidity when there is a delay in treatment. This particular fracture has a high misdiagnosis rate of approximately 20%.

The foot is usually very swollen and tender over the tarsometatarsal joint. Plantar ecchymosis has been described as a relatively common finding in patients with Lisfranc fracture–dislocations (17).

When examining an AP foot x-ray, the physician should look for a fracture at the base of the second metatarsal and assess alignment of the cuneiform bones with the metatarsals. The space between the bases of the metatarsal bones is widened (Fig. 45.6). The standard foot x-ray series can miss up to 50% of Lisfranc fractures. If there is suspicion and standard plain films are normal, then stress- or weight-bearing AP and lateral views can be obtained to reveal the widening (17).

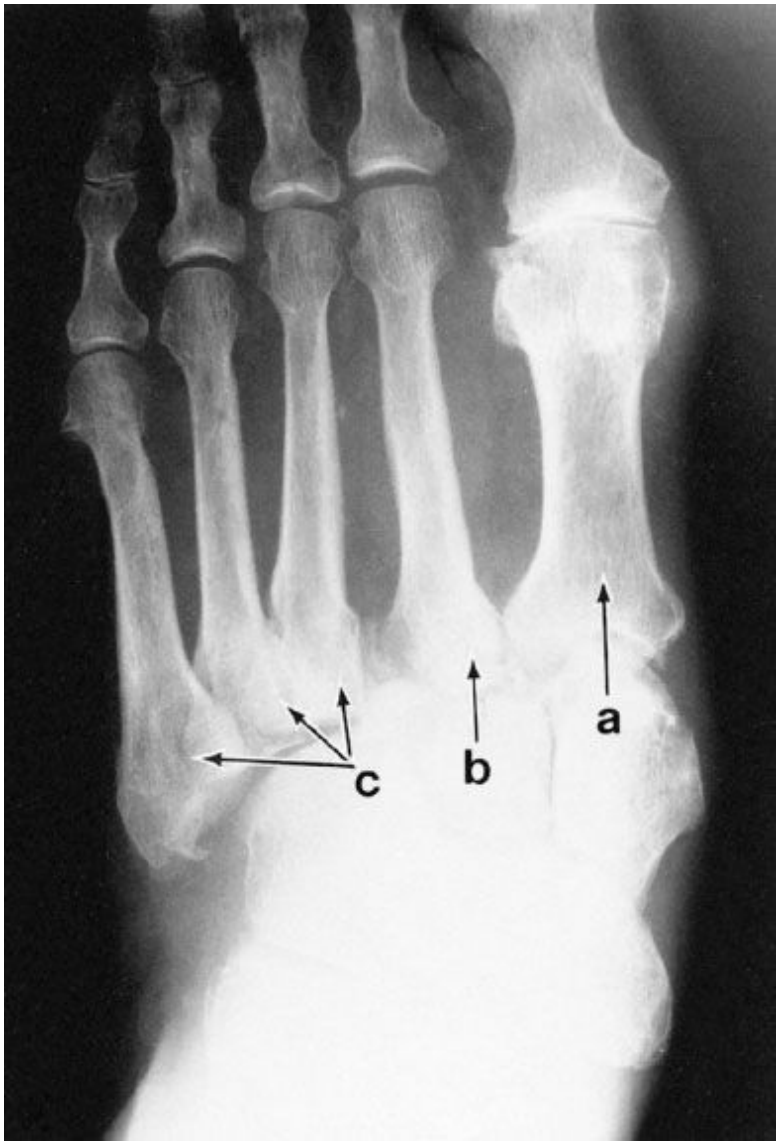

FIGURE 45.6 Radiograph of a Lisfranc dislocation: (a) first metatarsal; (b) second metatarsal; (c) third, fourth, and fifth metatarsals, which have been dislocated laterally.

Lisfranc fracture–dislocations require orthopedic consultation in the ED. These injuries require open reduction and internal fixation to improve outcome and reduce complications. If an orthopedic consultant is not immediately available, the physician should provide analgesia and place the patient in a short-leg posterior splint, preferably with a sugar tong splint. The patient should be nonweight bearing. Orthopedic follow-up should occur within 24 to 48 hours,

and the timing of definitive treatment and the degree of reduction are critical to the outcome.

Midfoot Fractures

Fractures of the midfoot (cuboid, navicular, and cuneiforms) are rare and usually occur from direct blunt trauma. Most midfoot injuries involve a combination of fractures, isolated bone fractures are the exception. There is typically focal tenderness and swelling over the fractured bones.

Midfoot fractures are usually visible on plain radiographs. Nondisplaced fractures can be immobilized and nonweight bearing with a posterior splint. They can be discharged with prompt orthopedic follow-up for evaluation and a short-leg cast for 6 to 8 weeks.

Proximal Fifth Metatarsal Fractures

Fractures of the fifth metatarsal usually result from an ankle inversion mechanism. The *Jones* and *pseudo-Jones* fractures present with pain over the base of the fifth metatarsal. A *Jones fracture* is a transverse fracture at the proximal diaphysis of the fifth metatarsal. A *pseudo-Jones* or *Dancer's fracture* is an avulsion fracture of the proximal end of the fifth metatarsal by the peroneus brevis tendon resulting from plantar flexion and inversion of the foot.

Palpation of the fifth metatarsal is essential in any patient with an ankle-twisting injury to determine the need for foot films in addition to ankle films to make the diagnosis of Jones or pseudo-Jones fractures (eFig. 45.6). The Ottawa criteria are useful to determine the need for foot x-rays (Table 45.2).

eFIGURE 45.6 Proximal fifth metatarsal injuries. A: Avulsion or pseudo-Jones fracture. B: Jones fracture.

TABLE 45.2
Ottawa Criteria for Foot Radiographs

A foot radiographic series is required in patients aged 18–55 only if there is pain in the midfoot and any of the following findings:

1. Bone tenderness at the base of the fifth metatarsal
2. Bone tenderness at the navicular bone
3. Inability to bear weight for four steps both immediately and in the emergency department

From Ankel F. The Ankle. In: Hart RG, Rittenberry TJ, Uehara DT, eds. *Handbook of orthopedic emergencies*. Philadelphia, PA: Lippincott-Raven Publishers; 1999, with permission.

Jones fractures have a high incidence of delayed healing or nonunion. Orthopedic evaluation in the ED is recommended. If immediate consultation is not available, the foot should be immobilized with a posterior splint with or without a sugar tong splint, and the patient should have an orthopedic referral in 24 to 48 hours. Athletes are usually treated operatively, and nonathletes are treated with a walking cast for 4 to 6 weeks (17).

Pseudo-Jones fractures are stable and can be treated with a hard-sole shoe or a *Jones dressing* with weight bearing as tolerated. A *Jones dressing* is a bulky dressing used for injuries that require moderate immobilization when swelling is expected. The dressing consists of multiple layers: a thick layer of Webril (cotton roll), followed by an ACE wrap (elastic bandage), then another layer of Webril and another layer of ACE wrap.

Forefoot Injuries

The most common metatarsal and phalangeal fractures result from direct trauma and present with swelling, tenderness, and ecchymosis. Dislocations of the metatarsophalangeal (MP) and interphalangeal (IP) joints are caused by dorsiflexion and compression of the phalanges. In addition to swelling and tenderness, there is usually visible deformity.

More subtle stress fractures can occur to the second and third metatarsal bones. During push off, the maximum load is placed on the forefoot. As a result, these bones are prone to stress fractures. Patients usually have a history of increased walking, jogging, or marching activity, and they complain of poorly localized pain in the foot with minimal swelling (17).

The neurovascular status of the foot should be documented, especially the presence of the dorsalis pedis pulse. Dislocations with neurovascular compromise should be reduced immediately; otherwise it is prudent to assess the plain films for fractures before manipulation.

Plain films are adequate to evaluate for acute traumatic fractures and dislocations. However, initial radiographs will often not reveal stress fractures. Stress fractures are usually apparent 2 to 3 weeks later as callus formation or periosteal reaction, but they can also be detected earlier by bone scan.

In patients with MP joint dislocations, the phalanx is usually dorsally displaced. Reduction is performed by hyperextension, followed by longitudinal traction and dorsal pressure. Patients can be discharged with a dorsal toe splint, crutches, and orthopedic follow-up. IP joint dislocations can occur in a dorsal or volar direction. The reduction technique is similar for both types. Patients can be discharged after the injured toe is buddy taped to the adjacent toe. Patients should follow up with an orthopedist in a week because of the possibility of unstable dislocations.

Nondisplaced fractures should be placed in a short-leg splint and follow-up should be arranged. Displaced fractures require reduction by an orthopedist. Stress fractures or suspected stress fractures require close orthopedic follow-up and discontinuation of any pain-producing activity.

Turf Toe

Turf toe is a sprain of the MP joint of the great toe that results from pushing off of a hyperdorsiflexed toe. The toe is tender and swollen. An x-ray should be obtained to rule out fracture. Like most sprains, the treatment is joint rest with a hard-soled shoe limiting dorsiflexion, ice and analgesia, and ibuprofen or acetaminophen for pain. Orthopedic consultation is necessary only for patients with persistent pain beyond 1 to 2 weeks.

Plantar Fasciitis

Patients with plantar fasciitis complain of pain in the arch and heel of the foot that is worse in the morning or when climbing stairs. There is usually a history of overuse (hill running or sprinting) or poor arch support. Evaluation reveals tenderness over the plantar fascia and reproduction of the pain with dorsiflexion of the toes. If there is focal tenderness or a stress fracture is suspected, plain films of the foot are indicated. Treatment involves rest, ice, analgesia, and splinting for comfort. Follow-up with an orthopedist, sports medicine specialist, or physical therapist is recommended. These patients may require evaluation for an orthotic device or exercise program.

Puncture Wounds

Plantar puncture wounds have the potential for serious complications (e.g., soft tissue infection and osteomyelitis). Wounds should be inspected, cleansed, irrigated, and explored, especially if a foreign body is suspected. Deep probing, extensive coring, or debridement of vital tissue does not improve outcome. Radiographic studies are warranted if the history suggests a foreign body and exploration is inconclusive. Puncture through tennis shoes have been implicated in pseudomonal infections, but most soft tissue infections are due to *streptococcus* and *staphylococcus* species. Most cases of osteomyelitis are due to *pseudomonas* (18,19). The use of prophylactic antibiotic for puncture wounds to the foot is controversial. Given the risk of complications such as osteomyelitis, its use should be considered. If the decision is made to use antibiotics, a first-generation cephalosporin should be given. For clean, superficial wounds with no concern for retained foreign body, local wound care is the sufficient treatment. A wound check in 48 hours is recommended for contaminated wounds and those with possible retained foreign bodies.

Patients presenting with infection after a puncture wound should be treated with broad-spectrum antibiotics, and the physician should search for a foreign body via exploration, radiographs, or CT scan. Surgical consultation may be needed.

KEY TESTING

- Perform a complete neurovascular examination distal to injury
- Assess for ankle instability with provocative testing
- Obtain three-view ankle x-rays or three-view foot x-rays according to Ottawa Ankle Rule
- Obtain stress- or weight-bearing views to assess for Lisfranc injury if there is a high suspicion

CRITICAL INTERVENTIONS

- In a patient with neurovascular compromise and a visibly deformed extremity, reduce the fracture emergently to restore sensation and blood flow.
- Obtain radiographic confirmation in patients with dislocated joints without neurovascular compromise and then reduce the joint.
- In patients with open fractures, administer antibiotics and obtain emergent orthopedic consultation for wash-out and admission.
- Provide appropriate follow-up care for all patients with ankle and foot injuries.

DISPOSITION

Most patients with ankle or foot injuries should have close follow-up in the event that symptoms do not improve and further investigation and treatment are required. Exceptions are minor ankle sprains and turf toe. Patients who are sent home in a posterior short-leg or sugar tong splint should have orthopedic follow-up within 24 to 48 hours for reassessment and definitive immobilization with a cast.

Orthopedic consultation should be obtained in the ED for the following fractures and dislocations: plafond, bi-, or trimalleolar fractures; calcaneal, talar, or Jones fractures; Lisfanc fracture/dislocation; and ankle and subtalar dislocations. If orthopedic consultation is not immediately available, appropriate reduction or splinting should be performed, and arrangements should be made for orthopedic evaluation within 24 to 48 hours. Open fractures will require immediate orthopedic consultation.

Common Pitfalls

- Failure to palpate the base of the fifth metatarsal to evaluate for a Jones fracture.
- Treating a Jones fracture as a pseudo-Jones fracture.
- Failure to squeeze the proximal tibia–fibula area to evaluate for a Maisonneuve fracture in patients with presumed ankle sprains.
- Applying the Ottawa Ankle Rules to patients younger than 5 and older than 55 years.
- Failure to recognize a Lisfranc fracture.
- Treating grade I and II ankle sprains with prolonged immobilization rather than early mobilization and exercise.

PART 4 • SPECIAL CONSIDERATIONS

CHAPTER 46

Burns

Adam J. Singer and Steven Sandoval

The incidence of burn injuries requiring medical attention in the United States has declined from 2 million annually in the 1960s to an estimated 450,000 per year in 2012 (1). Approximately 40,000 burn injuries require hospitalization, and 3,400 of these people die. In the United States, in 2004, someone died in a fire on average every 135 minutes, and someone was injured every 30 minutes (2). Approximately 6% have a related inhalation injury, which raises mortality from about 5% to >25% (3). More than 60% of burns are <10% total body surface area (TBSA), so the emergency department (ED) may be the only location where many are treated. Seventy-six percent of burn or fire deaths in 2002 resulted from residential fires (4). Many of these deaths were related to smoke inhalation. Children younger than 5 years and adults older than 65 have higher mortality rates (5). Burns remain the third leading cause of unintentional death in children, surpassed only by motor vehicle collisions and drownings. In the general population, the most frequent source of burns is flames (40%) (6). Approximately 70% of pediatric burns are scalds from hot liquids associated with cooking or bathing, and nearly 20% of hot liquid burns involve neglect or abuse, particularly water immersion.

CLINICAL PRESENTATION

The severity of thermal trauma is determined mainly by the depth and size of injury, but it is also influenced by the presence of inhalation injury, circumferential burns, or specific locations of the burn injury, such as hands, feet, major joints, face, or genitalia (7).

Other factors that contribute to the severity of the injury include the causative factors, age of the patient, toxic exposures, concomitant traumatic injuries, and comorbidities.

The skin is a laminar structure with the outermost layer being the epidermis, composed of keratinocytes that arise from the stratum germinativum, migrate upward, and finally desquamate. Beneath the epidermis lies the dermis, which contains the epidermal appendages: hair follicles, sweat glands, and sebaceous glands that give rise to the new epidermis after injury. The dermis also contains blood vessels, nerve endings, immunocytes, fibroblasts, and elastin and collagen fibers. Under these two layers is the subcutaneous tissue.

The depth of injury depends on the source type, the source temperature, the length of exposure, and the skin thickness. A scald injury usually results in partial-thickness burns, whereas a flame injury typically results in full-thickness burns. Infants, young children, and the elderly have a thinner dermal layer of skin, which gives them a greater propensity for deep burns. Certain causative agents, such as grease, chemicals, and electricity, have the potential to cause a deeper, more severe injury because of their higher temperature, greater heat-transferring ability, and sustained effect. The systemic response to burn injuries is driven by the loss of the skin's barrier functions, the release of vasoactive mediators from the wound, and the subsequent infections that are commonly encountered (8).

Burns are traditionally classified based on depth of injury (eFig. 46.1), summarized in eTable 46.1.

TABLE 46.1
Criteria for Transfer of a Burn Patient to a Burn Center

Second-degree burns >10% total body surface area
Third-degree burns
Burns that involve the face, hands, feet, genitalia, perineum, and major joints
Chemical burns
Electrical burns including lightning injuries
Any burn with concomitant trauma in which the burn injuries pose the greatest risk to the patient
Inhalation injury
Patients with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality
Hospitals without qualified personnel or equipment for the care of the critically burned children

eTABLE 46.1
Classification of Burns

Degree	Thickness	Structures Comprised	Description	Time to Heal	Excision/ Grafting	Common Source
First	Superficial	Superficial epidermis	Red, painful, no blisters	Few days, no scar	No	Sun, hot liquids
Second	Partial thickness, superficial	Full epidermis, partial dermis	Red, painful, blistered, weeping	Up to 3 wks, no scar	No	Scalds, short flashes
	Partial thickness, deep	Full epidermis, deep dermis with epidermal appendages compromised	Red and blistered combined with waxy and dry areas; usually painful	Weeks to months, with scars	May need	Scalds, flames, oil, grease
Third	Full thickness	Full epidermis and dermis	Dry, leathery, pale or brown, inelastic, and painless	Months, heals by contraction	Yes	Flames, oil, grease, electricity, chemicals
Fourth	Full thickness	Full epidermis, dermis and underlying muscle, tendons, or bone	Dry, leathery, pale or brown, inelastic, and painless	Months, heals by contraction	Yes	Flames, oil, grease, electricity, chemicals

Superficial burns (first degree), such as those from sunlight or very short flash, are limited to the superficial epidermal layers. They are erythematous and painful, do not form blisters, are sensate, and heal within 1 week without scars. These burns are not included in calculations of TBSA.

Second-degree burns are divided into superficial and deep partial-thickness burns based on the depth of injury to the dermis. Superficial partial-thickness burns, from scalds or short flashes, involve the entire epidermis and the uppermost dermis. Since they spare important structures, and leave epidermal appendages in the dermis, they generally heal without scarring in 2 weeks as epidermal cells migrate from these surrounding normal skin and the remaining appendages. They are erythematous, blistered, weeping, blanch, and very painful. Deep partial-thickness burns are usually caused by flames, oil, or grease. They involve deeper layers of the dermis with fewer remaining dermal structures and epidermal appendages. Such burns may have areas that are waxy and dry, may not blanch, and can be difficult to distinguish from full-thickness burns. Deep partial-thickness burns often take at least 2 to 3 weeks to heal resulting in scar formation. As a result, many deep partial-thickness wounds require excision and skin grafting for an optimal functional result (9).

Full-thickness burns can be caused by flames, scalds, and chemical and electrical contact. They destroy dermal structures (third-degree) or underlying tendons, muscle, and bone (fourth-degree). The skin appears dry, stiff, and leathery with a pale-to-brown color, does not blanch with pressure, and may exhibit underlying thrombosed vessels. The patient will generally not have pain on palpation and the

burn will be insensate. While third-degree burns may not be painful, it is important to remember that many patients have mixed burns and experience considerable pain. These injuries require at least 3 weeks to heal resulting in significant scarring and contractures.

Differentiating between deep partial-thickness and full-thickness burns may be difficult in the ED. In addition, burns are often dynamic in nature progressing in depth and extent over the first few days after injury. Despite various advances in technology, serial examinations by an experienced clinician is still the most common method for determining the depth of a burn (10). As a result close follow-up, preferably by a burn specialist, is required.

DIFFERENTIAL DIAGNOSIS

Although burn-injured patients usually present with a straightforward history, this situation is not universal. Some presentations may be the result of self-inflicted or nonaccidental injury. Children with unreported hot liquid ingestion or steam inhalation have been initially managed as having croup, laryngomalacia, and tracheobronchitis (11). Several dermatologic conditions such as toxic epidermal necrolysis, Stevens–Johnson syndrome, staphylococcal scalded skin syndrome, and purpura fulminans may present with bullae and skin sloughing much like burn patients. These patients are often referred to burn centers for definitive management of the large wounds.

Burn injuries to the skin do not occur in isolation. The emergency physician must consider associated injuries. Internal injuries may be sustained as burn victims attempt to escape the fire. Furthermore, patients may have been thrown during an explosion. Inhalation injuries may be present. Because burn victims often require immediate airway management, they may not be able to provide an appropriate history. In patients with central nervous system (CNS) or cardiopulmonary depression, carbon monoxide poisoning and cyanide toxicity should be considered, particularly in industrial settings.

Because up to 20% of pediatric burns are a result of abuse or neglect, the emergency physician must consider the possibility of

abuse when evaluating burn-injured children (12). Intentional burn injuries are suggested by a history inconsistent with injuries or the child's developmental stage, conflicting histories from caregivers and child, a delay in seeking treatment, and a history of previous injury. Immersion injuries are common intentional burns, and key physical examination findings include uniformity of burn depth, absence of splash marks, sharply defined circumferential wound margins, flexor surface sparing, and stocking glove patterns. Suspected abuse must be reported, and the child may need to be admitted for further evaluation and protection.

Another consideration in children is household cleaners that often cause chemical burns. Ingestion should also be suspected in any young child with a chemical burn. Any dry chemicals should be gently brushed away and the burn should be copiously irrigated with room temperature water or normal saline for at least 20 to 30 minutes after removal of the child's clothing. Then the extent and depth of the burn can be assessed and treated (see Chapter 312).

ED EVALUATION

All burn-injured patients should be evaluated first as trauma patients using a systematic approach following the Advanced Trauma Life Support guidelines. Adhering to an organized approach improves patient outcomes.

Airway evaluation in the burn patient primarily centers on the concern for inhalation injury. A history of closed-space exposure to hot gases, steam, or products of combustion supports inhalation injury, as do physical examination findings of carbonaceous sputum, singed facial hairs, tachypnea, stridor, wheezing, cough, dysphonia, loss of consciousness, and altered mental status. Although elevated carboxyhemoglobin or cyanide levels also raise suspicion of inhalation injury, reliance on laboratory tests or radiographs cannot be utilized to determine the need for intubation. Patients with suspected inhalation injury may require early prophylactic intubation because progressive airway edema may preclude successful intubation once the patient is in respiratory distress (see Chapter 320). Direct visualization of the airway under topical

anesthesia, with or without dissociative anesthesia with ketamine, using fiberoptic, video, or standard laryngoscopy is helpful in questionable cases. While extreme vigilance is required, overzealous endotracheal intubation should also be avoided.

All burn patients with suspected inhalation injury should receive 100% humidified oxygen via nonrebreather mask during the evaluation of their respiratory status. Patients with inhalation injury, comorbidities, or circumferential burns of the neck and chest may develop respiratory compromise and may require intubation. Serial chest x-rays are of value, but the initial ED chest x-ray is often normal. Arterial blood gas (ABG) or venous blood gas measurements of carboxyhemoglobin should be obtained in patients with headache, syncope, nausea, or altered mental status. Noninvasive point-of-care devices that measure carboxyhemoglobin are also available (13). Although of limited utility in the ED, other tests to evaluate for inhalation injury include Pa_{O_2}/Fi_{O_2} ratio and xenon and technetium scanning. Bronchoscopy is considered the gold standard when diagnosing inhalation injury. These tests guide ventilatory management and decision making regarding transferring patients to specialized burn centers, although clinical impression suffices for the majority of situations in the ED.

Evaluation of the circulatory system is often difficult in the severely burned patient. Level of consciousness may be altered because of inhaled toxins, blood loss from coexisting trauma, or "burn shock." *Burn shock* refers to hypovolemic shock caused by increased blood flow to the wound, capillary leak, decreased cardiac output, and "third spacing" (extracellular and extravascular fluid shifts). Blood pressure measurement and peripheral pulses may be difficult to obtain and unreliable secondary to pain and catecholamine response. Capillary refill and skin color may also be difficult to assess in severely burned patients. Circulation distal to circumferential burns should be evaluated repeatedly. Emergent escharotomy is indicated if distal perfusion remains poor despite adequate intravenous (IV) volume resuscitation.

The physician should quickly determine the neurologic status of the patient. Any alteration of mental status should prompt immediate

reevaluation of oxygenation, ventilation, and perfusion. Concern for CNS trauma warrants head computed tomography (CT) scanning.

The patient should be completely undressed to facilitate a thorough examination and halt ongoing injury. Usually the burning process has ceased prior to the ED evaluation, but certain fabrics can ignite and melt into residues that continue to burn the patient. Chemicals or other substances may be embedded in the clothing. Any substance should be safely removed, and the involved skin surface should be copiously irrigated with water. Dry chemicals should be carefully brushed off before irrigation.

The secondary survey includes a systematic head-to-toe thorough examination. Key components of the history should now be obtained. These components include documentation of the mechanism and time of injury, closed-space exposure, substances consumed by flames, and prehospital interventions.

After the initial stabilization of the burn patient, the physician should determine the extent of the burn injury by calculating the percentage of TBSA that is burned. The TBSA burn should be subdivided into partial-thickness and full-thickness percentages. This analysis will facilitate further patient management and categorization of the injury severity. There are various methods for calculating the TBSA of burn injury. Superficial burns (first-degree) are not included in calculations of TBSA.

Classically, the “rule of nines” has been used in adult patients (Fig. 46.1). The head, each arm, and each half of each leg approximates 9% TBSA. The torso is assigned 18% each for the anterior and posterior aspects. The genitals are 1% TBSA. The “rule of nines” is not applicable in the pediatric population as the head compromises a larger TBSA (18%) and the legs a smaller TBSA (14%). This evaluation is a good rough estimate, but it can lead to overestimation and inappropriate patient transfer to burn centers. Lund and Browder charts are more accurate in all age groups and should be used after the initial resuscitation is complete (eFigs. 46.2 and 46.3). Another method for small burns is using the patient’s hand to estimate the TBSA. The palmar surface of the hand (excluding fingers) represents approximately 0.5% TBSA (14).

Further radiographic evaluation including x-rays and CT scans should be performed based on the mechanism of injury. In addition to ABG determination, baseline hematocrit, electrolytes, and glucose, a pregnancy test should be obtained in females of childbearing age. Cardiac monitoring and an electrocardiogram may be necessary for

burns associated with electrical injuries (see Chapter 349). Human studies in critically ill patients have demonstrated that blood lactate levels are highly accurate as a guide to the efficacy of resuscitation. Although admission lactate values have been shown to be higher in nonsurvivors, no cutoff value has been consistently associated with mortality (15).

KEY TESTING

- If inhalation injury is suspected, a CXR and ABG with CO levels may be required.
- For inhalation injury, bronchoscopy may also be required.
- With burn shock a CBC and metabolic panel may be required.

ED MANAGEMENT

The ED management of burn patients is focused on four main aspects of care: (a) airway management, (b) fluid resuscitation, (c) pain control, and (d) appropriate management of associated injuries.

As with all emergency patients, the physician should consider the ABCs (airway, breathing, and circulation) as part of the initial assessment. All clothing should be removed as soon as possible. If there has been associated trauma, the neck should be immobilized until a cervical spine injury has been ruled out. Until a good history of the circumstances of the injuries is obtained, significantly burned patients should be given humidified 100% oxygen by a nonrebreathing mask.

Airway Management

In severely burned patients, an expeditious decision must be made regarding potential airway damage. Intubation should be performed before the airway is lost. Intubation should be performed in unconscious patients with a history of prolonged smoke or fire exposure in a confined space and in patients with a high suspicion for airway edema (stridor, voice changes, increasing respiratory distress, hypoxia despite 100% oxygen, and poor peak flow). While airway management can be performed using rapid-sequence

orotracheal intubation technique, awake intubation with topical anesthesia with or without dissociative anesthesia with ketamine should be strongly considered if a difficult airway is likely with immediate availability of a surgical airway setup. If rapid-sequence intubation is used, succinylcholine can be safely administered within 12 to 24 hours of a burn injury. Succinylcholine should be avoided in patients 24 to 48 hours following a thermal injury and for at least 1 year after the burned skin has healed due to the risk of fatal hyperkalemia (16).

Many patients require positive end-expiratory pressure (PEEP) to keep the distal airways open. PEEP should begin at 5 cm H_2O. Bronchodilators may be effective if secretions or particulate inhalation leads to bronchospasm. Recent studies have shown improved outcomes and reduced risk of acute lung injury with low tidal volume (6 mL/kg) ventilation (17). High peak pressures (>35 cm H_2O) should be avoided, which may require some degree of permissive hypercapnea where CO_2 levels are allowed to rise above normal. Since bronchoscopy and pulmonary toilette are often required, endotracheal intubation should be performed with the largest-sized endotracheal tube possible.

Fluid Resuscitation

With large burns massive fluid shifts can occur even though total body water remains unchanged. IV fluids should be administered to adults and children with burns covering 20% of their TBSA or greater. A large number of fluid resuscitation formulas are available. With all formulas, calculation of fluid requirements should only serve as an initial estimate with frequent adjustments based on patient response. Overzealous hydration termed “fluid creep” is all too common and may result in worse outcomes due to compartment syndromes in the abdomen and extremities (18).

The most commonly used resuscitation formula is the Parkland formula that requires 4 mL/kg of lactated Ringers solution for every 1% TBSA of second- and third-degree burns over the first 24 hours, half of which is given within the first 8 hours after injury. The

modified Brooke formula that calls for 2 mL/kg/% TBSA burned is also recommended by the American Burn Association (19). The US Army Institute of Surgical Research has recently proposed a simplified formula termed “the rule of tens” in which 10 mL is given per hour for every 1% TBSA burn (20). With all formulas, careful attention to the patient’s condition is necessary to avoid over- and under-resuscitation. A good method to monitor the adequacy of fluid resuscitation is to maintain a urine output between 0.5 and 1 mL/kg/hour in adults and between 1 and 1.5 mL/kg/hour in children. While colloids (such as albumin or plasma) may be advantageous after the first 12 to 24 hours, their use in the first 12 hours after injury is not recommended. Hypertonic saline may be considered, but should only be used by specialists experienced in its use. The volume of fluid necessary to resuscitate burn patients depends on the severity of injury, physiologic status, age, and associated injuries. Two large-bore IV lines should be placed through unburned skin if possible. The patient should be placed on a cardiac monitor, and a urinary catheter should be placed to monitor output. The amount of fluid needed to treat the burn shock should be calculated keeping in mind the additional fluid loss from other sources (i.e., trauma and inhalation injury). Patients with special fluid management problems such as heart failure, renal insufficiency, or on dialysis may require more aggressive central monitoring of hemodynamic parameters.

The burned child presents a special challenge, because resuscitation therapy must be more precise than for an adult with a similar burn. Children require more fluid for burn shock resuscitation than adults with similar thermal injury; fluid requirements for children average 5.8 mL/kg/% burn over 24 hours (7). In addition, children commonly require IV resuscitation for even relatively small burns (10% to 20% TBSA). The use of hypertonic saline and albumin is better accepted in children than in adults. There are two formulas used for fluid resuscitation in pediatrics (eTable 46.2) (21). Both formulas are relatively easy to use, and both appear to result in similar outcomes. The presence of inhalation injury increases fluid requirements for resuscitation from burn shock after thermal injury.

Several authors have documented that patients with inhalation injury require crystalloid at a rate of 5.7 mL/kg/% burn over the first 24 hours (7). Fluid resuscitation utilizing a calculation of 6 mL/kg/% burn (over the first 24 hours) should work well in the ED. The first half should be given in the first 8 hours and the rest in the next 16 hours.

[a]The Galveston resuscitation solution is prepared by mixing with 950 mL of LR.
TBSA, total body surface area; LR, lactated Ringer solution.

Pain Management

Pain can be severe, particularly in patients with partial-thickness burns and analgesia is often neglected (22). While full-thickness burns tend to be painless because nerve endings have been destroyed, many patients have mixed burns of varying depths, some of which can be extremely painful. All pain medications should be given via IV in small, frequent aliquots, titrated to pain relief to avoid adverse events such as hypotension or respiratory depression. Morphine remains the narcotic of choice; doses of 0.1 mg/kg in the young patient and 0.05 mg/kg in the elderly are usually well

tolerated. Fentanyl in doses of 1 to 2 μg/kg IV over 1 to 3 minutes is also a safe option. Because of its shorter duration (45 to 90 minutes) and potential for hypotension with rapid administration, this medication should be used as an alternative for patients intolerant to morphine. If the patient is extremely anxious and is not hypoxic or hypotensive, small doses of IV lorazepam (1 to 2 mg) may be used. In stable patients with severe pain that require procedures, such as hand escharotomies, major debridement, or fracture reductions, moderate or deep sedation is warranted. Small aliquots of ketamine (10 to 20 mg IV) should be considered in patients that appear tolerant to opioids.

Management of Associated Injuries

The standard treatment for burn patients with concomitant carbon monoxide exposure is to administer 100% oxygen. Hyperbaric oxygen therapy should be considered for those with documented serious exposure to carbon monoxide (carboxyhemoglobin level >25% with depressed mental status). Patients must be hemodynamically stable and not require ongoing burn resuscitation (see Chapter 311).

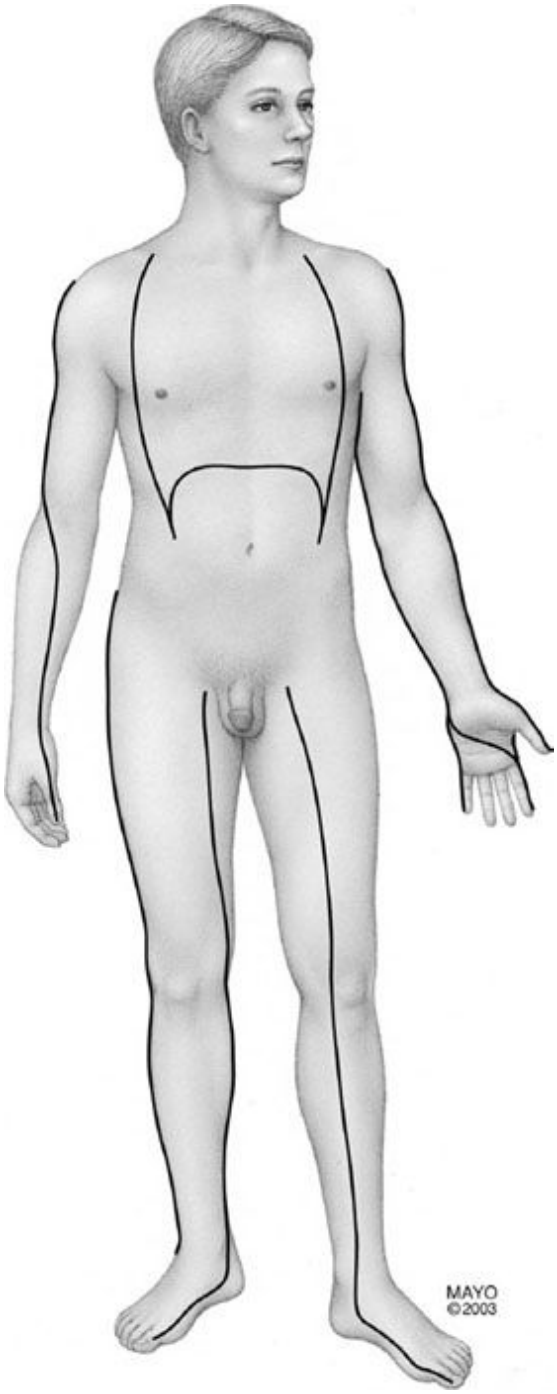
Cyanide is another product of incomplete combustion that may be inhaled by house fire victims. Isolated cyanide-related fatalities are rare and tend to be associated with high carboxyhemoglobin levels. Furthermore, laboratory confirmation of cyanide poisoning is always a retrospective event. The diagnosis must be considered and treatment administered long before definitive laboratory tests are available. Burn victims with inhalational exposures do not require specific antidotal therapy, if significant recovery has occurred before reaching medical attention. Many patients have survived cyanide poisoning with supportive care alone. Patients who exhibit persistent metabolic acidosis despite adequate fluid resuscitation, normal carbon monoxide levels, and the absence of other major injuries should be treated for cyanide toxicity (23) (see Chapters 313 and 320).

Hypothermia can contribute to coagulopathy and can result in decreased circulation to the wound and extension of a partial-

thickness burn. Hypothermia should be prevented during resuscitation. Patients who have sustained a burn >25% TBSA should have a nasogastric tube placed because they may develop gastric atony and distension that may compromise ventilation as well as an ileus. The emergency physician should update tetanus prophylaxis for all burn patients as needed.

Deep venous thrombosis has been found to occur in up to 23% of patients suffering from thermal injuries, so prophylaxis should be considered for those who are going to be immobilized (24).

Full-thickness burns create a leathery coagulum of necrotic tissues known as the eschar. If the full-thickness burn on an extremity is circumferential, the inflexible eschar and progressive edema beneath the eschar can lead to increased compartment pressures that impede venous return initially and arterial inflow ultimately. If the circumferential burn involves the chest and upper abdomen, the restriction of chest expansion and diaphragm excursion can result in respiratory compromise. If the patient is in severe respiratory distress and has sustained circumferential burns to the chest, an immediate escharotomy may be necessary. If a surgeon is not available or is delayed, emergent escharotomy may be necessary to preserve a limb or a life. Incisions should be made in the anterior axillary line connected by a third incision in the form of an inverted "V" (eFig. 46.4). An incision through the burn eschar to the underlying subcutaneous fat can be accomplished by using a scalpel or electrocautery. Bulging of the subcutaneous fat with "splitting" of the stiff eschar indicates adequate depth of incision. The escharotomy generally should be extended slightly beyond the eschar both proximally and distally to ensure adequate release. Because the eschar and underlying tissue are insensate, analgesia is not required, but sedation should be considered. Bleeding should be minimal and can be treated effectively with gentle pressure.



eFIGURE 46.4 Escharotomy sites.

Escharotomy is indicated in limbs with distal cyanosis, decreased capillary refill, decreased pulses, or progressive neurologic changes. Serial Doppler flow measurements of vessels distal to the burn are useful in deciding whether an escharotomy is adequate. Poor or

absent pulse oximetry signals from the limb may also indicate diminished or inadequate perfusion. Incisions should be made on the radial and ulnar borders of the arm and forearm and along the midaxial lines of the digits. Incisions are made on the medial and lateral borders of the lower extremities, including involved joints, with care to avoid superficial blood vessels and nerves (eFig. 46.3).

Wound Care

Patients with major wounds that require admission to a burn unit should have sterile dressings or sterile sheets placed over their wounds to decrease exposure to in-hospital multiresistant organisms. If the patient's burns are such that hospitalization is not necessary, the burns should be cleaned with water and a mild soap. Any loose or nonadherent necrotic skin should be gently removed and any large (>2 cm) or tense blisters should be aseptically aspirated with a large-bore needle. First-degree burns do not require any dressing or topical therapy. However, topical aloe vera or an NSAID my help relieve pain and inflammation (25). Second-degree burns can be treated either with once- or twice-daily applications of a topical antibacterial ointment and outer bulky dressing or one of many advanced occlusive dressings (26). Use of occlusive dressings reduces painful dressing changes and speeds healing (9). Since occlusive dressings can be left on the wound for prolonged periods (approximately 1 week) they are also cost effective. Saturated or foul smelling dressings require more frequent changes. Ideally, the dressing should absorb exudate, adhere to the wound bed, and allow easy nontraumatic removal. A silicone-based foam dressing that slowly releases small amounts of silver (which inhibits gram-positive and gram-negative bacteria as well as fungi) meets many of these requirements. When compared with the more traditional topical antimicrobial agent silver sulfadiazine (SSD), this dressing was associated with faster healing and less pain (27). Other commercial occlusive dressings are also available. While still widely used, SSD delays re-epithelialization and is not recommended (28). Full-thickness burns can be covered with a topical antimicrobial ointment and referred to a burn specialist for excision and skin grafting.

Burns to the hand represent a particular challenge. Separate dressings should be used for each finger, and the hand should be immobilized in the position of function (wrist extension, metaphalangeal flexion, interphalangeal extension) that is opposite the position assumed by the burned hand. The extremity should be elevated and joints must be exercised, particularly in the case of burns that cross joints.

Finally, patients should be cautioned that burned skin is sun sensitive for up to a year (29). Therefore, patients should limit sun exposure and when necessary use sunblock agents.

CRITICAL INTERVENTIONS

- Manage the airway immediately in unconscious patients and in those with suspected inhalation injury (stridor, increasing respiratory distress, hypoxia, or poor peak flow).
- Completely undress the burn patient to facilitate a thorough examination and halt ongoing injury.
- Administer 100% oxygen by face mask to patients with suspected carbon monoxide exposure.
- Calculate the amount of fluid needed to treat the burn shock, keeping in mind the additional fluid loss from other sources, for example, trauma and inhalation injury.
- Administer pain medication IV in small frequent aliquots, titrated to pain relief.
- As soon as the patient is stabilized, initiate transfer to a burn center when indicated.

DISPOSITION

Burns should be rechecked in 24 to 48 hours. Some EDs manage their own follow-up burn care for superficial partial-thickness burns. Patients with small deep partial-thickness or full-thickness burns should be referred to a burn-care specialist in 2 to 4 days for consideration of skin grafting and physical therapy. Hospitalization should be considered, even for minor burns, for patients who are immunocompromised, very young, elderly, or patients with poor

home situations or possible abuse. Published criteria for admission or transfer to a burn center are outlined in Table 46.1.

Common Pitfalls

- Delay in intubating a patient with a compromised airway.
- Failure to detect child abuse in suspected immersion burns.
- Failure to diagnose compartment syndrome, especially in the hand.
- Failure to calculate fluid requirements from the time of the burn injury.
- Overestimating or underestimating the size of the burn.
- Failure to assess and treat pain appropriately.

CHAPTER 47
Replantation

James L. Larson, Jr

Advances in microsurgery have enabled surgeons to perform replantation procedures on almost all parts of the body. Viability is the only one consideration when evaluating for replantation. The most important factor is the ultimate function of the replantation. Decisions by the emergency physician can significantly impact the viability and function of the replantation.

CLINICAL PRESENTATION

The majority of replantations involve digits injured in industrial accidents (1). Cutting machines, press machines, and belts are the leaders in producing amputations. Significant causes of injury and amputation in children are bicycle chain rings and spokes, including those on stationary exercise bikes (2).

DIFFERENTIAL DIAGNOSIS

An amputated part is a completely severed part of the body, and replantation is the reattachment of an amputated part. An incomplete amputation is partially attached, but the part has lost arterial circulation. The repair of an incomplete amputation is a revascularization. Revascularization is more successful than replantation, because the venous outflow system may be intact.

ED EVALUATION

Identification and treatment of life-threatening injuries takes precedence over the evaluation for potential replantation. A

systematic approach to patients with traumatic injuries is necessary to avoid distraction from amputations (see Chapter 18, General Principles of Trauma). Serious undetected concomitant injuries have been found in patients after transfer to a tertiary care facility for replantation (3).

Indications and Contraindications for Replantation

The evaluation of a patient with an amputation or near-amputation should be expeditious. The key considerations are identifying the injuries and the potential for replantation. Amputations that are considered for replantation are listed in Table 47.1. The decision to proceed with replantation is based on potential viability and long-term function. Success rates have been reported to be 66% to 91% for digital replantations (4). A working knowledge of factors that impact success will facilitate patient care and case discussion with the surgeon.

TABLE 47.1
Replantation Candidates

Upper Extremity
Indications
Any part in a child
Thumb
Multiple digits
Palm
Wrist
Forearm
Elbow and above (sharp mechanism of injury)
Finger distal to flexor digitorum superficialis insertion
Relative Contraindications
Single digits proximal to flexor digitorum superficialis insertion
Crushed or mangled parts
Multiple level amputations
Other Replantation Candidates
Lower extremity amputation (sharp mechanism of injury)
Ear
Scalp
Lip
Nose
Penis

From Pederson WC. Replantation. *Plast Reconstr Surg.* 2001;103:823–841.

The mechanism of the amputation and resulting condition of the anatomic structures are most significant. Guillotine-like "sharp" amputations are more amenable to surgical repair than crush and avulsion mechanisms. Injuries at one level are easier to replant than multiple insults along an extremity. Children are more likely to have a good result from a replantation, and surgeons are more likely to proceed in pediatric cases (6).

There are several relative contraindications to replantation. Multiply-injured patients who require surgery or prolonged resuscitation for traumatic injuries are not candidates for a prolonged replantation procedure. Patients with complex medical problems that affect vascular integrity, immune function, and healing may be poor candidates for replantation. Patients without sufficient mental capacity or judgment to comply with postoperative

rehabilitation are unlikely to have success with replantation (5). Ultimately the decision to proceed with replantation is made by the consulting surgeon. All potential replantation cases, even those with relative contraindications, should be discussed with a replantation surgeon.

KEY TESTING

- Radiographs of the amputation
- Radiographs of the involved extremity
- These should not delay transfer

Replantation Sites

The digits of the hand are the most frequent sites of replantation. Replantation of the thumb is considered even when function of the replanted thumb is potentially limited. Even a nonfunctioning thumb is important because of its role in opposition. Single-finger replantation proximal to the insertion of the flexor digitorum superficialis (the center portion of the middle phalanx) is usually not performed because of poor functional outcomes. These patients have almost no return of flexion. In contrast, replantation of amputations at the level of the distal interphalangeal joint usually results in a good functional outcome. Fingertip replantations are now considered more frequently, because they consist of an ideal flap repair requiring only the anastomosis of an artery and a vein (7). Multiple-finger amputations are usually considered for replantation. Replantation of hand and wrist amputations results in more function than a prosthesis. Replantation of forearm, elbow, and proximal arm injuries are more successful after a sharp mechanism of injury in young healthy patients.

Replantation of lower extremity amputations is less common. Injuries to the lower extremity often result from a crushing mechanism. The large muscle mass of the lower extremity is less tolerant of ischemia (5). Children and younger adults with noncrushing injuries are the best candidates for repair. Other

amputations in which replantation should be considered include ears, lips, nose, scalp, and penis.

ED MANAGEMENT

The priorities in management of an amputation are decreasing the ongoing ischemia in the amputated part and expediting the time to the operating room for definitive repair. Hemorrhage is a frequent complication in amputations. Direct pressure is the preferred method to control bleeding. Tourniquets may be used to control hemorrhage temporarily and to facilitate evaluation of the wound. Tourniquets should not be used as the primary means of hemostasis. Prolonged use of a tourniquet can produce increased loss of function. Blind clamping or ligation should not be performed to avoid damage to vessels and nerves that may be needed for the definitive repair.

Care of the amputated part can prolong its viability and improve the success of the surgical repair. All tissues that are available should be kept. Smaller portions of skin can be used for wound coverage. The amputated part should be cleaned with normal saline solution to remove gross contaminants. Alcohol, iodine, formaldehyde, or other cleaning solutions should not be used. The amputated part should be wrapped in saline-moistened gauze and placed in a sealed plastic bag or container. The sealed bag or container with the amputated part is then placed in a water and ice bath (Figure 47.1). To avoid freezing the tissue, the amputated part should not be placed directly on ice. “Dry” ice should not be used. An amputated limb can survive 6 hours of warm ischemia and 12 hours of cold ischemia. Amputated digits can tolerate ischemia for longer periods of time (8). Incomplete amputations should be splinted to minimize further trauma and to maintain vascular integrity. Tetanus prophylaxis (0.5 mL tetanus toxoid) should be administered to patients who are more than 5 years from their last booster. Tetanus immune globulin should be given to those who have not been primarily immunized. Patients with open fractures or

contaminated wounds should receive a first-generation cephalosporin and an aminoglycoside as prophylactic antibiotics (9).

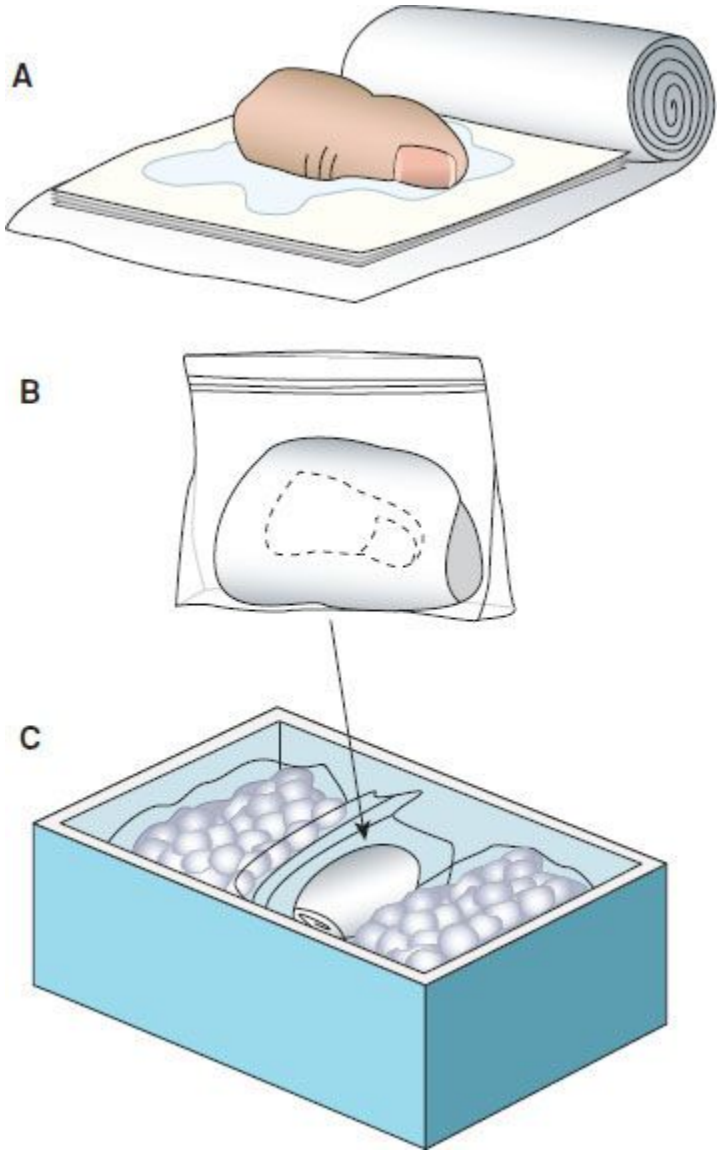

FIGURE 47.1 Replantation. The wound should be rinsed with saline solution. Do not scrub or apply antiseptic solution to the wound. The amputated part should be rinsed in saline. Do not scrub or apply antiseptic solution to the amputated part. A: Wrap the part in a saline-moistened sterile gauze or a towel, depending on the size. B: Set the wrapped part in a waterproof plastic bag or plastic container. C: Place the bagged part in an insulated container cooled by separate plastic bags containing ice or an ice water bath.

CRITICAL INTERVENTIONS

- Contact replantation surgeon early
- Control hemorrhage only with direct pressure
- Place the amputated part in a waterproof container after wrapping it in saline-soaked gauze. Place the waterproof container in an ice and water bath
- Administer tetanus toxoid and antibiotics
- Provide protection by splinting incomplete amputations

DISPOSITION

Early communication with a replantation surgeon is critical because replantation is a time-sensitive process. Having protocols in place that identify specialists and medical centers capable of performing replantations is important to expedite definitive care. One group has used mobile phones with cameras to evaluate potential replantation candidates prior to transfer (10). To avoid disappointment, the patient and family should not be told a replantation will occur. They should be told a replantation surgeon will evaluate the patient for possible replantation.

Common Pitfalls

- Failure to recognize concomitant serious injury.
- Failure to notify replantation surgeon early.
- Indiscriminant use of clamps or prolonged tourniquets to control hemorrhage.
- Failure to properly cool the amputated part.

CHAPTER 48

Acute Compartment Syndrome

Andrew D. Perron, Christopher T. Bowe, and Christine Irish

Acute compartment syndrome is a serious life- and limb-threate-ning complication of extremity trauma. Fractures, crush injuries, burns, and arterial injuries all can result in an acute compartment syndrome. Compartment syndrome is defined as the presence of pathologically elevated intramuscular pressures within confined osseofascial compartments resulting first in tissue ischemia and ultimately infarction and subsequent contractures if not treated in a timely and appropriate manner (1). Dr. Richard Von Volkmann first described this entity in 1881; he noted the complication of muscle ischemia, paralysis, and ultimate contracture in a child with a supracondylar fracture (2,3). The various compartments in the extremities are composed of muscle groups bound by dense fascial tissue planes that result in limited ability to accommodate increased pressure. In addition to muscle, these compartments contain various nerves and blood vessels. Elevated pressure in these spaces, above normal physiologic ranges, can compromise capillary blood flow and produce predictable clinical signs and symptoms. Delays in diagnosis and treatment can result in myonecrosis, permanent nerve damage, distal ischemic injury, and muscle contracture. The exact incidence of compartment syndrome is unknown, although it is thought to be relatively rare. Three-quarters of cases are associated with fractures. Fractures of the tibia are the most likely to result in compartment syndrome; the incidence in patients with tibial fractures is reported to range from 1% to 29% (2). The most frequently involved

compartments are the anterior compartment of the lower leg and the flexor compartment in the forearm (2). Table 48.1 lists the common locations of compartment syndromes.

TABLE 48.1
Common Locations of Compartment Syndromes

Upper Limb Compartments	Lower Limb Compartments	Miscellaneous Compartments
Arm	**Buttock**	**Pelvic**
Deltoid	Gluteal	Iliacus
Biceps	**Thigh**	
Forearm	Quadriceps	
Dorsal	**Leg**	
Volar	Anterior	
Hand	Lateral	
Interosseous	Superficial posterior	
	Deep posterior	

Modified from Matsen FA. *Compartmental Syndromes*. New York, NY: Grune & Stratton; 1980.

The pathophysiology of compartment syndrome involves local hydrostatic and osmotic pressure conditions within the myofascial compartment. When the intracompartmental pressure increases above a specific level due to the above factors, perfusion to the compartment is impaired, resulting in disruption of skeletal muscle metabolic processes. Cell wall membrane integrity is compromised, leading to cytolysis with the release of osmotically active cellular contents into the extracellular compartment. This draws additional fluid from plasma into the interstitial space. The net effect is increased intracompartmental pressure and further impairment of perfusion to the closed space of the myofascial compartment as well as to distal structures in that vascular distribution. This progressively leads to compromise of circulation and nerve conduction and ultimately to irreversible damage to the contents of the compartment (4).

Normal compartment pressure is below 10 to 12 mm Hg (2). Capillary blood flow depends on the pressure gradient between the

arterial and venous systems. With elevated compartmental pressures, this gradient is interrupted, compromising the blood flow across the capillary bed. When the pressure within a compartment rises sufficiently to interrupt this arteriovenous gradient, blood flow will be reduced to the point at which the metabolic demands cannot be met. Then functional abnormalities and compartment syndrome occur (2). Two general mechanisms can result in elevated compartment pressures: Either an *extrinsic* compressive force constricts the compartment (e.g., a cast) or there is an *intrinsic* increase in the size of the fascia-bound compartment owing to edema or hemorrhage.

Clinically significant reduction of blood flow and blood oxygenation can occur at tissue pressures above 20 mm Hg (5,6). Cellular metabolic derangements are closely associated with the difference between mean arterial blood pressure and compartment pressure. This difference is known as the *delta P*. In one study, the lowest delta P that was compatible with a normal metabolic state was 30 mm Hg in normal muscle (7). The length of time that tissue can tolerate elevated pressures before pathologic changes occur is less clear. Sensory changes including paresthesias and hypesthesia can develop within 30 minutes of ischemia, whereas irreversible nerve damage begins as soon as 6 hours and almost universally after 12 to 24 hours (2).

Other factors should also be considered when assessing potential compartment syndrome. Externally applied pressure (i.e., casting) tends to produce less elevation in compartment pressures as compared to similar levels of internally developed pressures (i.e., edema or hemorrhage) (8). Postischemic compartment syndrome is caused by revascularization after a prolonged period of ischemia (2), leading to the release of vasoactive factors that result in fluid extravasation and elevated pressures. Concurrent hypotension, hypoxia, and associated premorbid conditions such as peripheral vascular disease adversely affect the ability of ischemic tissue to tolerate even mildly elevated tissue pressures.

CLINICAL PRESENTATION

Pain out of proportion to examination findings is the classically described clinical finding in acute compartment syndrome. This assumes an awake, neurologically intact patient. Unfortunately, many patients at risk for compartment syndrome are severely injured or impaired and cannot relate the degree of pain they are experiencing. When reported, the pain is often described as deep, aching, and poorly localized and does not typically respond to immobilization or analgesic medications alone. Increasing analgesic requirements may be the only clue to a developing compartment syndrome. Classically, passive stretching of involved muscles produces intense pain, as does compression of an affected compartment. Weakness or paresis of muscle function is a late finding. Distal hypesthesias or paresthesias may be noted in the distributions of nerves passing through the compartment. Two-point discrimination and light touch are considered more sensitive than pinprick when assessing sensation. Tenseness of externally palpable compartments is the earliest and most objective finding, although tenseness of compartments such as the deep posterior compartment of the lower leg and the iliacus compartment can be difficult to assess due to anatomic location. Findings of compartment syndrome can present within 2 hours of injury but may first appear up to 6 days later (2). Progressive worsening over time helps to distinguish compartment syndrome from other injuries that cause primary nerve and muscle damage.

Griffith's mnemonic, the *five Ps* (*p*ain, *p*allor, *p*ulselessness, *p*aresthesias/*p*aresis, and poikolothermia), is traditionally used for this clinical entity. However, pulses are most often maintained, and the skin does not typically develop pallor (1). The presence of all five of these signs more accurately reflects the *late* findings of acute arterial obstruction or insufficiency. As noted previously, the reliance on the clinical examination makes it difficult to assess emergency department (ED) patients with altered sensorium, acute intoxication, spinal cord injuries, or overlying extensive burns, as well as children. Moreover, obtunded patients are often at risk for compartment syndrome by compression, entrapment, or unknown mechanisms of trauma. Overdose-related compartment syndromes tend to affect the

lower extremities (9,10). Critically ill pediatric and adult patients may experience iatrogenic causes of compartment syndrome produced by intravenous and intraosseous infiltrations, transfusions under pressure, or tourniquet malfunction. Table 48.2 lists common etiologies of compartment syndrome. Owing to dense eschar, severely burned patients lose most, if not all, clinical signs of compartment syndrome. In these more complex cases, the clinician should have a lower threshold for using invasive monitoring.

TABLE 48.2
Common Etiologies of Compartment Syndromes Seen in Emergency Medicine

Increased compartment content
Infiltrated infusion
Bleeding
Vascular injury
Coagulation defect
Increased capillary permeability
Reperfusion after ischemia
Trauma
Fracture
Contusion
Intensive use of muscles
Exercise
Seizures
Eclampsia
Tetany
Burns
Cold
Snakebite
Increased capillary pressure
Venous obstruction
Diminished serum osmolarity
Nephrotic syndrome
Externally Applied Pressure
Casts, dressings, splints, pneumatic garment
Lying on limb

From Matsen FA. *Compartmental Syndromes*. New York, NY: Grune & Stratton; 1980, with permission.

The clinical findings for specific anatomic compartments are summarized in Table 48.3. Figure 48.1 illustrates the anatomy for the two most common sites. The three most common etiologies of an acute compartment syndrome are fractures, crush injury, and reperfusion of an ischemic limb. The lower leg and forearm have relatively "tight" compartments and are the most common sites for developing compartment syndrome. In the pediatric population, fractures are the most common cause, specifically supracondylar fractures. Open fractures are *not* protective against compartment syndrome, as the tear in the fascia is usually quite small and does not allow decompression of the compartment when pressure is elevated. Overall, the most common fracture etiologies for compartment syndrome include tibial shaft, supracondylar, and forearm fractures (7).

TABLE 48.3
Compartment Syndromes and Associated Physical Signs

Compartment	Painful Passive Movement	Location of Tenseness	Muscles Weakened	Sensory Loss
Forearm				
Dorsal	Thumb and finger flexion	Dorsal forearm	Thumb and finger extensors	—
	Thumb and finger extension	Volar forearm	Thumb and finger flexors	Ulnar and median nerves
Hand				
Interosseous	Adduction, abduction of metacarpophalangeal joints	Dorsum of hand between metacarpals	Interosseous	—
Leg				
Anterior	Toe flexion	Anterior aspect of leg	Toe extensors and tibialis anterior	Deep peroneal nerve
Lateral	Foot inversion	Lateral aspect of leg over fibula	Peroneal muscles	Superficial and deep peroneal nerves
Superficial posterior	Foot dorsiflexion	Calf	Soleus and gastrocnemius	—
Deep posterior	Toe extension	Distal medial leg between Achilles tendon and tibia	Toe flexors and tibialis posterior	Posterior tibial nerve
Pelvic				
Iliacus	Hip extension	Not palpable	Iliacus, psoas major and psoas minor	Femoral nerve

DIFFERENTIAL DIAGNOSIS

Differential diagnostic considerations include deep vein thrombosis, necrotizing fasciitis, arterial embolus or insufficiency, gas gangrene, myositis, and rhabdomyolysis.

ED EVALUATION

Laboratory and radiologic studies cannot confirm or rule out the diagnosis of compartment syndrome but may help in assessing for other etiologies and secondary complications such as rhabdomyolysis. Significant elevation of serum creatinine phosphokinase may indicate severe muscle damage or ischemia but is not helpful for early diagnosis (2). The critical diagnostic test for compartment syndrome is the direct measurement of intracompartmental pressures. This is especially important in those patients who are unreliable because of distracting injury or altered sensorium. These direct tissue measurements can also be used to provide ongoing monitoring in patients who are at high risk for development of a compartment syndrome, as in the case of a crush injury. Various pressure measurement techniques have been described, such as the central venous pressure manometer, the wick catheter, the slit catheter, and the portable Stryker handheld monitor. Experimental noninvasive methods of compartment pressure measurement have been described but are not in widespread clinical use currently. These include near-infrared spectroscopy, which measures the levels of muscle hemoglobin and myoglobin; laser Doppler flowmetry; and 99Tcm-methoxyisobutyl scintigraphy (2). The direct measurement techniques all provide acceptable accuracy, although the self-assembled needle manometer has been shown to be the least accurate and least reproducible (2). Most compartments are superficial, but access to deeper ones such as the gluteal and deep posterior compartments may require a spinal needle.

Whatever the method employed, once the compartment pressure has been obtained, there is ongoing debate over which pressure levels warrant a fasciotomy. Absolute pressures of >30 mm Hg have been suggested as an indication for fasciotomy. Alternatively, a "delta P" (the difference between the diastolic pressure and the compartment pressure) of <30 mm Hg has been suggested as being more specific for the requirement of a fasciotomy (2,7). These pressure measurements must be assessed in the context of hypotension, anemia, hypoxia, or other factors that would increase the tissue sensitivity for ischemia at less elevated pressures. Nerve conduction studies and arteriography are used primarily to distinguish primary nerve and arterial injuries and not useful in the acute diagnosis of compartment syndrome.

It should be noted that pulse oximetry has been advocated as a simple, noninvasive indicator of vascular compromise. This is *not* true. Clinical studies using pulse oximetry have shown a sensitivity of 40% for vascular compromise at clinically significant elevated compartment pressures (11). With a >50% risk of a false-negative result, pulse oximetry is not recommended in the evaluation of this disease process.

KEY TESTING

Compartment pressure measurement:

- If elevated compartment pressure is suspected, pressure testing is strongly suggested (unless there is clear evidence of compromise, in which case operative fasciotomy may occur by the surgeon without taking the time to assess intracompartmental pressures).
- Many techniques are described (wick, slit catheter, Stryker). The Stryker pressure manometer is a self-contained unit that assesses intracompartmental pressure using a needle and a calibrated digital readout. Knowledge of both the anatomic layout of the fascial compartments as well as the mechanics of the manometer itself is required for accurate use.
- Absolute compartment pressures >30 mm Hg/delta-P <30 mm Hg are generally used cutoffs as indications for fasciotomy. Normal compartment pressure is <10 mm Hg.

ED MANAGEMENT

The key to management of ED patients with compartment syndrome is early consideration and diagnosis. Surgical fasciotomy is the definitive treatment and surgical consultation should be initiated early. Surgical decompression should ideally be performed emergently, as soon as possible after the diagnosis is made (2,7). Supportive care is aimed at resuscitation and stabilization of the patient and preparation for appropriate operative intervention.

In patients who are suspected of having compartment syndrome owing to casts, bivalving and spreading of the cast may be necessary and can produce an almost 65% reduction in applied external pressures while maintaining alignment (12). Complete removal of the cast can further reduce pressure by up to 85% (4). Elevation of an extremity at risk to the level of the heart is recommended, as this promotes venous drainage without compromising arterial inflow (4). Ice should be avoided, as it can further compromise microvascular blood flow. The emergency physician should remove aggravating factors specific to the involved extremity, such as MAST suits or pneumatic splints, and treat systemic factors such as hypotension, anemia, and hypoxia.

CRITICAL INTERVENTIONS

- Measure intracompartmental pressures.
- Initiate surgical consultation early.
- Elevate the involved extremity to the level of the heart in the least restrictive dressing possible.

DISPOSITION

Patients with suspected compartment syndrome require emergent surgical or orthopedic consultation. Patients are typically admitted for observation and repeated clinical examinations and pressure measurements if they do not undergo immediate surgical intervention. Patients with multiple trauma may require intensive care unit admission for management of other associated injuries.

Common Pitfalls

- Failure to consider the diagnosis of compartment syndrome.
- Failure to recognize early signs and symptoms of compartment syndrome.
- Attributing the signs and symptoms of compartment syndrome to other types of injuries.
- Failure to do a thorough extremity and neurologic examination, especially in patients who are intoxicated or unreliable.

CHAPTER 49

Ballistics

Jason Imperato and Leon D. Sanchez

Ballistics is the scientific study of the characteristics of projectiles, how they move in flight, and how they impart tissue damage. The majority of projectiles that cause significant injury in the United States are in the form of firearm injuries. According to 2011 data, there were 32,163 deaths involving firearms with even higher numbers involving serious injury (1). These injuries can be classified as violence related, accidental, or self-inflicted.

Ballistic science is typically divided into three stages: internal, external, and terminal (or wound) ballistics. *Internal* ballistics describes the forces that apply to a projectile from the time the propellant is ignited to the time the projectile leaves the barrel. *External* ballistics refers to the forces that act on the bullet in flight. *Terminal* ballistics is the behavior of the bullet once it impacts the target (2).

A firearm is a weapon designed to expel a projectile by the action of highly combustible, gas-generating gunpowder. Firearms are generally classified as handguns (i.e., pistols and revolvers), rifles, and shotguns. Most rifled firearms (i.e., handgun or rifle) have barrels with internal grooves, referred to as *rifling,* that impart spin to the bullet, enhancing inflight stability and accuracy. When the cartridge is fired, the burning of the powder generates gas in a contained space and the pressure generated by the gas propels the bullet forward. The bullet accelerates while inside the barrel and reaches its maximum speed, or muzzle velocity, upon exit.

Bullets are rotated around their long axes by the rifling of the barrel, which, once in the air, gives them sufficient gyroscopic

stability to maintain the point-forward position while in flight. Without gyroscopic stabilization, bullets would preferentially travel in the more stable *base-forward* orientation where the greater mass of the bullet is. Bullets fired from a properly designed rifled barrel *yaw* no more than a few degrees during flight. The yaw angle is the angle between the long axis of the bullet and the line of flight. This angle is greatest as the bullet exits the barrel and is reduced as the gyroscopic spin stabilizes the bullet's flight through the air.

Once a bullet enters a denser medium, the gyroscopic spin is insufficient to stabilize the bullet. As a result, when a bullet enters tissue, it will begin to tumble and deform. Depending on the makeup of the bullet and the properties of the tissue through which it travels, it may expand, fragment, or remain in one piece (3–13).

Bullet mass, which is related to the diameter and length of the bullet, is a major determinant of how deeply the bullet will penetrate the tissue. Bullet construction, such as whether the bullet is solid lead with no bullet jacket, is partially jacketed, or has a full metal jacket, is a primary determinant of how the bullet will deform or fragment once in tissue. The majority of bullets in use today are at least partially jacketed. The jacket is a layer of hard metal that surrounds what is typically a lead core. Without a jacket, lead bullets fired at speeds of >600 m/s would have some of the lead stripped by the rifling of the barrel (5). Jacketing allows bullets to reach greater muzzle velocities. Though military bullets are fully jacketed (14), civilian bullets usually have the lead core exposed at the tip (soft point). The tip is often further modified into different varieties of hollow-point bullets. The exposure of lead at the tip will cause the softer lead to deform much more than a fully jacketed bullet upon entry into tissue. These hollow-point bullets are designed to expand and deform as they penetrate tissue. A soft- or hollow-point bullet will deform earlier in its travel through tissue than a comparable fully jacketed projectile. As a result, the injury patterns will be different, although the claims that soft- or hollow-point bullets cause more tissue destruction are not consistently borne out.

Shotguns differ from rifles and pistols in that they have a smooth barrel that discharges hot gases, wad, and either multiple projectiles or a single projectile (rifled slug). Shot charges containing multiple projectiles spread out from the muzzle in a cone-like pattern. The distance from the muzzle of the shotgun to the point of impact of the projectiles is a key determinant of the magnitude of injury. At short range (<6 m), the shot charge containing multiple projectiles results predominantly in a single-hole wound (diameter ≤ 6 cm) that communicates with a deep underlying wound with massive tissue destruction. At this short range, soft tissue impact deforms the individual pellets, increasing their original cross section with a concomitant increase in tissue crush or hole size. The multiple pellets result in severe disruption between the multiple wound channels. A gradual decrease in the amount of pellet deformation and tissue destruction occurs as the distance of the impact range increases. When the impact range exceeds 7 m, the multiple projectiles result in numerous discrete wounds that are not associated with underlying massive tissue destruction (5).

Shotguns also can discharge rifled slugs that are designed for killing larger animals. The muzzle velocity of rifled slugs (487 m/s) is approximately half that of nonexpanding, fully jacketed rifle projectiles. The rifled slug does not hold the point orientation that it has as it is propelled from the muzzle of the gun but drifts toward a sideways orientation as it moves toward the target. The rifled slugs experience a 25% decrease in velocity as the impact range increases from 5 to 45 m. At short range (≤ 45 m), the slug deforms on striking the tissue, thereby enhancing the size of the cavity.

CLINICAL PRESENTATION

The nature of a projectile wound is dependent on both missile and tissue characteristics. As discussed earlier, missile characteristics are partly inherent and partly conferred by the weapon firing the projectile. Tissue characteristics also strongly affect the nature of the wound.

Tissue is injured by a bullet via two mechanisms: tissue crush and tissue stretch. These two mechanisms correspond to the permanent and temporary cavities created by the passage of the projectile through the tissue (6–9). As the bullet travels through tissue, it will crush tissue that is directly in its path. This is the primary method of injury from gunshot wounds. The most important determinant of injury is the properties of the tissue that the bullet crushes. The tissue that is crushed corresponds to the permanent cavity formed by the bullet. If the bullet is traveling with its pointed end forward and its long axis parallel to the longitudinal axis of flight (0 degrees of yaw), it crushes a tube of tissue approximately equal to its diameter. When the bullet yaws to 90 degrees, the entire long axis of the bullet strikes the tissue, amplifying the amount of tissue crushed.

Passage of the projectile at a high rate of speed also displaces other tissue away from the path of the projectile. As the tissue stretches away from the path of the projectile, a temporary cavity that exists for a brief time (measured in milliseconds) is formed. The temporary cavity is comparable to the splash formed by throwing a stone into a pool of water. By definition, no tissue is present in the temporary cavity. The stretch of tissue away from the temporary cavity can injure tissue to different degrees depending on the tissue elasticity defined as the resistance of tissue to stretch. The same stretch that causes moderate contusion and functional changes in the relatively elastic muscle, skin, lung, and bowel wall can cause catastrophic disruption of the inelastic liver, heart, and brain. Muscle, skin, and lung are flexible and elastic, having the physical characteristics of good energy absorbers. Though temporary cavitation stretches these tissues, their elastic properties allow them to maintain their structure and function. For example, muscle, when disrupted, will have an area of devitalized nonfunctioning tissue surrounding the permanent cavity whereas tissue farther away, which was stretched by the temporary cavity, is still structurally sound and maintains its contractile function. In comparison, the inelastic liver is fractured and rendered nonviable to a much greater degree by the temporary cavity (15). The brain is a special case of

inelastic tissue. Not only is brain tissue very sensitive to structural disruption but this is magnified by the fact that the brain is encased in a solid container (the skull) that prevents tissue displacement. As a bullet penetrates the skull, temporary cavitation will increase pressure within the skull, and this pressure will be relieved either through the entrance or exit wound.

The size of the temporary cavity depends on the energy of the projectile, the surface area the projectile presents to the tissue as it moves through it, and the mass of tissue displaced. As the bullet tumbles through tissue from the point-forward orientation to the final base-forward orientation, it will present its greatest surface area at 90 degrees of rotation. It is at this point where maximal tissue displacement will occur and the size of the temporary cavity is greatest.

These permanent and temporary cavities are the sole wounding mechanisms of missiles. The sonic shock wave generated by supersonic missiles does not cause either tissue displacement or detectable damage. Projectile fragmentation can greatly enhance the effects of the temporary cavity by providing points of weakness on which the stretching effects of cavitation are focused, rather than being absorbed evenly by the tissue mass. Fragmentation can refer to the projectile's forming multiple parts or to secondary fragments such as clothing, bone, or teeth that develop from being struck by the projectile.

ED EVALUATION

Gunshot injuries frequently do not occur in isolation. As a result, the emergency physician must evaluate the patient for not only the penetrating injury resulting from the gunshot wound but the blunt injury that may result from the victim's falling to the ground after being struck by the projectile.

The initial evaluation of the gunshot victim is similar to that of any multiple trauma patient and should focus on rapidly identifying life-threatening conditions. Patients should be evaluated by the Advanced Trauma Life Support (ATLS) Guidelines (14). This

includes an assessment of the primary survey (airway, breathing, circulation, disability) with rapid attention to immediately life-threatening injuries, followed by the secondary survey, ongoing monitoring of vital signs and pulse oximetry, and initial stabilizing interventions as indicated.

A careful history is important in obtaining useful information about the number and types of injuries sustained. Patients who are awake should be asked how many shots they heard and any other information they have relating to the event such as their distance from the weapon and the type of weapon utilized.

The physical examination should focus on the detection of penetrating or perforating injuries. A careful examination of the patient including the back, under the hair, axillae, and gluteal folds will help identify injuries. The location of the external wounds may suggest a track for the projectile, but the physical examination is generally not sufficient to determine the direction and extent of the penetrating projectiles due to the cavitation effects of the projectile through body tissues. Penetrating projectiles may ricochet off of bony structures altering the trajectory of the permanent cavity produced. A small external wound may belie massive internal injuries that are not immediately evident on examination (4). The identification of an initial wound should not negate the need for a complete survey of the patient to avoid missing other injuries.

Radiographs of the areas the bullet is thought to have traversed are indicated to identify the position of the projectiles. It is best to obtain at least two radiographs in planes separated by 90 degrees to determine a more accurate position. If the patient is clinically stable, a computed tomography (CT) scan may aid in the assessment. Laboratory studies should be ordered as clinically indicated and guided by ATLS Guidelines. The evaluation and management of injuries is best conducted in conjunction with a trauma surgeon and should follow the algorithms presented in previous chapters. (See Chapters 18, 32, 34, and 36.)

Gunshot wounds must be reported to the appropriate authorities. In most cases, shootings become the subject of a criminal investigation by law enforcement authorities. Therefore, the medical

record and patient property should be preserved as evidence. If a patient's clothing is cut, care should be taken to avoid cutting through the portions a bullet might have traversed. Any material that needs to be saved for law enforcement should be placed in paper bags, as plastic bags will trap moisture and thereby degrade evidence.

The location of all wounds identified should be recorded in the medical record, including comments on the presence of any powder residue observed surrounding the wound. It is often difficult to differentiate entrance from exit wounds. Although it is often thought that the smaller wound must be the entrance wound, this is not always true. It is best to record the size and location of the wounds, rather than using the terms *entrance* and *exit*. If a bullet is recovered, the emergency physician should avoid making any markings on the sides of the bullet because this will interfere with the forensic evaluation of rifling patterns (5). Any marking of recovered bullets that may be necessary for the preservation of chain of custody should therefore be done at the nose or base.

KEY TESTING

- Complete blood count, blood gas, serum electrolytes, renal function, liver function tests, lactic acid, and urinalysis
- Type and crossmatch for blood products
- FAST scan
- Radiographs to identify path and position of projectile
- CT—as indicated

ED MANAGEMENT

The evaluation, resuscitation, and ongoing management of the patient with a gunshot wound should proceed as it would for any other victim of multiple trauma in both the prehospital setting and the emergency department (ED). For prehospital personnel, it is important that the scene be secured and declared safe before approaching the victims (11). The treatment of gunshot wounds is best conducted in consultation with a trauma surgeon. If resources

are unavailable, the decision to transfer the patient should be made early in the course of treatment.

Wounds that may have crossed the mediastinum require a thorough evaluation, even in stable patients. Potential injury to the aorta, heart, pericardium, lungs, great vessels, tracheobronchial tree, and esophagus must be ruled out. Rapid reversal of hypoxia is often necessary, with supplemental oxygen and airway control, if the patient is unable to protect their own airway or respiratory distress is present. Patients who present with unstable vital signs or who become unstable during evaluation should receive bilateral chest tubes to treat pneumothorax, hemothorax, or hemopneumothorax. Bedside ultrasound should be used to identify the presence of pericardial tamponade. If present, pericardiocentesis and ED thoracotomy may be necessary. Surgical exploration is often indicated in these patients (1,10). See Chapter 32.

Patients with penetrating gunshot wounds to the abdomen usually require an exploratory laparotomy, even in the presence of stable vital signs. A focused assessment with sonography in trauma (FAST) examination may be helpful in the early detection of hemoperitoneum. Patients with back or flank wounds can be evaluated by CT and observation, as long as they maintain stable vital signs. These patients may also benefit from surgical exploration. This decision must be made in conjunction with the trauma surgeon. See Chapter 34.

Injuries to the extremities require evaluation of the distal neurovascular status. A bullet does not need to transect a vessel to cause injury. The development of compartment syndrome as swelling of the injured area develops should be considered. If arterial injury is suspected, angiography is indicated. Fractures from a gunshot wound should be treated as open fracture, and early antibiotics should be administered. Debridement of devitalized soft tissue is often necessary (12,13).

Gunshot wounds to the head are often not survivable. For patients with this type of injury who arrive at the hospital alive, consultation with a neurosurgeon is indicated. Injuries to the spine can occur even when the bullet does not actually pass through the vertebral

canal, as temporary cavitation can damage the cord without the presence of crushed tissue. The use of steroids is not indicated for penetrating cord injuries. The presence of a CNS injury should not delay the assessment for thoracoabdominal injuries, which can be rapidly fatal.

CRITICAL INTERVENTIONS

- Carefully examine the back, scalp, axillae, and gluteal folds for wounds in patients with penetrating trauma.
- Obtain trauma surgery consultation early in the management of patients with gunshot wounds.
- Report gunshot wounds to the appropriate authorities.

All penetrating injuries should be considered highly contaminated. As a result, adequate wound irrigation, prophylactic antibiotics and tetanus vaccination should be addressed. See Chapter 21.

DISPOSITION

Gunshot victims are ideally managed in conjunction with a trauma surgeon. Those patients with significant suspected injury generally require emergent operative intervention and close inpatient monitoring often in the critical care setting. Those patients who do not need immediate operative intervention can be managed more conservatively. Because it is often difficult to assess the full extent of injury from a gunshot wound, a prolonged observation of 12 to 24 hours is often required.

If a trauma surgeon is not available at the receiving hospital, transfer to a regional trauma center must be considered early in the course of treatment. Prior to transfer, stabilizing interventions may be necessary and can include endotracheal intubation, mechanical ventilation, tube thoracostomy, and volume resuscitation.

Common Pitfalls

- Failure to identify all wounds. All patients with suspected gunshot wounds must be completely undressed and carefully examined, as small skin wounds can be difficult to identify
- Failure to transfer gunshot victims to another facility promptly when a qualified trauma surgeon is not available
- Delaying the evaluation for thoracoabdominal injuries in stable patients with gunshot wounds
- Failure to notify the proper law enforcement authorities after a gunshot injury

CHAPTER 50 Blast Injuries

David W. Callaway and Leon D. Sanchez

During the period from 1996 to 2006 global terrorism-related bombings have increased fourfold with associated injuries increasing nearly eightfold (1). In the United States alone, there were over 36,000 explosion-related events and greater than 5,900 injuries from 1983 to 2002 (2). The extent of blast-related trauma is determined by a complex interaction of the physical components of the explosive device (e.g., size, explosive choice, delivery system, and adulterants), the environment (e.g., open versus confined space, distance from blast, reflecting surfaces, structural collapse, or medium in which the blast is transmitted), and intrinsic host factors such as age and comorbidities (3).

Conventional explosives are categorized as either *high-order* or *low-order*. High-order explosives (HE), such as TNT, Semtex, and dynamite produce a supersonic overpressure shock wave that results in rapid transient increases in ambient pressure (peak overpressure). This shock wave causes rapid external loading on the body, especially at points of air–tissue interface and is responsible for primary blast injuries (PBIs). High-order explosive detonations also result in secondary, tertiary, and quaternary blast injuries (Table 50.1). In contrast, low-order explosives (LE), such as pipe bombs and petroleum-based bombs result in subsonic explosions without resulting peak overpressure.

In HE detonations, the blast wave is composed of three components: the positive phase, the negative phase, and subsequent blast wind. During the *positive* phase, the blast wave expands radially at the speed of sound, causing a sudden increase in the ambient

pressure (peak overpressure). This peak overpressure is responsible for PBIs. The biologic effect of the PBI depends directly on the level of peak overpressure and the duration of this positive phase. In the following *negative* phase, pressure drops below ambient levels, creating a vacuum and subsequent blast wind. The *blast wind* generates projectiles and can throw victims, resulting in secondary and tertiary blast injuries.

Blast wave propagation depends on the medium in which the explosion is detonated. As the shock wave expands, the overpressure decreases, and the velocity of propagation diminishes. In open air, the peak pressure of the shock wave falls off as the inverse of the distance from the explosion to the third power. In denser media, such as water, explosions produce shock waves that have a much higher peak overpressure and a faster rate of propagation than comparable explosions in air (1). The compressive shock wave results in greater blast loading on the victim and more severe injuries. The shock waves reflect off the surface of the water, creating tension waves that interact with the blast wave and diminish wave propagation. As a result, the overpressure effects increase with depth of submersion. Explosions within confined spaces are subject to reflection and magnification of the blast wave, leading to greater overpressure, longer positive phase duration, and an increased incidence of PBIs and death (Fig. 50.1).

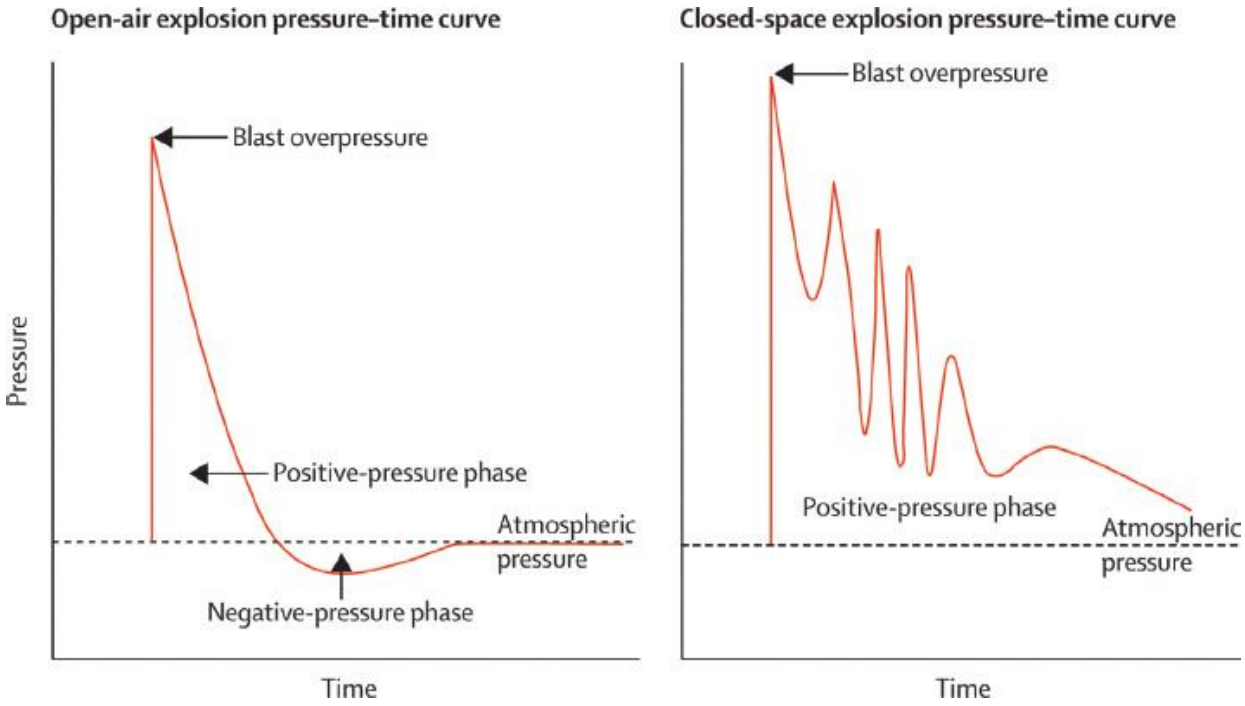

FIGURE 50.1 Difference in pressure curves between open- and closed spaces. (From Wolf SJ, Bebarta VS, Bonnett CJ, et al. Blast injuries. Lancet. 2009;374(9687):405–415.)

CLINICAL PRESENTATION

Blast injuries are classified into four categories: primary, secondary, tertiary, and quaternary (Table 50.1). PBI is unique to HE explosions. As the shock wave passes through biologic tissue, the injury is greatest at the interface between tissues of different densities, such as the lungs, the tympanic membrane (TM), and the bowel. The organ most vulnerable to PBI is the TM, followed by the lungs (4–8). The incidence of PBI in open space explosions is 10%, as compared to 38% in confined spaces (9). PBI is relatively uncommon in *survivors* of major explosive attacks. Many victims with PBI are very close to the source of the explosion and succumb to secondary and tertiary injuries prior to receiving medical care.

TABLE 50.1
Mechanisms of High-Order Explosive Blast Injury

Category	Characteristics	Affected Body Region	Types of Injuries
Primary (high-order explosives)	Impact of blast wave (overpressure) with body surface	Gas-filled structures and areas of air–fluid interface (e.g., lungs, middle ear, and intestines)	• Blast lung injury • TM rupture • Middle ear damage • Abdominal perforation/hemorrhage • Globe rupture • Concussion
Secondary	Result of flying debris/bomb fragments	Any body region	• Penetrating or blunt injuries (may be occult)
Tertiary	Result of individual being thrown by blast wind or structural collapse	Any body region, especially extremities	• Fractures • Traumatic amputations • Crush injuries • Closed- and open-head injuries
Quaternary	All other explosion-related injuries or illnesses (including exacerbation of pre-existing conditions)	Any body region	• Burns (chemical, electric, scalds) • Crush injuries • Angina/AMI • COPD, asthma • Asphyxiation (carbon monoxide or cyanide)

Modified from Almogy G, Mintz Y, Zamir G, et al. Suicide bombing attacks: Can external signs predict internal injuries? *Ann Surg.* 2006; 243(4):541–546.

Secondary blast injury (SBI) predominates in victims presenting to emergency departments (EDs) (10). In SBI, the blast wave can propel objects, either intrinsic (e.g., shrapnel) or extrinsic (e.g., components of the target such as metal from a bus door) to the device that result in both blunt and penetrating trauma. The effective range of injury in SBI is greater than for PBI. *Tertiary blast injuries* are a result of the victims being thrown by the blast wind or by subsequent structural collapse. *Quaternary blast injuries* comprise a broad range of blast-related injuries that include burns, toxic inhalations (e.g., cyanide or carbon monoxide), asphyxiation, particulate inhalation, and exacerbation of pre-existing conditions. Quaternary blast injuries are common in industrial explosions.

An overwhelming majority (80% to 90%) of blast survivors present to the ED with non–life-threatening secondary, tertiary, and quaternary injuries (11,12). Soft tissue injuries (burns, abrasions, and embedded foreign bodies) are by far the most common injuries from terrorist bombings. Nine percent to 22% of victims will present with critical injuries (13). Studies of terrorist bombing incidents reveal

that 50% of surviving casualties present to treatment facilities within the first hour (8,10). In general, there is a biphasic presentation, with more critically ill patients presenting in the “second wave” (8,11).

The TM is the structure most sensitive to peak overpressure and most commonly injured in blast victims, seen in up to 9% to 47% of blast survivors with significant injuries (14,15). Depending upon the orientation of the victim to the blast, increases in ambient pressure of 2 to 5 psi can result in rupture of the TM. The most common PBI is a linear tear in the inferior portion (pars tensa) of the TM. With increases in overpressure, the blast wave may also result in damage to the cochlea or ossicle dislocation (resulting in sensorineural hearing loss and tinnitus) (16). There is debate about the correlation between TM rupture and more life-threatening PBI. Isolated TM rupture does not appear to predict serious PBI reliably and with sufficient sensitivity (17,18,19). There is increasing evidence that suggests TM rupture as a predictor of significant concussive closed head injury.

The lung is the second most commonly affected organ in PBI. The threshold for lung damage is approximately 15 psi of peak overpressure, with moderate to severe lung damage observed with 50 psi (4). The advancing blast wave creates a pressure differential across the alveolar–capillary interface that results in damage to the lung parenchyma. Blast lung injury (BLI) is a unique injury defined by diffuse lung contusions, pulmonary edema, and occasionally pneumothorax or hemothorax. BLI is the most common fatal PBI among initial survivors.

The blast wave can also cause diffused parenchymal lacerations and can create fistulas between the alveolar spaces and the pulmonary veins. Venoalveolar fistulas allow air into the pulmonary venous system, which can then travel to the left side of the heart and enter the systemic circulation. Arterial air embolisms can result in sudden death, neurologic syndromes (e.g., cerebral or spinal infarction), and myocardial ischemia seen in some victims in the immediate postblast period.

Blast injury to the bowel requires higher peak overpressure and is more frequent in confined space or underwater blasts than in open-

air explosions. The blast wave can cause serosal tears, intramural hemorrhages, or bowel perforation. Shear injuries to mesenteric vessels can cause ischemia or infarction that leads to delayed intestinal rupture. The colon (primarily the ileocecal region) is the visceral organ most frequently injured in PBIs. Solid organ damage is rare and directly related to proximity to the blast.

DIFFERENTIAL DIAGNOSIS

An accurate history of the timing, location, and proximity to the explosion is critical to the diagnosis and initial management of blast injuries. In patients with signs of respiratory distress, BLI should be suspected. The clinician should also consider cardiac contusions, reactive airway disease, acute myocardial infarction, toxic exposure (e.g., carbon monoxide or cyanide), or exacerbation of other underlying diseases. The differential diagnosis of shock in the blast victim must include BLI, hemorrhagic shock, spinal shock, ammonia nitrate exposure (explosive adulterant), acute myocardial infarction, and acute arterial embolism.

The etiology of altered mental status in the blast victim ranges from physiologic shock (e.g., hypovolemic, cardiogenic, or neurogenic) to closed head injury to psychogenic shock. Hearing loss may be from TM rupture, ossicle dislocation, foreign body impaction, or temporary stunning of the vestibular–cochlear system.

ED EVALUATION

Blast trauma does not occur in isolation. Emergency physicians must evaluate blast victims for blunt and penetrating trauma, blast-specific injuries, and exacerbations of chronic disease. The initial evaluation of the blast victim focuses on rapidly identifying life-threatening conditions and risk stratifying multiple patients.

One approach is to segregate patients based on the presence or absence of external signs of trauma. Patients in apparent distress or with signs of external trauma should be evaluated based on the ATLS Guidelines with secondary and tertiary examination focusing on ENT, ocular, and neurologic examination. Of note, the Injury Severity Score grossly underestimates the complexity of injury and

the necessary resource utilization (9). In patients without apparent life-threatening injury, the main goal of initial evaluation is to identify PBI that may be obscured by secondary or tertiary wounds. The provider should obtain a *focused history* including location of blast (confined space or open air), distance of victim from blast, status of additional casualties, any details regarding the explosion (e.g., single suicide bomber, vehicle borne improvised explosive device, or presence of industrial chemicals, etc.). History should focus on *symptoms* concerning for PBI including chest pain, shortness of breath, cough, abdominal pain, tinnitus, or focal neurologic deficits. Concerning *physical examination* findings include tachypnea, hypoxia, decreased breath sounds, oropharyngeal pettechiae, chest wall crepitance, or abdominal tenderness. While absence of TM rupture does not preclude serious PBI, TM rupture should raise suspicion for more serious PBI and possible closed head injury (8,10). Any patient with a ruptured TM or with cardiopulmonary symptoms requires a chest radiograph to evaluate for BLI.

Routine laboratory testing is rarely useful in the management of PBIs. The arterial blood gas (ABG) is one exception. The ABG is particularly useful in the symptomatic patient, and oxygen desaturation may be the earliest sign of decompensation in the patient with BLI. The ABG may also assist with the diagnosis and management of toxic exposures to chemicals such as cyanide or carbon monoxide.

KEY TESTING

- Chest x-ray for suspected BLI
- ABG for suspected BLI

ED MANAGEMENT

Upon notification of an explosion and potential mass casualty incident (MCI), a triage area should be established at the entrance to the ED. The triage area may be needed for decontamination procedures and should be physically separate from treatment areas. Unlike traditional trauma triage where overtriage rates of 50% are

accepted as the standard, in MCI blast scenarios, overtriage can actually result in increased overall mortality for initial survivors by taxing the emergency response system and delaying care for the critically ill (5).

Initial stabilization, resuscitation, and ongoing management should proceed in a similar fashion to other victims of multiple trauma. The focus is on identifying patients with moderate-to-severe, yet correctable, blast trauma. Immediate attention should be paid to signs of significant BLI (i.e., tachypnea, shortness of breath, altered mental status), controllable extremity hemorrhage, and abdominal trauma.

Otoscopic examination of the TM should be conducted early in the patient assessment. Asymptomatic patients with intact TMs rarely have significant PBI (19). TM perforation has a high rate of spontaneous healing, especially if the tear is small and marginal in location (20). For large and central perforations, an otolaryngologist should be consulted, and immediate paper patching has been advocated (18). Treatment in the ED is generally expectant. The external auditory canal should be kept clean and dry; there is no need for routine irrigation or use of topical solutions. Some literature suggests the use of antibiotic suspensions for traumatic TM rupture (16). Otolaryngology follow-up is appropriate for patients that do not need evaluation in the ED.

Primary BLI has a reported mortality of nearly 70% (21). Initially, chest radiography should be performed and supplemental oxygen administered via nasal cannula or nonrebreather. Complications such as pneumothorax and hemothorax should be treated aggressively with early tube thoracostomy. Positive pressure ventilation in patients with BLI may cause or exacerbate pneumothorax, increase the alveolar-to-pulmonary vein pressure gradient, and potentiate systemic air embolization. Some studies suggest that a Pa_{O_2}/Fi_{O_2} ratio of <200 can be used as an indication for mechanical ventilation. For patients with severe pulmonary blast injuries, lung protective ventilation strategies are important. A regimen of volume-controlled, synchronized, intermittent, mandatory ventilation with small tidal volumes (5 to 7 mL/kg), limited peak inspiratory

pressure, and permissive hypercapnia ($PaCO_2 \leq 57$ mm Hg) appears beneficial (22,23).

General anesthesia is poorly tolerated in patients with PBI during the first 24 to 48 hours. If not contraindicated, regional or spinal anesthesia should be considered for patients who require surgery. Intravenous fluid management should be carefully monitored and fluid overload avoided. There exists significant debate regarding the role of permissive hypotension in blast and polytrauma resuscitation (24). Pulmonary artery and arterial catheters may be required to manage fluids appropriately. No definitive evidence supports the routine use of antibiotics or corticosteroids.

The blast victim presenting in shock should be evaluated and treated based on standard ATLS Guidelines. The clinician should also be aware that blast load focused on the thorax can produce a unique, vagally mediated cardiogenic shock without compensatory vasoconstriction (13). Patients may present with the triad of hypotension, bradycardia, and apnea (12,25).

For victims with systemic air emboli, hyperbaric oxygen (HBO) therapy is indicated. HBO therapy can be effective for cerebral air emboli, even up to 12 hours after the acute event. The Trendelenburg and the left lateral decubitus positions are sometimes advocated to reduce embolization to the brain and coronary circulation but there is no conclusive evidence of benefit in the literature.

Intestinal PBI is rare except in submersion blast injuries. Clinical symptoms may not manifest for 6 to 72 hours, and computed tomography or serial examination is indicated in patients with significant abdominal pain, tenderness, tenesmus, or penetrating injuries. Abdominal blast injury is managed in the same manner as any other blunt force trauma to the abdomen.

Secondary and tertiary injuries predominate in explosive MCI events. Extremity injuries are particularly common. From 1% to 7% of victims will present with traumatic amputations (1). Early tourniquet application should be considered for potentially life-threatening extremity injuries. Lacerations, abrasions, fractures, and burns resulting from secondary and tertiary blast injury can be

managed as in other trauma patients. Fragments generated by small explosions tend to produce wounds with little damage and can usually be managed without extensive wound exploration for removal of fragments (18). Generally, shrapnel wounds should be treated as low-velocity gunshot wounds. With high-velocity fragment wounds, as many fragments as possible should be excised and the wound left open for delayed primary closure. All penetrating secondary and tertiary injuries should be considered highly contaminated, and proper wound care and tetanus prophylaxis are therefore important. Ocular injuries occur in 10% of blast victims and are often occult. Penetrating ocular injuries require prompt ophthalmology consultation. Patients with crush injuries, compartment syndrome, burns, or soft tissue injuries should be managed in the standard fashion.

CRITICAL INTERVENTIONS

- Triage blast victims rapidly and accurately.
- Consider early activation of the hospital mass casualty system.
- Obtain detailed history regarding the explosive event to risk stratify victims.
- Perform a careful primary and secondary survey, examining the back, scalp, axillae, and gluteal folds for penetrating wounds.
- Perform a thorough pulmonary examination and early evaluation for ruptured TM in all blast victims.

DISPOSITION

Blast victims with significant injuries or signs of polytrauma require evaluation by a trauma surgeon or referral to a trauma center. Survivors with significant BLI, hemorrhagic shock, or intestinal damage generally manifest symptoms within the first hours after the blast; they often require emergent operative intervention, ICU admission, and close monitoring. Patients with suspected arterial air embolism require stabilization and urgent hyperbaric treatment. If transfer is required and air transport is employed, pressurized aircraft or low-altitude flights are important to limit the likelihood of

exacerbation of arterial air embolism or the development of clinical pneumothorax.

The majority of blast victims are not critically ill (8,13). Asymptomatic patients with isolated TM rupture should receive a chest radiograph and, if it is negative, they can be discharged after a brief period (6 to 8 hours) of observation. Most TM ruptures, especially if they involve $<80\%$ of the surface, heal spontaneously without long-term sequelae. Patients with middle- or inner ear symptoms should be referred to an otolaryngologist. Patients with ongoing abdominal symptoms should be admitted for observation and serial examinations. Patients with loss of consciousness or ongoing neurologic complaints should be admitted and observed.

Common Pitfalls

- Failure to appreciate that triage both at the scene and in the emergency department is an important determinant of survival for critically injured victims of explosions
- Failure to appreciate the importance of scene history, especially structural collapse, time of extraction, distance from explosion potential chemical contaminants, and number of victims
- Failure to recognize symptoms suggestive of cerebral, spinal, or myocardial ischemia resulting from arterial air embolism
- Failure to appreciate that positive pressure ventilation poses a significant risk for pneumothorax and for producing systemic air embolization in patients with blast lung

CHAPTER 51

Hanging and Strangulation Injuries

Leon D. Sanchez and Richard E. Wolfe

Strangulation occurs when pressure is applied to the neck. This common injury accounts for 2.5% of traumatic deaths worldwide. Men are three to five times more likely to be victims than women, and those injured are most often between the ages of 21 to 40 (1). Causes of death from strangulation have been attributed to asphyxia, arterial occlusion, spinal cord injuries, and cardiac arrest due to pressure on the vasoactive centers of the great vessels. The specific role played by each of these causes as well as the types of injuries depend on the method used to apply pressure, the force, and the duration of the strangulation. To better manage this injury, it is helpful to subdivide strangulation by the methods used to apply the pressure: hanging, garroting, or throttling.

Hanging occurs when the ligature pressure is applied by the weight of the individual's body as part of a judicial, homicidal, suicidal, or accidental event. Although judicial hangings are rarely performed today, hanging is the third most common form of suicide after firearms and ingestions. Men attempt hanging three times more often than women do. Newly jailed prisoners are at particular risk. Complete hanging refers to the body being suspended, and incomplete hanging describes situations where the body exerts pressure but is not suspended. Accidental hangings are most commonly incomplete. Children and individuals who practice autoerotic asphyxiation are the most common victims of accidental hanging (1).

Garroting or ligature strangulation involves pressure being applied to the neck by a ligature just as in hanging. The difference is that the force used to exert this pressure is something other than the individual's body weight. Throttling can be considered a type of garroting where the ligature is the assailant's hands, which exert the pressure directly.

CLINICAL PRESENTATION

Hanging or strangulation may result in injury to vascular structures in the neck. Venous obstruction results from forces applied to the jugular system (2,3). This leads to vascular congestion and cerebral hypoxia. As a result of the hypoxia, the neck musculature is thought to relax, leading to further compression that can lead to arterial and airway occlusion (2). Injury to the arteries is caused by hyperextension and rotation of the head. The carotid artery can be stretched over the transverse process of C2 or compressed by direct pressure over the transverse process of C6 (2,4). This can result in an intimal tear (4,5). Vertebral artery flow is not affected by direct pressure except at the extremes of rotation and lateral flexion (2).

Neurologic injury after hanging results from decreases in ventilation and cerebral perfusion. Autonomic stimulation from pressure on the carotid bodies or vagal sheath can lead to cardiac arrest (3,6). Hypoxia secondary to upper-airway obstruction plays a role in the development of neurologic injury or death but is thought to be second in importance to ischemia. Ischemic injury is caused by venous vascular congestion and arterial compression, both of which result in decreased cerebral flow (3,7–9). Increased intracranial pressure (ICP) secondary to cerebral edema is common in patients with altered mental status (10,11). Nevertheless, delayed neurologic sequelae are rare, and even patients who present with a low Glasgow Coma Scale (GCS) often recover fully (3,8,9).

Injury to the laryngotracheal apparatus may be caused by compression or traction of the involved structures. Manifestations of these injuries may not be evident at presentation (12). Most airway injuries by themselves are not life threatening (3). In one study that

looked at 112 deaths and 59 survivors of strangulation, only one case required emergent operative management (13). None of the deaths could be attributed to airway injury (13). Fractures of the hyoid bone and thyroid cartilage are seen with some regularity, whereas cricoid fractures are less common (13,14). The incidence of these fractures increases with greater age of the patient, probably due to calcification of the structures (14). Throttling victims have a much higher incidence of fractures as compared to hanging victims. The incidence of thyroid and hyoid fractures in hanging victims ranges from 10% to 15%; cricoid fractures are rare. Throttling victims have an incidence of fractures ranging from 30% to 40% (3,13,14). Even with the higher rates of injury in throttling victims, injuries to the laryngotracheal apparatus are rarely life threatening. Asphyxia from upper-airway obstruction due to the ligature itself is also rare, although pressure from the ligature can displace the tongue upward and obstruct the airway (6,9).

In the late 19th and early 20th centuries, British postmortem studies of judicial hangings demonstrated that a minimum drop force (patient weight multiplied by the length of the drop) was needed to cause a cervical spine fracture. The required drop height varies depending on factors such as the weight of the subject, the neck musculature, and the strength of the bone itself. Although generally a drop height greater than the patient's height is required to cause a spinal fracture, in rare circumstances shorter drop heights can produce these injuries. The minimum reported drop height is 3 ft (15,16). The most common spinal injury with long drops is disjointing of the second from the third cervical vertebra and bilateral fractures of the second cervical vertebra, the classic hangman's fracture (Figs. 51.1 and 51.2). The position of the knot is important.

FIGURE 51.1 Lateral radiograph of cervical spine. Fracture of the posterior elements of C2 is indicated by the arrow. (Image courtesy of Marc Camacho, MD.)

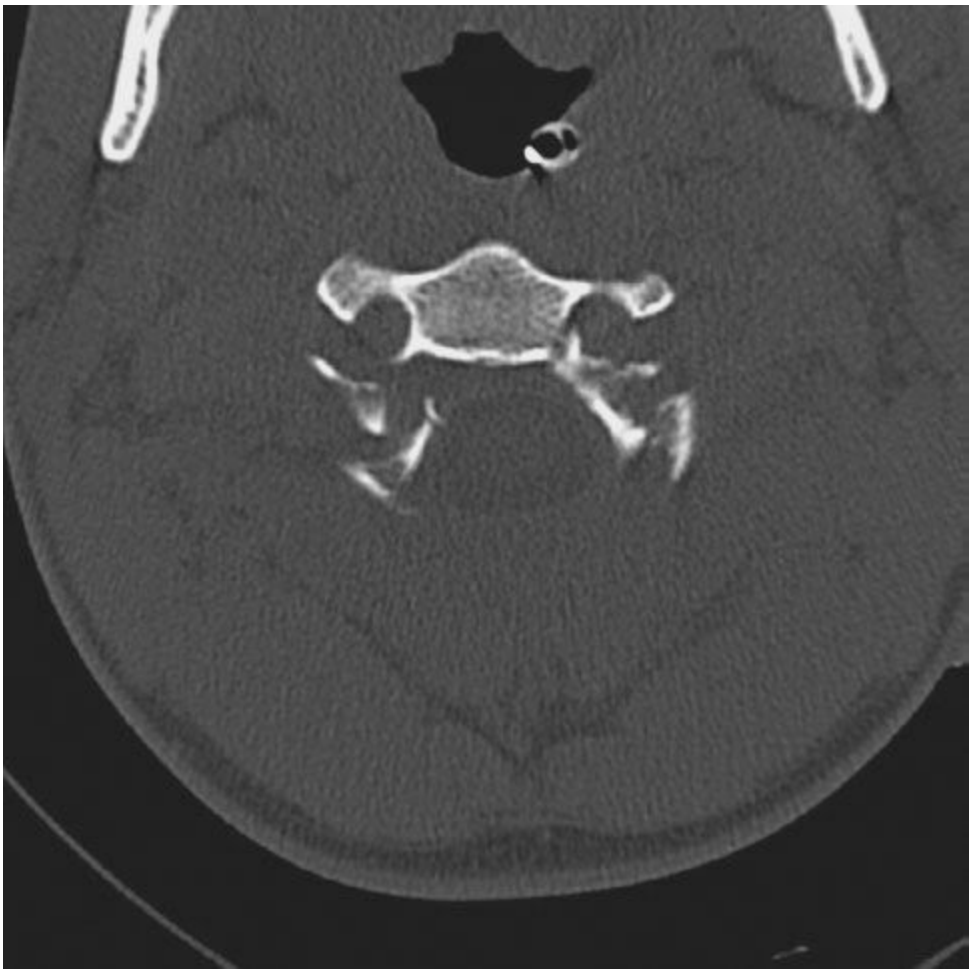

FIGURE 51.2 Axial image of computed tomogram of C2 showing bilateral pedicle fractures. (Image courtesy of Marc Camacho, MD.)

In typical (nonjudicial) hangings, the knot is placed under the occiput and has the greatest ability to cause arterial occlusion rather than a spinal fracture. A hangman's fracture will most likely occur when the knot is placed under the chin (submental) to ensure hyperextension, yet many judicial hangings were performed with the knot on the side of the jaw (subaural) which was less likely to result in a spine fracture and cord transection (17,18). Despite drops from body height and knot placement under the chin, even "proper" judicial hangings do not always cause cervical spine fractures (14,17,19). In complete suicidal and accidental hangings, most victims have negligible drop distances, and few sustain cervical spine fractures (7,9,16,20).

Pulmonary complications from strangulation injury include pulmonary edema, aspiration pneumonia, and the adult respiratory distress syndrome (ARDS). Pulmonary edema is thought to be caused by markedly increased pulmonary transvenous pressures from forced inspiratory efforts against an occluded upper airway (21). Aspiration pneumonia in patients with a depressed mental status is reported in case series of strangulation victims (3,9,10). The ARDS in strangulation victims is secondary to brain hypoxia (22). Brain hypoxia leads to autonomic mediated vasoconstriction of the pulmonary venules, leading to ARDS and possibly contributing to pulmonary edema (22,23).

The clinical presentation of a patient with a strangulation injury can vary widely. The presenting mental status and GCS are related to the duration of hanging. The GCS is a poor predictor of the patient's final outcome, and patients presenting with very low scores have a strong likelihood of surviving the injury with a normal mental status. Ligature marks are often, but not always, present (9). Subconjunctival, gingival, and oral petechial hemorrhages may be observed. These are thought to be caused by vascular congestion (13). Patients may also present with hoarseness or voice change (6), both of which may represent injury to the laryngotracheal apparatus. Subcutaneous emphysema can also be present (13). Occasionally, patients will present with frank stridor. Tachypnea can be an early sign of aspiration pneumonia or pulmonary edema (6,21).

Mental status changes may be secondary to brain anoxia, preexisting mental illness, or posttraumatic response to the event (6,9). In many of these patients, the evaluation may be more difficult owing to the presence of alcohol or other substances (6). One study found that 70% of hanging patients had concomitant drug or alcohol ingestion (16). Throttling victims often present after a domestic abuse incident and frequently will not volunteer the fact that they were throttled unless specifically asked (24).

ED EVALUATION

After immediate life-threats have been addressed, a more extensive history and physical examination should be performed. The presence of alcohol and other substances in these patients is common and may complicate the examination. In alert patients, attention should be paid to the evaluation of the laryngotracheal apparatus and to the pulmonary status. The presence of hoarseness, difficulty in swallowing, or other complaints that raise suspicion for laryngotracheal injury should prompt a more extensive workup. Although relatively rare, studies have shown an incidence of cervical spine fractures after suicidal near-hanging that may be as high as 7% (11,25). Imaging of the cervical spine may thus be indicated in the emergency evaluation of these patients and may reveal soft tissue swelling or a hyoid bone fracture. Evidence of laryngeal edema should be followed by prompt otolaryngology consultation. Computed tomography (CT) of the neck can be very helpful in delineating an injury to the laryngeal skeleton. Early control of the airway should be considered in these patients.

Pulmonary complications are the leading cause of death in patients who survive to hospital admission. Pulse oximetry and chest radiographs should be routinely performed in these patients. Manifestations of pulmonary edema and ARDS may be delayed by several hours. Aspiration pneumonia is also common and more likely in those patients with a depressed mental status.

Vascular injuries that are clinically significant are essentially restricted to the arterial tree. Although extremely rare, clinical signs of arterial dissection should prompt further workup. The most common signs that should raise suspicion for dissection are neurologic abnormalities consistent with a transient ischemic attack or cerebrovascular accident, Horner syndrome, amaurosis fugax, unexplained nausea or vomiting, and vertigo. Headache and neck pain are also common presenting complaints, although they are nonspecific.

The gold standard for detection of vascular injuries is four-vessel angiography. Magnetic resonance angiography and CT angiography are reasonable alternatives if angiography is unavailable or if they are available faster than angiography, as they may help delineate

the injury and expedite the workup. However, these "techniques" may miss injuries, and a negative MRI or CT result does not completely rule out the diagnosis. Doppler ultrasonography is not useful for the evaluation of the vertebral arteries but can provide useful information about the carotid arteries; however, the sensitivity of duplex ultrasound is not high enough to completely rule out carotid injury. In patients in whom there is a high suspicion for arterial injury, four-vessel angiography remains the test of choice. If unavailable, transfer of the patient to another institution should be considered.

KEY TESTING

- CXR to evaluate for pulmonary edema, ARDS, and aspiration pneumonia
- Cervical spine CT or plain films to evaluate for fracture. As angiography (CTA) may often be done CT/CTA may obviate need for plain films
- Angiography for vascular injuries (CTA, MRA, angiography)

ED MANAGEMENT

The initial presentation of the patient will dictate the need for early management of the airway owing to respiratory distress or poor neurologic status. Cervical spine injury is extraordinarily rare in strangulation victims, and excessive cervical spine precautions need not be taken. Airway injuries severe enough to interfere with airway management are uncommon, and intubation using rapid sequence intubation is recommended. When possible, ICP blunting techniques should be used during the intubation. Positive end-expiratory pressure should be instituted early, as these patients are at high risk for the development of pulmonary edema and ARDS.

Once the life-threats have been addressed, special attention should be paid to psychosocial issues. Throttling and ligature strangulation victims are often victims of domestic abuse. It may not be safe for these patients to be discharged even in the absence of medically important injuries. In the adult population, hangings are

predominantly a result of suicide attempts. Ingestion of toxic substances in these patients is common and should be ruled out. These patients should be separated from their property and placed under direct observation to avoid further attempts at harming themselves. Psychiatric consultation is indicated.

CRITICAL INTERVENTIONS

- Ensure a patent airway. Monitor the respiratory status closely and manage the airway if needed.
- Obtain early otolaryngology consultation for suspected laryngotracheal injuries.
- Consider the possibility of increased ICP in patients with a depressed sensorium.
- If there is evidence of increased ICP, obtain neurosurgical consultation and initiate measures to decrease ICP.
- Consider toxic ingestions.
- Address the psychiatric or social issues that are at the root of the strangulation once immediate life-threats have been managed.

DISPOSITION

Owing to the presence of delayed neurologic and pulmonary complications in strangling victims, observation for at least a 24-hour period is recommended. Otolaryngology and neurosurgical consultation should be considered when warranted. Psychiatric consultation as well as social work involvement may be necessary.

Common Pitfalls

- Failure to consider early airway management.
- Failure to diagnose vascular dissections.
- Failure to involve otolaryngology and neurosurgery when needed.
- Failure to consider interpersonal violence.
- Failure to consider toxic ingestions.
- Failure to involve psychiatry.
- Early discharge of the patient.

CHAPTER 52

Trauma in Pregnancy

Bonnie Lau and Susan B. Promes

Significant trauma affects approximately 7% of pregnant women (1). In fact, trauma was reported to be the leading cause of death during pregnancy in at least one series (2). Statistically, pregnant women sustain approximately 4.1 trauma-related hospitalizations per 1,000 deliveries (3). The pregnant trauma patient presents a unique challenge to the emergency department (ED) team caring for her. Not only is the physician caring for two patients, but both of the patients have their own unique needs. In general, when faced with a pregnant trauma patient, the emergency physician should resuscitate the mother first. The well-being of the unborn fetus is dependent upon the hemodynamic stability of the mother.

It is imperative that the physician caring for the gravid woman be aware of the physiologic changes that occur during pregnancy and the impact these changes may have on the resuscitation of the pregnant woman and her unborn fetus (eTable 52.1). This knowledge will be critical to the evaluation and treatment of the woman and her unborn child.

eTABLE 52.1
Changes in Maternal Physiology During Pregnancy

Cardiovascular system	↑ cardiac output
	↑ pulse to 80–95 bpm
	↓ BP in second trimester
	↓ central venous pressure left axis deviation on electrocardiogram
	↓ venous return when patient supine
Respiratory system	↑ respiratory rate
	↑ tidal volume
	↑ minute ventilation
	↓ functional residual capacity
	+ respiratory alkalosis
	↑ oxygen consumption
Hematologic system	↑ blood volume producing a dilutional anemia
	↑ white blood cell count
	↓ platelet count
	↑ erythrocyte sedimentation rate
	↑ fibrinogen, factors VII, VIII, IX and X
	↑ risk thromboembolic disease
Urinary system	↓ motility in collecting system
	↑ glomerular filtration rate
	↓ BUN and creatinine levels
	↑ glucose excretion
Gastrointestinal system	↓ motility
	↓ tone in lower esophageal sphincter
	↑ dilation of hemorrhoidal veins
	↑ risk of gallstone formation
	↑ spider angiomas & palmar erythema
	↓ albumin & total protein levels
	↑ serum alkaline phosphatase
Musculoskeletal system	↓ total calcium levels
	↑ ligamentous laxity
Endocrine system	↑ aldosterone & cortisol levels
	↑ peripheral resistance to insulin
Central nervous system	↓ coordination in late gestation
	↑ emotional lability

Airway. Although airway anatomy does not change significantly, progesterone causes smooth muscle relaxation, affecting the lower esophageal sphincter and increasing the risk of aspiration.

Breathing. The diaphragm is gradually pushed up 3 to 4 cm during pregnancy, causing a 25% decrease in functional residual capacity

and resulting in decreased maternal oxygen reserve. Pulmonary function is further compromised by increased oxygen consumption. Starting in the first trimester, stimulation of the medullary respiratory center by progesterone increases minute ventilation by up to 50% (a result of increased tidal volume). This is accompanied by a 10-mm Hg increase in PO_2, a 10-mm Hg decrease in PCO_2, and a compensatory decrease in bicarbonate to about 19.5 mEq/L. These physiologic changes result in less respiratory reserve in the pregnant trauma patient.

Circulation. Pregnancy is a high-flow, low-resistance state of cardiovascular homeostasis. Heart rate increases until the end of the second trimester, when it plateaus at 10 to 15 beats above baseline. Systolic, and to a greater extent diastolic, blood pressure decrease during the first and second trimesters, returning to prepregnancy baseline levels during the third trimester. Cardiac output increases by 40% by the end of the first trimester and persists at this level, causing a cardiac flow murmur in 90% of pregnant women. By the third trimester, there is increased vascular congestion in the pelvis and a 50% decrease in the velocity of venous flow in the lower limbs (4). These changes predispose the gravid patient to deep venous thrombosis as well as increased bleeding from lower extremity and pelvic trauma.

In addition, several hematologic changes accompany pregnancy. A 50% increase in blood volume and concomitant increase in red blood cell mass by only 20% to 30% results in a 3% to 6% drop in hematocrit. The white blood cell count increases to 12,000 to 18,000/μL by the second trimester and may increase to 25,000/μL with stress. The prothrombin and partial thromboplastin times are somewhat decreased. Coagulation factors rise gradually and exceed fibrinolytic activity by the third trimester.

The fetus has a higher hemoglobin concentration than the mother, and fetal hemoglobin has a higher affinity for oxygen. As a result, fetal oxygen consumption does not decrease until oxygen delivery decreases by 50% (5). This allows the fetus to tolerate brief periods

of maternal hypoxia and hypoperfusion. In late pregnancy, the fetus is capable of redistributing blood to the heart and brain (6).

CLINICAL PRESENTATION

Critically ill pregnant trauma patients may present with normal vital signs due to the physiologic changes that occur in pregnancy; this should not give the emergency physician a false sense of security. Pregnant women have increased blood volume as they near term, so blood loss must be excessive before hypotension occurs. Abdominal pain in the pregnant trauma patient may be due to common intra-abdominal injuries associated with blunt trauma. Other causes of life-threatening problems include uterine rupture, placental abruption, and premature labor.

Pregnant trauma patients tend to have a slightly different injury pattern when compared to the general trauma population, with increased intra-abdominal injuries and decreased traumatic brain injuries (7). In penetrating trauma, this may be due to changes in maternal anatomy with increasing gestational age. The diaphragm and intra-abdominal contents are displaced upward by the enlarging uterus; hence, injury patterns will vary from the general population. For example, someone with a stab wound to the left upper quadrant is at increased risk for intestinal injury because the uterus displaces the intestinal contents superiorly.

Whether the pregnant patient is involved in blunt or penetrating trauma, the fetus in addition to the mother is at risk for injury. Even minor maternal injuries can lead to placental abruption, uterine rupture, fetal–maternal hemorrhage, and premature birth. The emergency physician should look for signs of occult injury that are manifested by uterine irritability, vaginal bleeding, and fetal tachycardia.

DIFFERENTIAL DIAGNOSIS

The emergency physician caring for the pregnant trauma patient should first consider the typical injury patterns that are associated with a given mechanism of injury. The pregnant trauma patient is

not immune to common traumatic injuries. While the emergency physician is evaluating the pregnant patient for common injuries, the physician should also consider the unique role the gravid uterus plays in the traumatic event. As the uterus enlarges during pregnancy, changes in intra-abdominal anatomy alter the injury pattern. For example, the diaphragm moves cephalad into the thoracic cavity. Subsequently, in a pregnant patient who sustains a penetrating injury to the chest, the physician should have a greater suspicion for a diaphragmatic injury. In addition, the large gravid uterus displaces the intra-abdominal contents, making bowel injuries less common and injury to the uterus more common in blunt trauma. A few important injuries associated with pregnancy include placental abruption, uterine rupture, maternal–fetal hemorrhage, and premature labor. The greater the severity of maternal trauma, the more likely a significant fetal insult will occur. Pearlman and Tintinalli (8) reported a fetal loss rate of 41% with life-threatening maternal injuries while the fetal loss rate was 1.6% with nonlife-threatening injuries.

Seizures in trauma patients are generally associated with head injuries. However, in the gravid trauma patient, the emergency physician must also consider eclampsia as the etiology of the seizure and subsequent trauma.

ED EVALUATION

As the survival of the fetus is dependent upon maternal resuscitation, the evaluation of the pregnant trauma patient should proceed in a step-wise fashion. Advanced trauma life support principles should be followed as in the nonpregnant trauma patient. However, during the primary and secondary trauma surveys, the emergency physician must apply a detailed understanding of the physiologic changes that occur in the pregnant state to detect potentially life-threatening conditions. The airway must be managed aggressively. All pregnant trauma patients should be placed on oxygen, since oxygen consumption is increased with pregnancy, and it is important to avoid fetal hypoxia. When evaluating the

circulatory status, the physician should remember that the second-trimester pregnant patient without significant injuries may have an elevated heart rate and lower blood pressure. Conversely, she may also have significant life-threatening hemorrhage without alteration in vital signs due to the physiologic increase in cardiac output and intravascular volume.

After the primary survey, a complete history should be obtained, including last menstrual period, estimated date of delivery, previous pregnancy history, and any problems associated with the pregnancy.

The fetus is evaluated during the secondary survey. The fundal height should be assessed, recognizing that a fundal height at or above the level of the umbilicus may indicate a potentially viable fetus. The distance between the symphysis pubis and the uterine fundus measured in centimeters approximates gestational age in weeks (Fig. 52.1). The threshold for fetal viability is 23 to 24 weeks depending on the resources available at the facility to care for the neonate (9). The presence of fetal heart tones should be documented. In patients at 20 weeks or more gestation, cardiotocographic monitoring should be obtained as soon as possible. This gives the physician information regarding fetal–maternal well-being. A normal fetal heart rate is between 120 and 160 bpm. Fetal tachycardia, fetal bradycardia, contractions, loss of beat-to-beat variability, or late or prolonged decelerations after contractions may be signs of fetal distress heralding such pathologic states as placental abruption or occult maternal shock. If the patient has vaginal bleeding, then a sterile vaginal speculum examination should be performed to identify the source of bleeding, being mindful of potential placenta previa. Aside from evaluation of the pregnancy itself, a speculum examination may reveal signs of genitourinary trauma such as lacerations from pelvic fractures or penetrating trauma.

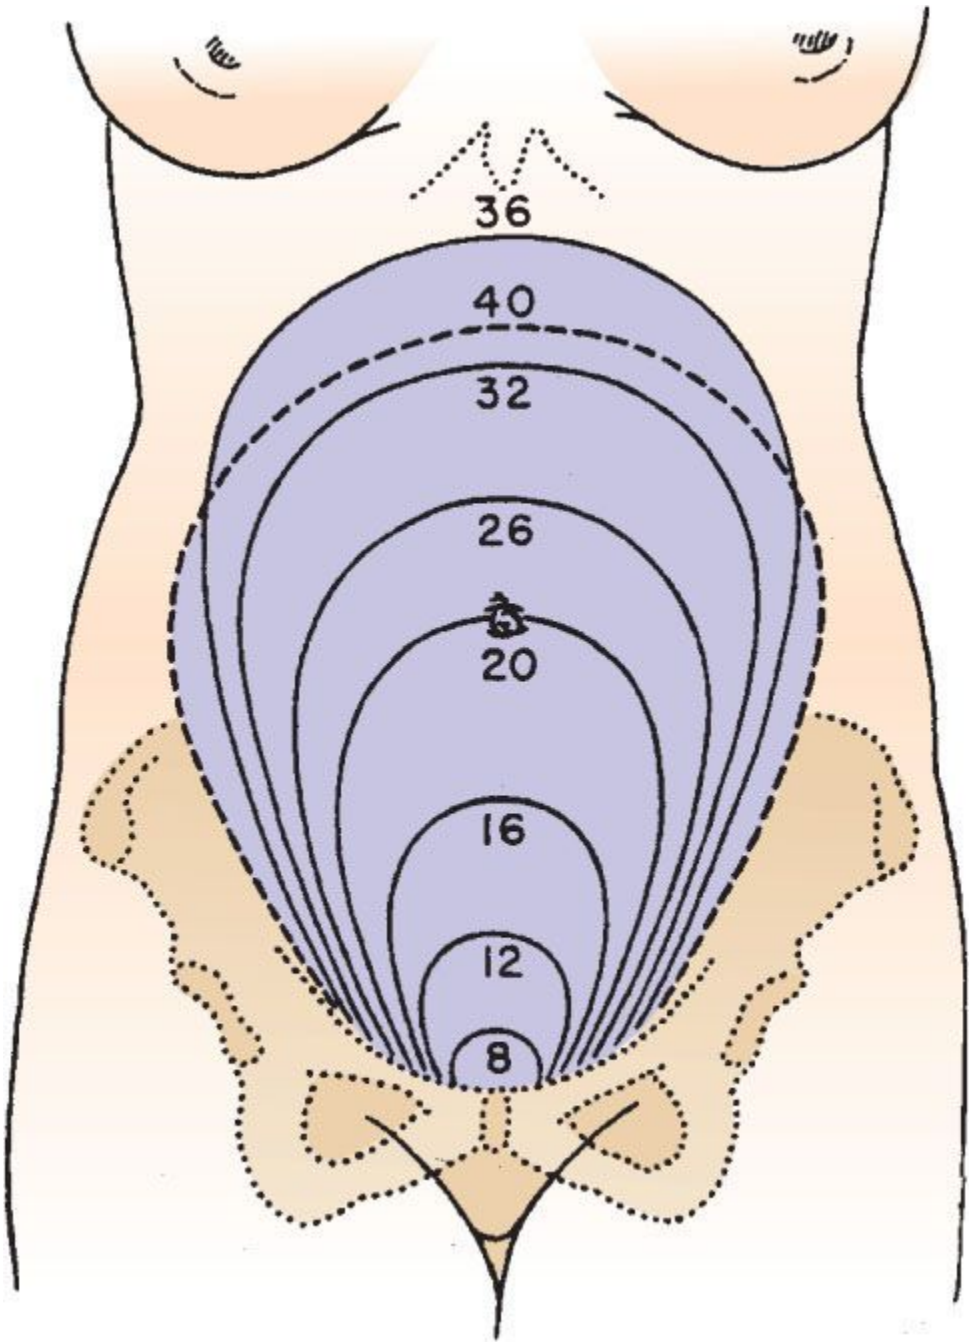

FIGURE 52.1 The height of the uterine fundus at different gestational dates.

Upon completion of the primary and secondary surveys, the clinician should tailor further diagnostic studies to the individual patient. As the fetus is dependent on maternal well-being, diagnostic tests and therapy should be directed primarily at the care of the

mother and should not be delayed because of the pregnancy. As classic signs of shock may present late, a more detailed initial workup may be appropriate in pregnancy. The hematologic changes of pregnancy must be considered when evaluating any laboratory results. It is important to remember that pregnant women have a "dilutional anemia" due to their increased blood volume (eTable 52.2). They also have an elevated white blood cell count and sedimentation rate. Fibrinogen levels are increased, as are coagulation factors. All pregnant trauma patients should have blood type determination as all Rh-negative women require Rho(D) immune globulin (RhoGAM). The recommended dose for all Rh-negative gravidas is 300 μg unless there is risk of massive isoimmunization. Based on the results of a Kleihauer–Betke (KB) test, additional RhoGAM (300 μg per 30 mL of estimated fetomaternal hemorrhage) may be warranted (10,11).

eTABLE 52.2
Hemoglobin Values in Pregnancy

Gestational Age (Weeks)	Mean Hemoglobin (g/dL)	Fifth Percentile (g/dL)
12	12.2	11.0
16	11.8	10.6
20	11.6	10.5
24	11.6	10.5
28	11.8	10.7
32	12.1	11.0
36	12.5	11.4
40	12.9	11.9

Adapted from U.S. Department of Health and Human Services: *MMWR* 1989;38:400–404.

The Eastern Association for the Surgery of Trauma (EAST) recommends a major change in the management of pregnant trauma patients in which physicians would order a KB test for all pregnant patients ≥20 weeks of gestation, regardless of Rh status (10–12).

This recommendation is based on the results of two class II and one class III studies in which investigators found that a positive KB test regardless of Rh status detected *all* cases of preterm labor (5,10,12). Given that the EAST level II recommendation was based on only three studies, no change in ED management can be suggested at this time. Therefore, patients with a potentially viable fetus (i.e., ≥20 weeks of gestation) sustaining a traumatic injury should have cardiotocographic monitoring for a minimum of 6 hours (12).

Ultrasound examination (13) can be used to evaluate for a traumatic pericardial effusion and tamponade or to demonstrate free fluid in the abdomen. In addition, it may help determine fetal age, position, and amniotic fluid volume. However, its limitations must be recognized. Ultrasound may miss placental abruption; the reported sensitivity is only 24% (14). This diagnosis is made by signs of maternal compromise or fetal distress on cardiotocographic monitoring and not generally by ultrasound.

As fetal outcome is dependent upon maternal condition and resuscitation, radiographic studies should not be withheld to prevent fetal radiation exposure. However, knowledge of the underlying principles of fetal radiation exposure must be understood by the practitioner to address patient concerns and guide appropriate evaluation (eTable 52.3). The issues of concern include risk of fetal demise, fetal malformation, childhood cancer, and fetal neurodevelopment versus the risk of missed injury that would require intervention. In the first 10 days of pregnancy, the response to significant radiation exposure is an all-or-none response. From 10 days to 10 weeks, the fetus is at greatest risk for radiation-related malformation. After 20 weeks, the fetus does not appear to be at increased risk of malformation (15). Fortunately, exposure to <5 to 10 rads does not increase the baseline risk of malformation. The increased risk of childhood cancers from prenatal radiation exposure is unclear. However, the associated risk of in utero radiation with childhood cancers has been estimated at 8% increase in childhood cancers per 100 rads. To place this in perspective, this is equivalent to an excess absolute risk of childhood cancer from 0.00006 to 0.00008 for each 100 mrad (16,17). The risk of growth restriction,

microcephaly, and mental retardation are highest at 8 to 15 weeks and appear to be associated with high-dose radiation of at least 20 to 40 rad (10). Most shielded plain film radiographs, brain computed tomography (CT), and chest CT scans are well below these concerning levels. The risk of a significant missed injury is usually higher than the risk of adverse sequelae from radiation in injured patients. However, an abdominal CT scan may deliver 3 to 9 rads to the fetus. The emergency physician may consider shielding the uterus and scanning only the upper abdomen to rule out solid organ injury and subsequently observing the patient and monitoring her clinically for signs of increasing abdominal pain, worsening anemia, fetal distress, or maternal hemodynamic changes.

eTABLE 52.3
Estimated Radiation Dose to Fetus per Radiograph

Cervical spine	<1 mrad
Chest	1–3 mrad
Abdomen	200–500 mrad
Pelvis	200–500 mrad
Lumbar spine	600–1,000 mrad
Hip/femur	100–450 mrad
CT head/chest with shielding	<1 rad
CT abdomen	3 rad
CT pelvis	3–9 rad

Diagnostic peritoneal lavage (DPL) may be performed in pregnancy using the supraumbilical technique. As with ultrasound, DPL cannot be used to evaluate the retroperitoneum. Exploratory laparotomy may be necessary during pregnancy, especially in patients with penetrating trauma to the upper abdomen. Although surgical exploration was previously recommended for all pregnant patients with penetrating trauma, some authors advocate nonoperative management with observation for penetrating wounds directly to the uterus if the patient is hemodynamically stable and

there are no signs of fetal distress (18–20). The determination of whether to perform a cesarean section at the time of exploration is based on evidence of fetal–maternal compromise detected on cardiotocographic monitoring.

KEY TESTING

- Type and screen (especially for Rh status)
- Consider Kleihauer–Betke test
- Any necessary radiographic studies
- Bedside ultrasound (pericardial effusion, free fluid in abdomen, fetal age/position, amniotic fluid volume)
- Cardiotocographic monitoring for at least 6 hours

ED MANAGEMENT

As with all trauma patients, the initial management of the pregnant trauma patient occurs simultaneously with the ED evaluation. Emphasis is placed on maternal resuscitation to maximize both maternal and fetal outcomes. Special care should be taken if the patient requires intubation. The pregnant patient's airway may be edematous. The gravid woman is at increased risk of aspiration secondary to delayed gastric emptying and decreased lower esophageal sphincter tone. In addition, gravidas have decreased oxygen reserves and may require early intubation to maximize oxygenation and ventilation; also, they may desaturate rapidly after paralysis (21). In later pregnancy, if a chest tube is necessary, it should be placed one to two rib spaces higher than usual, as the diaphragm will be elevated. This, along with palpation of the diaphragm with a finger during thoracostomy placement, will prevent inadvertent intra-abdominal placement of the tube.

After the 20th week of pregnancy, the trauma patient is at risk for the *supine hypotensive syndrome,* the result of uterine compression of the inferior vena cava by the gravid uterus, leading to decreased venous return to the heart. All pregnant trauma patients of 20 weeks or greater gestation who are supine should, therefore, be placed in 15 degrees of left lateral tilt to prevent this compression (10,11,20).

Aggressive early resuscitation is particularly important as gravid patients may not develop overt signs of hypovolemia until they are in the late stages of shock. Changes in uterine blood flow, which can lead to fetal distress, occur before maternal vital signs change. Crystalloid fluid replacement should be started, and blood administered as necessary. Vasopressor support should be avoided as pressors significantly decrease uterine blood flow and do not address the likely underlying cause of hypotension, namely hemorrhage. Hemodynamic instability secondary to dysrhythmias that are amenable to defibrillation or cardioversion should be treated as such without concern for fetal injury.

There are several unique situations that the emergency physician must consider in the gravid trauma patient. Pelvic fractures may be particularly dangerous during pregnancy. They may lead to increased blood loss from dilated pelvic veins. They also may lead to direct fetal injury, resulting in a high incidence of fetal morbidity and mortality. Medical antishock trousers have no role in the management of the gravid trauma patient.

Uterine injury is uncommon in the first trimester, as the bony pelvis protects the small gravid uterus. However, later in pregnancy minor uterine injury, such as contusion, is relatively common. This usually presents with uterine contractions, which resolve spontaneously in 90% of cases. Rarely, blunt abdominal trauma can cause uterine rupture, which can present with catastrophic blood loss and fetal demise (5,8). This may be diagnosed on physical examination by palpating a flattened uterus or fetal parts free in the abdominal cavity. Ultrasound can also be used to identify a traumatic uterine rupture.

Placental abruption, a premature separation of the placenta from the uterine wall, is common with blunt abdominal trauma and can cause fetal distress. It occurs in 1% to 3% of pregnant women with minor trauma and in 40% to 50% of pregnant women with major life-threatening trauma (6,8). Abruption may present with vaginal bleeding, abdominal pain and tenderness, uterine contractions, or fetal distress. However, it may be occult and, moreover, may be missed on ultrasound examination. The most sensitive test for the

evaluation of placental abruption is cardiotocographic monitoring to detect uterine irritability and fetal distress. Cesarean section may be necessary to save the fetus in severe cases of placental abruption.

Amniotic fluid embolism can occur with trauma and placental abruption. Debris and amniotic fluid become lodged in the maternal respiratory system, causing sudden dyspnea, hypoxia, and hypotension. These patients are also at risk for developing disseminated intravascular coagulation. Treatment of amniotic fluid embolism in patients is supportive, but the mortality rate unfortunately is high. Cardiopulmonary bypass has been used successfully to treat severe cases.

Fetal outcomes in pregnant patients with burns are directly related to the extent of the burn and the gestational age of the fetus. A burn of $<20\%$ total body surface area usually does not lead to pregnancy complications, but extensive burns may lead to fetal demise or premature labor (22). Conversely, maternal outcomes in the setting of burns are not affected by pregnancy.

The burn patient should also be assessed for carbon monoxide exposure. There is increased binding of carbon monoxide by fetal hemoglobin, resulting in increased carbon monoxide exposure to the fetus. All symptomatic patients or those with a carboxyhemoglobin level greater than 15% should be placed on 100% oxygen by mask and should be considered for hyperbaric oxygen therapy (23).

If the pregnant trauma patient arrests, the clinician should consider a perimortem cesarean section if there is a potentially viable fetus (≥ 23 weeks of gestation). As time is critical to the survival of the fetus, the procedure should be initiated promptly and should be performed by the most experienced physician available. Delivery within 5 minutes of maternal arrest leads to a higher rate of fetal survival with good neurologic outcome. Survival rapidly declines to 5% (usually with neurologic sequelae) if the procedure is not performed until 15 minutes after maternal arrest (24). Using a number 10 blade, a midline vertical incision should be made from the epigastrium to the pubic symphysis. Ideally, the clinician should make one incision that goes from the skin down to the uterus. The uterine incision is then performed vertically from the fundus to the

reflection of the bladder. The placenta is incised if necessary. The child is delivered and the cord clamped and cut. Neonatal resuscitation should be aggressive and should begin immediately. With delivery of the infant, maternal hemodynamics may actually improve because of increased venous return. It is thus important to continue maternal resuscitative efforts (airway management and CPR) during and after perimortem cesarean section.

CRITICAL INTERVENTIONS

- Resuscitate the mother adequately to resuscitate the fetus.
- Identify and treat early shock prior to development of abnormal vital signs.
- Position the patient in a 15-degree leftward tilt to prevent the *supine hypotensive syndrome*.
- Any pregnant trauma patient with a potentially viable fetus should be admitted for cardiotocographic monitoring for at least 6 hours, even when there are only minor injuries.
- Administer RhoGAM 300 μg intramuscularly (IM) to all Rh-negative patients.

DISPOSITION

Routine obstetric (OB) consultation in all pregnant trauma patients has been recommended by various organizations, although the evidence of improved outcomes with this intervention is lacking. Clearly, appropriate consultation is necessary for the best management of the pregnant trauma patient. Trauma surgery, OB and gynecology, and neonatology may be necessary for the multidisciplinary care of the pregnant trauma patient. The need for consultation is determined by the patient's potential injuries and the estimated gestational age of the fetus. At a minimum, pregnant trauma patients with a viable fetus ($\geq$20 weeks) should receive OB consultation and 6 hours of cardiotocographic monitoring (10). This includes gravid trauma patients with little or no evidence of maternal injury. If monitoring detects an abnormality (vaginal bleeding, abdominal pain, contractions, or fetal heart rate

abnormalities) during this initial observation period, the period of monitoring should be extended to 24 to 48 hours (6,10,25). Although the fetus is not viable until 23 weeks at the earliest, some sources recommend monitoring for all patients who are more than 20 weeks pregnant (9). This recommendation is based on the fact that some obstetricians will attempt tocolysis if there is evidence of premature labor in this group.

Prior to disposition, injury prevention issues must be addressed. The possibility of interpersonal violence or intentional injury cannot be overstated. Data suggest that there is a rise in the rate of domestic violence as the pregnancy progresses. The health care provider should also discuss appropriate seatbelt use prior to discharge. The lap belt should be worn low over the iliac crest, and the shoulder restraint should cross above the uterus. When indicated, the emergency physician must remember tetanus prophylaxis. Standard guidelines for tetanus prophylaxis should be followed. No adjustments are needed in pregnancy.

Common Pitfalls

- Inadequate early maternal resuscitation.
- Failure to perform cardiotocographic monitoring.
- Failure to perform necessary radiographs for fear of fetal complications.
- Failure to treat fetal–maternal hemorrhage in Rh-negative trauma patients.
- Delay in performing a perimortem cesarean section with maternal cardiopulmonary arrest.

CHAPTER 53

Trauma in Older Adults

Timothy F. Platts-Mills and Sasha D. Adams

The increase in the number of active and independent older US adults has led to an unfortunate corresponding increase in the proportion of older trauma patients (1). Common mechanisms of injury in older adults include falls, motor vehicle collisions, and recreational activities (2). Although geriatric patients currently account for 10% to 15% of all trauma in the United States, it has been projected that this will increase to nearly 40% by 2050 (3,4). This is important because injury patterns and physiologic responses to injury differ between older and younger adults. Further, older trauma victims consume more health care resources, account for more health care expenditures, and have worse outcomes after trauma than younger individuals (5).

Approximately 28% of all traumatic deaths in the United States occur in adults of age 65 or older, and trauma is the fifth leading cause of mortality among geriatric patients. The case-fatality rate for adults of age $\geq$65 ranges from 15% to 30% versus 4% to 8% for those $<$65 years of age (4,6). Though there is evidence to suggest that risk of poor outcome from trauma begins to rise as early as age 40, the risk of death clearly increases after age 65 (7). Despite the risk associated with trauma in older adults, it is important to recognize that survival can be improved through early, aggressive management (6).

CLINICAL PRESENTATION

Injury severity is an important factor in the outcome of older trauma patients. The extent of injury is determined in part by the causal mechanism, but, for similar events, the severity of injury tends to be greater for older than for younger individuals. For example, falls from height and pedestrian-struck incidents are three to four times more likely to result in death for older adults than younger adults and account for nearly 50% of trauma deaths in older adults (8,9). The disproportionate increase in severity among older patients is attributable to a combination of age-related anatomic and physiologic changes. Pre-existing medical conditions, present in approximately 40% of those of age 65 to 74; 65% of those of age 75 to 84; and 90% of those of age ≥85, compromise older adults' response to injury, as does polypharmacy (10).

Pathophysiology

Cardiovascular

Myocyte degeneration leads to a progressive loss of cardiac function with aging (decrement in cardiac index ~1% per year), which limits the ability of older individuals to maintain cardiac output in the presence of diminished filling pressure (10). This is further impaired by a decrease in the number and responsiveness of β-adrenergic receptors and fibrosis of the conduction system, which diminish the chronotropic and inotropic response to catecholamine stimulation. Coronary artery disease may exacerbate the situation by limiting oxygen delivery to the remaining functional myocardium, increasing the risk of ischemia and subsequent cardiac decompensation. Concurrent stiffening of peripheral vessels from atherosclerosis and a general increase in systemic vascular resistance (~1% per year) also occur. This works to preserve blood pressure despite a reduction in forward flow but also results in diminished compliance, which increases susceptibility to injury by shearing forces.

These changes and concurrent use of antihypertensive medications create a cardiovascular system that is less responsive to the drop in intravascular volume that can occur with trauma. Older patients often do not develop tachycardia in response to

hypovolemia, and those with hypertension at baseline may experience a substantial drop in blood pressure without meeting usual criteria for hypotension. As a result, abnormal vital signs are an insensitive indicator of life-threatening injury in older trauma patients, and triage systems should not rely solely on vital signs to identify high-risk patients (11).

Pulmonary

A decline in chest wall elasticity and lung compliance occurs with aging, leading to reductions in functional vital capacity and forced expiratory volume and an increase in residual volume (10). By limiting air movement, these alterations enhance the potential for carbon dioxide retention during periods of hypoventilation and barotrauma with positive-pressure ventilation. Because mucociliary clearance is also diminished, there is an increased risk of mucous plugging from secretions and pneumonia from bronchial obstruction. A progressive loss of alveoli is known to occur as well, which causes a decrease in diffusion capacity and arterial oxygen tension, manifesting as an age-dependent decline in the partial pressure of oxygen. Such changes are strongly potentiated by a history of smoking.

Injuries to the chest wall and lung can impair respiratory mechanics and dramatically increase the work of breathing. As such, they are not well tolerated in older adults. Older patients are particularly susceptible to rib fractures (estimated incidence, ~60%), which may occur even with minor force.

Renal

Renal function diminishes with advancing age due to a combination of progressive glomerular loss and decreases in renal blood flow. This results in a steady decline in glomerular filtration rate (GFR) and consequently, creatinine clearance. Serum creatinine concentration, however, does not accurately assess renal function, particularly in older individuals who have significantly reduced muscle mass. Direct measurement of creatinine clearance or estimation of GFR using validated formulae, therefore, is the preferred method for quantification of renal function in the older

trauma patient. In addition, these effects can be exacerbated by chronic diuretic use or suboptimal fluid intake with a resultant chronic hypovolemia.

Older patients are at high risk for deterioration in renal function even from brief periods of hypoperfusion. During the initial care of the injured older adult, the benefits of ensuring adequate renal blood flow by providing additional fluid must be balanced against the negative effects of aggressive fluid resuscitation, which may exacerbate uncontrolled hemorrhage, accelerate coagulopathy, and increase risk of pulmonary edema (12). Although urine output is considered a useful marker of renal perfusion in younger patients, it is less reliable in older individuals (13). This is due to a progressive reduction in urine concentrating ability, which permits ongoing production of seemingly adequate amounts of dilute urine even in the face of significant hypovolemia. Caution should also be exercised when using agents that have known nephrotoxic effects, particularly nonsteroidal anti-inflammatory medications and intravenous contrast agents.

Musculoskeletal

Osteoporosis is present to some degree in most older individuals, making them highly susceptible to fractures, and it is six times more prevalent in women than in men (14). The bones of the hip, wrist, and spine are at greatest risk and may be injured with minimal force. A seemingly straightforward fracture may result in substantial morbidity and risk of death in the older patient. Fractures often require operative fixation, subjecting the older patient to perioperative complications, whereas nonoperative therapy limits mobility and puts the patient at risk for skin breakdown, pulmonary embolus, and pneumonia. Pain medication, difficulty bearing weight, and mobility equipment devices may worsen balance, resulting in a high risk of falls and injury during the recovery period.

Dermatologic

Thinning of the epidermis, loss of dermal blood vessels, flattening of the dermal–epidermal junction, collagen degeneration, and loss of

subcutaneous tissue all occur with aging and increase the likelihood of damage when frictional or compressive forces are applied to the skin (10). These changes also slow wound healing, which increases the potential for infection and reduces the effectiveness of temperature autoregulation.

Neurologic

Progressive brain atrophy and dural adherence to the skull occur with aging. These changes lead to an increase in the subdural space surrounding the brain, and a stretching of the parasagittal bridging veins, making them more prone to rupture. As a result, older adults have a propensity for the development of subdural hematoma after head trauma; the rate is nearly two times that of younger patients (4.4% vs. 2.4%) (15). Because of brain volume loss, a substantial amount of blood can accumulate in the subdural space without producing a mass effect, leading to an increased risk of a delay between the time of injury and onset of symptoms. Cerebral contusions are also slightly more common in older than in younger adults. In contrast, epidural hematomas and depressed skull fractures are rarely seen (estimated prevalence of 0.5% and 0.2%, respectively) (10).

Mechanisms of Injury

Falls

Falls are responsible for the majority (~60%) of trauma in older adults. Falls in older adults often reflect underlying pathology or result from medication side effects. Falls commonly result in hip fractures, and an older adult with hip pain after a fall should be presumed to have a hip fracture. A negative plain radiograph does not exclude hip fracture, and computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained in patients for whom hip fracture is suspected but not seen on plain films.

Vehicle-Related Accidents

Automobile collisions and injuries of pedestrians are the second and third most common causes of trauma in older adults, respectively,

with the former accounting for an estimated 250,000 US ED visits each year (2). Though most older drivers modify their driving habits as they age (i.e., driving at slower speeds, driving shorter distances, and avoiding driving at night and in adverse weather conditions), older drivers have the highest rate of fatal collisions of any age group. Factors that contribute to vehicle crashes in older drivers include slower reaction times, decreased visual fields, sensory or cognitive deficits, distractions, and medications. Though older drivers are less likely to use drugs or alcohol than younger drivers, impaired driving may also be a factor.

Ambulatory limitations, gait disturbances, and sensory deficits (especially visual and auditory) place older adults at particular risk for being struck by an automobile. Older pedestrians who are struck are more likely to suffer injury, particularly of the head, chest, spine, pelvis, and tibia (9). Of those who survive the initial impact, in-hospital mortality exceeds 25%—nearly four times that of younger patients (9).

Burns

Thermal injuries in older adults are responsible for 13% of all burn unit admissions in the United States. Burns in the geriatric population are associated with extensive tissue damage and significant morbidity as many of these individuals do not have the reflexes, muscle strength, or motor coordination to move away from the source of heat until substantial injury has occurred. In addition, wound healing is slowed in older adults, increasing potential exposure to nosocomial infection and prolonging the time to recovery. Increased age is an independent risk factor for mortality after burn, and the sum of age in years and the percentage of body area burned can be used to estimate burn-related mortality (16).

Penetrating Trauma

Penetrating trauma is responsible for 5% to 10% of all traumatic events that occur in older adults versus 25% to 45% in younger adults (17). Though injuries are generally similar in location and severity to other age groups, firearm injuries in older adults are more likely to be self-inflicted, particularly if the individual is a

white male. Penetrating trauma in the geriatric population is associated with prolonged intensive care unit (ICU) and hospital stays.

Neglect or Abuse

Neglect or abuse is a pervasive problem among older adults (18). Risk factors for abuse include a shared living situation, social isolation from friends and relatives, physical impairments, dementia, and exposure to perpetrators with a history of mental illness or substance abuse. Because caretakers and victims may deny or minimize the extent of the problem, cases are often difficult to recognize. Warning signs for abuse and neglect include delays in seeking medical attention, inconsistent history between caregiver and patient, unexplained injuries (fractures or bruising), discrepancy between history and physical examination findings and diagnostic testing, severe malnutrition, and poor hygiene.

Common Injury Patterns

Head

Closed head injuries are common in older adults, and the head is the most common body area to be severely injured. The incidence of traumatic brain injury and intracranial hemorrhage is increased in those of age ≥ 65 who sustain closed head trauma (12.5% vs. 7.9% in the National Emergency X-Radiography Utilization Study [NEXUS] II), and outcomes are worse, particularly for those in whom the presenting Glasgow Coma Scale (GCS) is ≤ 8 (in-hospital mortality 53% to 76%) (19,20). Because $>75\%$ of these events are related to ground level falls, the history and initial examination can be falsely reassuring. Typical “low-risk” criteria (i.e., absence of loss of consciousness or a GCS of 15) do not exclude intracranial injury in older adults. Both of the large validated instruments designed to determine the need for head CT scan after minor trauma identify advanced age as a criterion for obtaining a head CT (21). Thus, liberal use of CT is recommended for older individuals with closed head trauma. This is particularly true for those on antiplatelet or anticoagulant medications. Patients on these medications with

evidence of intracranial hemorrhage require rapid and complete correction of their anticoagulation to prevent progression of brain injury (22).

Spine

The incidence of cervical spine injuries doubles in older adults, with a particular increase in the occurrence of C1 and C2 fractures (23). As with head trauma, the majority of cervical spine trauma in older adults results from ground level falls (23). Although the Canadian C-spine Rule includes age ≥ 65 as an independent "high-risk" criterion that mandates radiographic assessment for all older trauma patients, the NEXUS criteria do not include age and have been validated in a geriatric cohort (13).

Although spinal cord injury itself is rare, older adults are at increased risk for central cord syndrome owing to a high prevalence of underlying spondylosis and a greater likelihood of cervical hyperextension related to a fall. Classic findings of central cord syndrome include upper motor neuron weakness (arms > legs, distal > proximal) and variable sensory deficits. These patients are at risk for progression of symptoms and must be admitted and closely observed.

Fractures of the thoracic and lumbar spines are also relatively common and may be present in 40% of patients with identified injuries of the cervical spine. They often manifest as anterior wedge compression fractures, particularly in older females with underlying osteoporosis (14). Though neurologic complications are infrequent, such fractures can be a source of debilitating pain. Plain film radiographs or CT are usually sufficient for initial evaluation, but subsequent investigation using MRI or bone scanning may be required to identify occult fractures in those with persistent discomfort.

Chest and Abdomen

Pneumothorax, hemothorax, and pulmonary contusion should all be considered early in the evaluation of the older patient with thoracic trauma. Rib fractures in particular are a marker of more severe injury and are associated with a 19% increase in the risk of death.

Initial evaluation with a single-view chest radiograph is appropriate but may not delineate subtle rib injuries, underlying lung contusion, or small pneumothoraces. CT should be considered in those with a nondiagnostic chest x-ray and significant discomfort, physical examination findings, or respiratory difficulty.

Abdominal trauma in older adults results in injury patterns similar to those in younger patients. Prompt recognition of hemoperitoneum is critical as older individuals do not have the physiologic reserve to withstand large-volume blood loss. Though initial screening with ultrasound is reasonable, negative results should be interpreted with caution, particularly for those with significant abdominal pain. Patients with pain or tenderness should be further evaluated using CT.

Pelvis and Extremities

Fractures of the proximal femur and pelvis are common in older individuals and most often result from a ground level fall. Among pelvic fractures, lateral compression fractures predominate, and 75% involve injury to the pubic rami or acetabulum. As compared to younger patients, older patients with pelvic fractures experience complications such as hemorrhage more commonly, require angiography and ICU admission more frequently, and have an increased risk of death. Owing to trabecular bone thinning, falls that impact the hips and pelvis are more likely to result in injury to the femoral neck and greater trochanter than to the pelvic bones themselves. Falls with the upper extremity in extension may result in fracture to the distal radius or the proximal humerus.

DIFFERENTIAL DIAGNOSIS

Though the consequences of trauma in older adults often require immediate attention, it is essential to consider the precipitating event, particularly in patients with unwitnessed or poorly described falls or those involved in single vehicle collisions. Life-threatening medical conditions such as cerebral vascular accidents, transient ischemic attacks, myocardial infarctions, malignant cardiac dysrhythmias, and critical electrolyte abnormalities could have

precipitated the event and should be considered in all older trauma patients. Some individuals, particularly those who reside in assisted living facilities, may have advanced dementia or other neuropsychiatric conditions that preclude verbal communication. For these patients, discussion with primary caregivers and prehospital personnel regarding the circumstances of the event, pre-existing medical conditions, and baseline medications should be pursued. Involvement of a social worker or adult protective services is necessary if abuse or neglect is suspected.

ED EVALUATION

The initial evaluation and resuscitation of the older trauma patient closely parallels usual trauma protocols. Adequacy of airway protection and respiration should be assessed immediately. Older patients are prone to develop hypoxia, and supplemental oxygen should be administered upon presentation. To avoid precipitous decompensation, early intubation should be considered in those with significant thoracic injuries. For patients who require intubation, care must be taken to limit manipulation of the oropharynx and hyperextension of the neck. Broken dentures, if present, should be removed to prevent further injury, but intact dentures may facilitate bag-valve-mask ventilation and should be left in place until definitive airway control is achieved.

Early identification of hypoperfusion in the older trauma patient is also critical and should be assessed simultaneously with the assessment of airway and breathing. As noted earlier, usual indicators (i.e., heart rate >100 beats/min and systolic blood pressure <90 mm Hg) are insensitive markers of hypovolemia in older adults, and significant hypoperfusion may be present in patients without tachycardia and with systolic blood pressures of 90 to 130 mm Hg. Thus, for all patients with suspected intra-abdominal injury, a bedside focused assessment with sonography for trauma (FAST) should be completed to determine the presence of intra-abdominal hemorrhage and laboratories should be obtained to identify occult reductions in tissue oxygen delivery (24). Impaired

perfusion as indicated by a base deficit greater than 6 mEq/L or a lactic acid concentration $\geq$2.4 mmol/L correlates with greater trauma severity and mortality and is more sensitive than vital signs for identifying life-threatening injuries (15). Worsening of the base deficit or failure to clear lactic acid on serial measurement are particularly ominous signs and should be considered indicative of insufficient resuscitation or developing complications (i.e., blood loss or ischemia).

Advanced hemodynamic monitoring has been shown to be particularly beneficial in older trauma patients, reducing complications of hypoperfusion, including multiorgan system failure, and improving survival (6). Parameters such as cardiac output, systemic vascular resistance, and oxygen delivery and consumption can be measured, and targeted resuscitative efforts using crystalloid fluids, vasopressors, and inotropes can be initiated. Although pulmonary artery catheterization is the time-honored method, noninvasive technology such as thoracic bioimpedance and near-infrared spectroscopy can provide equally accurate data with lower risk and cost. Bedside cardiac ultrasound is a useful adjunct in differentiating volume deficiency versus cardiac dysfunction as causes of hypotension. Patients with low output and elevated preload can be rapidly evaluated for pericardial effusion, and a rough quantification of cardiac function can be determined (10).

Radiographic evaluation of the older trauma patient may need to be delayed if the patient is hemodynamically unstable. However, once the airway has been addressed and access obtained, it is usually possible to perform cross-sectional imaging simultaneously with resuscitation and monitoring. Most, if not all, patients with head trauma (regardless of mechanism or degree of injury) should undergo head CT, especially if they are taking anticoagulants or antiplatelet medications. Plain films have been the traditional method of radiographic assessment for potential cervical spine injury, but CT has emerged as the modality of choice for initial evaluation in those with high-risk mechanisms, altered mental status or intoxication, suspicious clinical findings, or anatomic variants likely to limit plain film interpretation. Head CT has the added

advantage that it can be performed concurrently with other CT scans. Patients with abnormalities on CT or a clinical suspicion of spinal cord injury despite a normal CT require MRI. Given the high prevalence of concomitant injuries, x-rays or CT of the entire spine should be obtained in individuals with cervical spine fractures, even in the absence of physical examination findings.

As previously noted, there should also be a low threshold for ordering CT to evaluate for potential thoracoabdominal injuries. Moreover, although plain films may be adequate for the evaluation of most musculoskeletal injury, further imaging with CT or MRI may be required in patients with negative x-rays but persistent pain. This is particularly important for hip fractures, which may be occult in up to 5% of cases. For patients with signs or symptoms suggestive of a life-threatening injury, the initial evaluation and treatment should be coordinated with a trauma surgeon-intensivist, preferably in a trauma center (25).

KEY TESTING

- With the exception of critically ill trauma patients, the ED evaluation of all trauma patients including older adults is focused on the exclusion of fractures and internal bleeding through the use of imaging.
- In contrast to younger adults, there are no validated criteria for identifying a subset of older adults with blunt head trauma who do not need CT scan. In older adults with loss of consciousness or visible signs of blunt trauma to the head, a head CT is appropriate.
- The NEXUS criteria have been validated in older adults and are a reasonable approach to determining the need for cervical spine imaging. A low-energy mechanism (e.g., ground level fall) does not exclude cervical spine fracture in older adults.
- Patients with either abdominal pain or tenderness should be evaluated with cross-sectional imaging.
- Trauma patients with chest pain that is obviously musculoskeletal (i.e., worse with movement and tender to

palpation) do not need an EKG or cardiac enzymes unless other indications for these tests are present.
- As in younger adults, no older adult trauma patients should be discharged until they have ambulated and had repeat vital signs which are similar to their usual vital signs over a reasonable period of observation, generally at least 3 hours.
- Older trauma patients taking anticoagulant therapy (e.g., Coumadin, direct thrombin inhibitors) should be admitted for observation or sent home only in the presence of a responsible party and given strict return precautions, even if all imaging tests are normal.

ED MANAGEMENT

Survival to hospital discharge with intact neurologic function may be achievable in more than half of severely injured older trauma patients. As such, the initial evaluation should proceed immediately with all therapeutic options open regardless of age. Treatment should involve optimization of perfusion using fluids preferentially, pressors and inotropes if necessary, and maximization of oxygen-carrying capacity using packed red cells for those with ongoing blood loss or a hemoglobin <8 g/dL. Other critical interventions include administration of vitamin K (10 mg IV), fresh-frozen plasma (4 units), or prothrombin complex concentrate (PCC) for those on anticoagulation with closed-head injury (12); use of broad-spectrum antibiotics for open fractures; and administration of opioid analgesics (with a low threshold for intubation) for patients with rib fractures. Adequate treatment of pain in older trauma patients reduces suffering and may also reduce both short- and long-term psychological distress associated with the event. Because elderly trauma patients are more than twice as likely to develop nosocomial infections and more than five times as likely to die as a result of trauma-related complications, it is also important to pay attention to preventive measures such as strict sterile technique during invasive procedures (e.g., central venous access or chest tube placement), and prevention of contrast-induced nephropathy by administering

the minimal amount of contrast needed and giving fluids to those receiving contrast.

Certain combinations of injuries and initial findings, such as severe thoracic or abdominal injury *and* moderate-to-severe (abbreviated injury scale ≥ 3) head injury, hypotension *and* evidence of profound shock (base deficit ≤ -12) are highly predictive of death. Under such circumstances, the decision to withdraw care in the ED may be reasonable but should be made in concert with the attending trauma surgeon, family members, and a palliative care or geriatric specialist, if available.

CRITICAL INTERVENTIONS

- Perform a comprehensive evaluation for ongoing bleeding using bedside ultrasound, serum markers (base deficit and lactic acid), and advanced hemodynamic monitoring (either invasive or noninvasive) with aggressive intervention for identified deficits.
- Use CT liberally for closed-head injury and possible cervical spine injury, particularly in patients with a history of anticoagulation.

DISPOSITION

The mechanism of injury, past medical history, and extent of current injuries should be considered when making disposition decisions. Because occult serious injury and subsequent clinical deterioration are well-recognized threats in older patients, most patients should be admitted for observation unless the mechanism is very minor. Patients with multiple comorbid conditions, limited capacity to follow through with important discharge instructions, or poor social support at home should be admitted. Patients with seemingly minor injuries, such as multiple rib fractures, require admission for observation and pain control, as they are at risk for complications. Appropriate social work consultation and home-safety evaluation should be arranged prior to discharge.

Common Pitfalls

- Assuming that a patient with normal vital signs is “stable.”

- Failure to recognize the potential significance of minor head trauma.
- Failure to evaluate for occult fractures (ribs and hip) in patients with persistent pain despite negative plain films.
- Failure to observe or hospitalize high-risk older patients with seemingly minor injuries.
- Failure to recognize abuse and neglect as the cause of injury.

SECTION V
Eye Emergencies

Section Editor: GREGORY W. HENDEY

Medical Foramen

CHAPTER 54 The Eye Examination

Matthew R. Babineau and Leon D. Sanchez

Ocular complaints comprise more than 3% of visits to the emergency department (ED) (1). The severity of these complaints vary from minor to vision threatening, and an emergency practitioner (EP) must be able to risk stratify these to ensure timely diagnosis and appropriate treatment. A thorough and accurate physical examination is therefore an essential skill of all emergency physicians.

ED EVALUATION

History

The history often provides enough information to allow the physician to focus on the appropriate segment of the visual system. Key historical points include age, trauma, current symptoms, ocular history, systemic illness, occupation, and allergies. The patient should be asked if they use corrective lenses (glasses or contact lenses). About 5% of nontraumatic eye complaints are the initial manifestation of systemic illness, so a review of systems should be conducted with special attention to cardiovascular and neurologic symptoms.

Pain and Discomfort

Pathology of the ocular surface or lids usually produces burning, itching, tearing, and foreign body sensation. Orbital or periorbital discomfort is usually described as a dull ache, and may be caused by pathology such as uveitis, episcleritis, scleritis, or acute glaucoma.

Peri- or retro-orbital pain may also be due to nonocular causes, such as sinus congestion, vascular or cluster headaches, or intracranial pathology (e.g., aneurysm, arteritis, infection, tumor). It is important to note that, because of sensory overflow from various segments of the fifth cranial nerve, it may be difficult to identify the source of pain by history alone.

Photophobia

Photophobia typically is due to painful contraction of an inflamed iris (as seen in iritis or uveitis), or from inadequate papillary constriction, resulting in excess light reaching the retina. Nonocular causes of photophobia include migraines and inflammation of the meninges (e.g., meningitis, subarachnoid hemorrhage).

Discharge and Tearing

Discharge is typically a by-product of inflammation of the ocular surface due to allergy or infection. Purulent discharge is suggestive of a bacterial infection. Epiphora (excess tearing) is typically due to emotion, irritation of the ocular surface (due to abrasions, infections, foreign bodies or chemical exposures), or abnormal drainage of tears through the lacrimal system (2).

Redness and Swelling

Redness and swelling of the sclera is most often due to inflammation caused by infections or allergies, though it can rarely be a sign of orbital venous congestion, as can be seen with orbital cellulitis, cavernous venous sinus thrombosis, thyroid ophthalmopathy, and fistulae. Intraocular inflammation will typically cause redness (especially in the perilimbal region), but swelling is rare (endophthalmitis, some cases of scleritis).

Visual Disturbances

Visual disturbances can be a symptom of pathology in the visual system anywhere from the cornea to occipital cortex, and are often related to a nonocular cause. “Blurred vision” may be a catchall term

used by patients to describe a number of different visual abnormalities, and the clinician must attempt to specify the exact nature of the disturbance. Glare or halos are caused by light scatter phenomena from unclear ocular media, as in mucinous tear film, corneal edema or epithelial abnormalities, cataract, and/or vitreous haze. Spots or floaters are often due to opacities within the vitreous. Vision loss should be classified as monocular (indicating pathology of the anterior visual pathway and circulation) versus binocular (indicating pathology of the neurovascular system posterior to the optic chiasm).

Diplopia

Diplopia may be caused by serious underlying disease (see Chapter 59). Monocular diplopia is rare and is caused by pathology within the cornea or lens. Binocular diplopia is caused by ocular motility disturbances, such as cranial nerve palsies or extraocular muscle disorders (e.g., entrapment following trauma).

THE OCULAR EXAMINATION

A systemic approach to the ocular examination will facilitate accurate diagnosis and exclusion of vision threatening pathology. The ocular examination can be divided into eight components

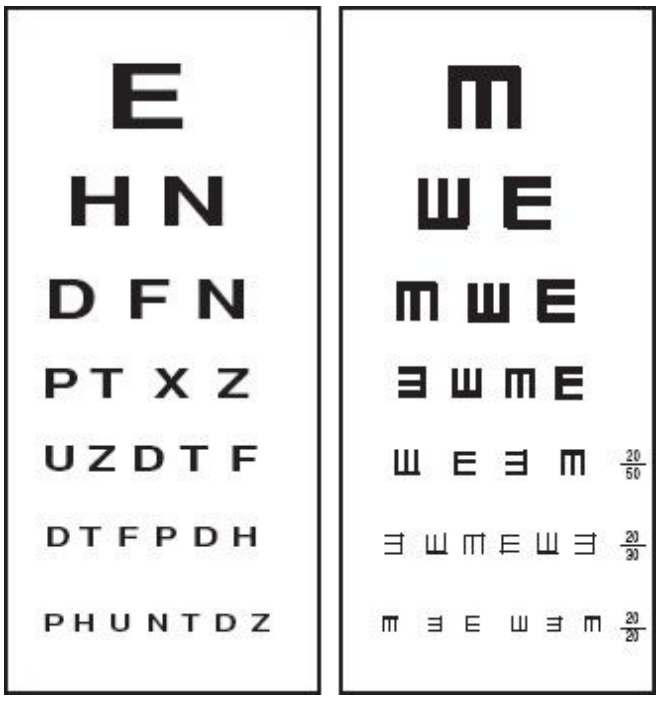
1. Visual acuity
2. Face and external eye
3. Extraocular muscles
4. Visual fields
5. Pupils
6. Anterior segments
7. Posterior segments
8. Intraocular pressure (IOP) measurement

VISUAL ACUITY

Visual acuity is the “vital sign of the eye” (3). There are various methods to measure visual acuity. Regardless of the method chosen, it is essential to measure each eye individually, with the other eye

completely covered, as patients may look around hands or through fingers. If corrective lenses are available, vision should be tested with these. The acuity of each eye should be documented individually (even if they are the same), and the presence or absence of corrective lenses should be documented as well.

The Snellen chart is the standard tool used to measure visual acuity (3) (eFig. 54.1). The patient is asked to read the smallest line that they can see (4). Visual acuity is expressed as a fraction, where the numerator is the distance of the patient from the chart, and the denominator is the distance at which a patient with normal vision can read the line of letters (2). For example, a visual acuity of 20/50 indicates that a patient can see from 20 feet that which someone with normal vision can read at 50 feet. A "near chart" held at 14 in from patient can replace a Snellen chart for patients who are unable to stand, and the visual acuity is recorded in the same fashion (3). The exception is that near-vision abnormalities can also be due to normal age-related presbyopia, or rarely, traumatic mydriasis (4).



eFIGURE 54.1 Snellen and tumbling E charts. The tumbling E chart can be used to test visual acuity in children or illiterate patients, by asking the patient to indicate which direction the E is "pointing."

(From Weber J RN and Kelley J RN. *Health Assessment in Nursing*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

If the visual acuity is not normal, the EP can test the patient using a pinhole card. A pinhole card will correct most refractive errors, so improved vision indicates an optical problem that can be addressed on a nonemergent basis (3). A pinhole card can be easily constructed by punching several holes in the center of a 3- × 5-in index card with an 18-g needle (4). Alternatively, the patient can be asked to view a near chart through the handheld ophthalmoscope, and progressively change the dial until vision is clearest. This will simulate use of corrective lenses (5).

If the patient cannot read the largest letter of the Snellen chart, he should be moved closer to the chart in 5-foot increments, until he can read it. If unable to read the chart at 5 feet, the patient should be asked to count fingers (CF) at 2 feet. If still unable to see, test whether the patient can detect hand motion (HM). If this fails, the patient should be tested for light perception (LP). If they are able to detect light, they should be asked to indicate which direction the light is coming from (this is called “LP with projection”). If there is no light perception (NLP), the patient is considered to be totally blind (6).

If a patient is unable to communicate, or is suspected of factitious blindness or malingering, the practitioner can ensure that the visual pathway is intact by checking for optokinetic nystagmus (4). To perform this test, an object such as newsprint or a tape measure is placed in front of the patient’s eyes, and the patient is asked to fixate on it as it rapidly passes from side to side in front of a patient. If the visual pathway is intact, the EP will note nystagmus-like eye movements which demonstrate that the patient is tracking (4). A variation can be performed using a large mirror held in front of the patient, and slowly moving it to either side of the patient. A patient with intact visual pathway will maintain some degree of eye contact as the mirror moves (4).

Face and External Eye

Obvious abnormalities (trauma, foreign bodies, edema, swelling, erythema) should be noted. The relative positions of the eye within the orbit should be evaluated by gross inspection. Unilateral proptosis may be due to trauma, orbital cellulitis or hemorrhage, cavernous sinus thrombosis, or other causes (6). Bilateral exophthalmos is most often due to hyperthyroidism (2,6). Enophthalmos is often due to an orbital fracture, and may be associated with other findings such as subconjunctival hemorrhage, restriction of upward gaze or hypoesthesia of cheek due to infraorbital nerve injury (2,6). Ex- or enophthalmos may be best appreciated by looking down at the patient's eyes from above their head (3). Proptosis should be differentiated from keratoconus, where the cornea is cone shaped and may give the illusion of exophthalmos (3).

The EP should note the relative positions of the lids, and the size of the palpebral fissure (the space between the upper lid and lower lid). While ptosis can be present from birth, acquired ptosis is often due to Horner syndrome, isolated CN III palsy, or trauma (2,6). It may also be an early sign of myasthenia gravis. In myasthenia, the EP can attempt to provoke the ptosis by asking the patient to look up for several minutes, to fatigue the palpebral muscles (2). Inability to close the lid may be due to a dysfunction of CN VII (i.e., in Bell palsy).

EXTRAOCULAR MOTILITY

Extraocular motility (EOM) should be tested in the six cardinal directions of gaze (right, left, up and right, up and left, down and left, down and right). It is especially important to assess in cases of trauma, suspected infection, or double vision (3). Each eye should be evaluated separately. Extraocular movements require complex coordination between the brain, cranial nerves III, IV, and VI as well as the four extraocular muscles, so abnormalities of gaze may represent pathology in any of these areas. If no deficits are obvious to the EP, the patient should be asked if they experience diplopia

with any movements, and if it is present only when both eyes are open, or only when looking through one eye. Binocular diplopia may be due to orbital infection/tumor/inflammation, nerve compression, or aneurysm in the circle of Willis (3). Monocular diplopia is due to ocular pathology (cornea, iris, lens, or retina) within that individual eye (3).

Nystagmus may be noted during testing of extraocular movements. The two broad types of nystagmus are "jerk nystagmus" (where the eye repetitively drifts slowly in one direction [slow phase], then rapidly returns to normal position [fast phase]) and "pendular nystagmus" (drift occurs slowly and equally in both directions, giving smooth back and forth movement of the eyes) (7). Nystagmus should be described in terms of type (jerk versus pendular), which extraocular motions provoke it (and/or if it is present in primary gaze), the direction of the nystagmus (lateral, vertical, torsional/rotatory), and whether it is extinguishable/fatigable.

Normal individuals may demonstrate a fatigable lateral jerk nystagmus with extremes of gaze (end-point nystagmus), or when fixating on stationary objects while moving (optokinetic nystagmus). Pathologic etiologies of nystagmus are usually due to CNS (thalamic hemorrhage, tumor, stroke, trauma, MS) or toxic/metabolic etiologies (including alcohol, lithium, barbiturates, phenytoin, salicylates, phencyclidine, Wernicke encephalopathy) (7).

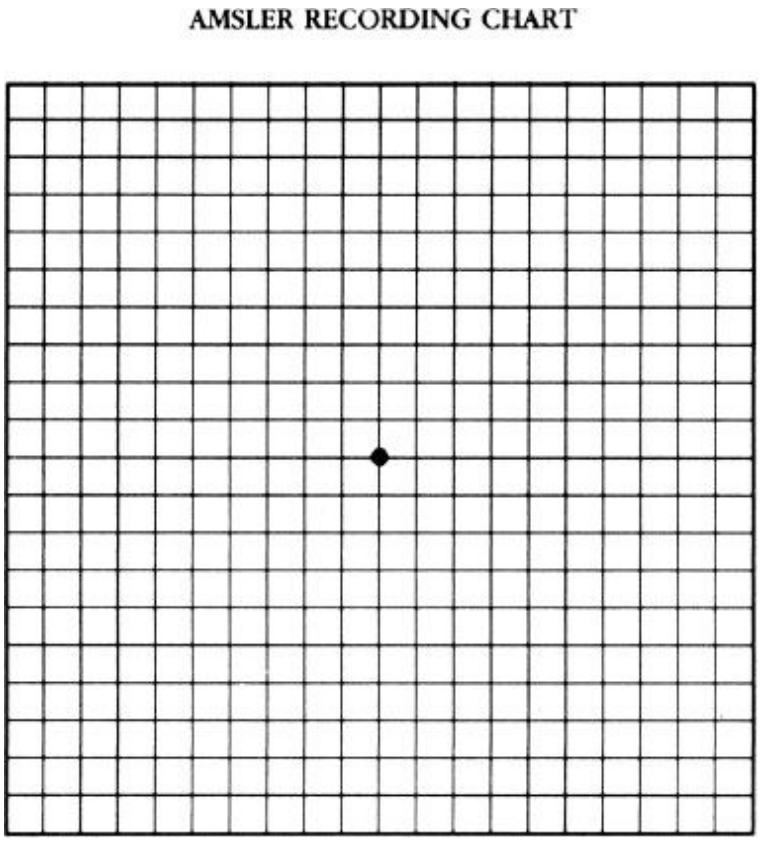
VISUAL FIELDS

The visual fields extend in each eye to 170 degrees horizontally, and 130 degrees vertically (2). Testing of the visual fields is an important test of the global visual path from eyes to occipital cortex. A monocular field deficit suggests ocular pathology, while deficits present in both eyes are often due to an intracerebral process. While formal perimetry is the most accurate way to assess visual fields, it is not practical in the ED, so EPs can test visual fields by confrontation field or the Amsler grid.

To perform confrontation field testing, the examiner faces the patient, and asks the patient to close one eye. The examiner closes the ipsilateral eye, and slowly moves a target (typically fingers) into

the visual field from a 45-degree angle. The object should be seen more or less simultaneously by the patient and the examiner. After testing in several areas, the process is repeated on the other eye. Any field deficit should be noted and documented (2).

To test the central 10 to 20 degrees of vision (the macula), an Amsler grid is used (eFig. 54.2). Using one eye at a time, the patient is asked to fixate on the central dot, and describe any wavy lines (metamorphopsia) or blind spots (scotoma). Abnormalities of Amsler grid testing typically indicate retinal pathology.



eFIGURE 54.2 Amsler grid. (From Harwood-Nuss A, Wolfson AB, et al. *The Clinical Practice of Emergency Medicine*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

PUPILS

The clinician should note the size, shape, and symmetry of the pupils. Normal pupils are typically 3 to 5 mm in diameter. Pupillary constriction is mediated by parasympathetic tone, and pupillary

dilation is mediated by sympathetic tone. Myriad disease processes, medications, and toxins can cause pupils to be abnormally small (miosis) or large (mydriasis) (Table 54.1). Unequal pupils (anisocoria) are often thought of as pathologic, however, 20% of normal individuals (2,6,8) may have a physiologic difference of 1 mm or less (essential anisocoria). Pathologic anisocoria can be due to Horner syndrome, uveitis, trauma, uncal herniation, CN III palsy, or due to drugs (including nebulized ipatropium) (6).

TABLE 54.1
Causes of Miosis and Mydriasis

Miotic Pupils		Mydriatic Pupils	
⇑ cholinergic	Pilocarpine drops, opiates	⇓ cholinergic	Atropine, CN III paralysis, Adie's Pupil, Antihistamines
⇓ Sympathetic	Horner syndrome, Aldomet, Reserpine	⇑ sympathetic	Phenylephrine, epinephrine, anxiety, cocaine, decongestants
Irritation to constrictor muscle	Iritis, histamine release from inflammation	Damaged constrictor muscle	High IOP (>40 mm Hg), trauma (especially with hyphema)

Data from Leitman MW. Manual for Eye Examination and Diagnosis. Wiley; 2011: 14 April 2013 <http://lib.myilibrary.com?ID = 345400>.

After noting the pupillary size, the pupillary light reflex should be tested, by shining a bright light into each pupil. The speed and degree of pupillary constriction should be observed in both the pupil receiving the light (direct response), and simultaneously in the other eye (consensual response). The light should then be swung between the two eyes (the swinging flashlight test), allowing the midbrain to sample the intensity of input from each eye, with the direct and consensual response noted. A pupil that dilates as the light is swung to it is referred to as relative afferent pupillary defect (or Marcus Gunn pupil) (6). This indicates a problem in the neuroretinal path of the affected eye, such as occurs in optic neuritis or a large retinal detachment (9). Other pupillary syndromes are found in Table 54.2. It should be noted that neuromuscular blocking agents do not acutely affect the pupillary light reflex, though some induction agents (e.g., ketamine) may depress this reflex (10,11).

TABLE 54.2
Pupillary Syndromes and their Physical Findings

Name	Physical Findings	Comments
Horner syndrome	Miotic pupil on affected side, may be accentuated in dim illumination	Due to lesion in sympathetic pathway (V). Unlike physiologic anisocoria, will not dilate in response to topical cocaine. + Anisocoria
Adie's tonic Pupil	Tonically dilated pupil with reduced direct and consensual light response. Reacts to accommodation, though slowly.	Due to a benign defect in the ciliary ganglion (parasympathetic innervation of eye), often due to infection. + Anisocoria.
Argyll Robertson pupil	Bilateral small pupils that constrict with accommodation but not with light ("light-near dissociation")	Highly specific for neurosyphilis. No anisocoria.
Marcus Gunn pupil	Affected pupil appears to dilate when swinging light shines in it.	In total CN II lesion (affected eye perceives no light), there is no effect. No anisocoria.

Anterior Segments

The anterior segments of the eye (conjunctiva, cornea, anterior chamber, iris, and lens) and the adnexa (eyelids, eyelashes, and lacrimal apparatus) are best evaluated using the slit lamp. While models vary, each slit lamp will have an illumination system and an observation system. The illumination system projects light through a slit aperture onto the patient's eye. The observation system is a binocular stereoscope which can provides 6 to 40× magnification. The observation system is mounted on a chassis that can be moved to allow the examiner to focus on the desired part of the eye.

To perform the examination, the patient's chin is placed on the chin rest, and the forehead against the forehead bar. The chin rest is adjusted so that the patient's eyes are aligned with the black line on the vertical pole next to the patient's face. The light source should be at 45 degrees from the clinician–patient axis, and the light should be set to a low-voltage, wide beam. The microscope should initially be set to the lowest magnification. The chassis is moved with the joystick until the eye comes into focus. Most of the examination can be performed using the low magnification, wide beam setting (4). Only when the cornea and anterior chamber are being examined must the beam be narrowed. The clinician may then begin a systematic evaluation of the anterior chamber. While any system may work, an easy to recall system is "L3C3." (Lids [and lashes], Lacrima, Lens [and iris], Conjunctiva [and sclera], Cornea, and Chamber [anterior]).

Lids and Lashes

Eyelids are evaluated for edema, erythema, trauma, and tenderness. Hordeolum (sty) is acute inflammation or infection of the glands of Zeis or Moll, around the lashes, that will point externally (Fig. 54.1A,B) (2). Chalazion is a chronic (may last for months) obstruction and inflammation of a meibomian gland, appearing as a mildly tender nodule along lid margins or on the palpebral conjunctiva, that will point internally (Fig. 54.1A,B) (12). These may not have typical signs of infection such as redness and swelling, and are often incidentally discovered (12). Diffuse erythema and edema of the lid may indicate a periorbital/preseptal cellulitis, which may be associated with adenopathy and fever (2). Orbital cellulitis may have a similar external appearance, but is often associated with ophthalmoplegia, pain with extraocular movements, and exophthalmos. In a patient who is being treated with antibiotics for lid cellulitis, shriveled skin on the lid may be an indication that the infection is responding to therapy (2).

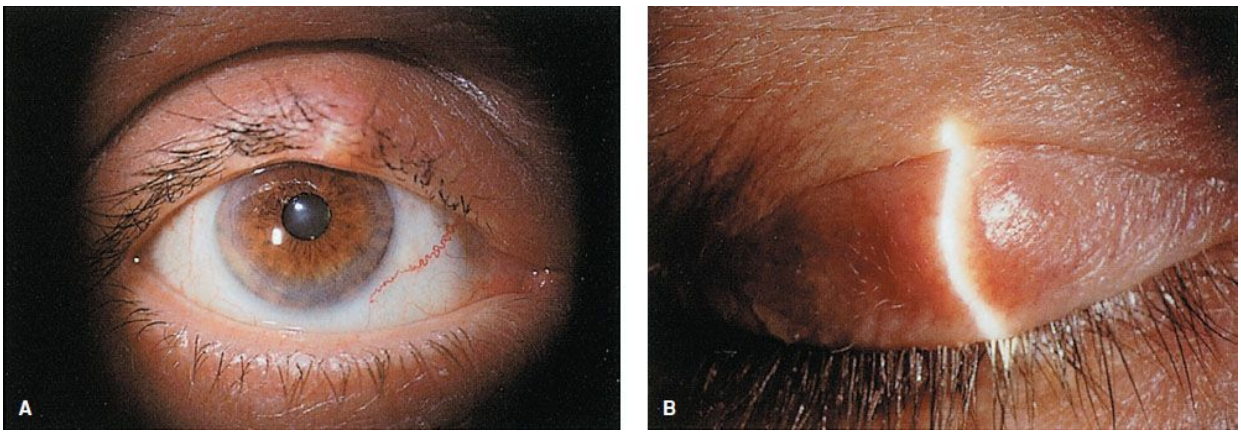


FIGURE 54.1 A: Hordeolum. (From Bickley LS. *Bates' Guide to Physical Examination and History Taking.* 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:178.) B: Chalazion. (From Bickley LS. *Bates' Guide to Physical Examination and History Taking.* 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:178.)

Blepharitis (anterior or posterior) is inflammation or infection of the lid margin, and also can manifest as an erythematous, edematous, pruritic eyelid (Fig. 54.2A,B). Anterior blepharitis is

often associated with scalp dandruff, and manifests as crusting, scaling redness, and ulcerative lesions around the eyelashes. Posterior blepharitis is secondary to obstruction and infection of meibomian glands, which are in contact with the surface of the eye. Expressing a white, pasty secretion from the meibomian glands is diagnostic of posterior blepharitis.

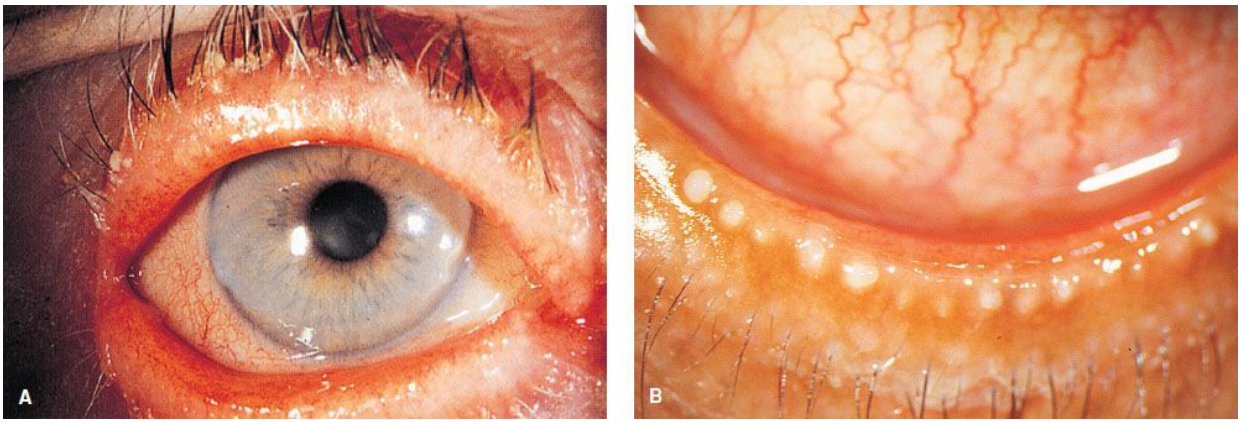

FIGURE 54.2 A: Anterior blepharitis. (From Tasman W, Jaeger E. *The Wills Eye Hospital Atlas of Clinical Ophthalmology*. 2nd ed. Lippincott Williams & Wilkins, 2001.) B: Posterior blepharitis. (From Tasman W, Jaeger E. *The Wills Eye Hospital Atlas of Clinical Ophthalmology*. 2nd ed. Lippincott Williams & Wilkins; 2001.)

Traumatic lacerations that violate the tarsal plate or the lid margin (especially if near the nasal canthus, where there is risk of injury to the lacrimal duct) should be referred emergently to ophthalmology for repair.

To examine the conjunctival surfaces of the superior eyelid, or to look for a foreign body, the lid should be everted. To do this, the patient is asked to look downward. The examiner then grasps the eye lashes at the lid margin, and uses a cotton-tipped applicator applied to the midportion of the upper lid as a fulcrum to evert the eyelid. The patient can look upward to return the eye to a normal position (2,3).

Lacrima

Excess tearing (epiphora) is common and should be noted. Diagnosis of lacrimal obstruction may be made by instilling fluorescein dye into the tear wells of each eye—in the obstructed eye, the fluorescein will dissipate more slowly, or run over the lid onto the cheek.

The lacrimal system can also become infected. Canaliculitis typically involves the lower canaliculi, and a red, "pouting" punctum is visualized (Fig. 54.3A,B) (7). Acute dacryocystitis presents as rapid onset of pain, erythema, edema, and purulent discharge in the medial canthal region (Fig. 54.3A,B). It may coexist with signs of sinusitis, and may progress to orbital or preseptal cellulitis (7). Chronic dacryocystitis typically is less dramatic, and may only be noted by expression of mucopurulent discharge with palpation of the nasolacrimal sac.

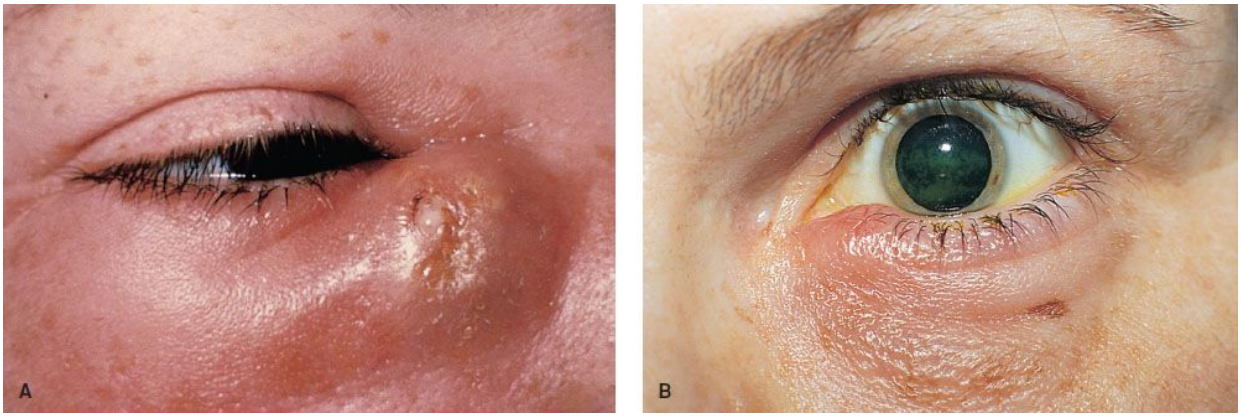

FIGURE 54.3 **A:** Acute dacryocystitis with draining fistula. (From Gold DH, MD, and Weingeist TA, MD, PhD. *Color Atlas of the Eye in Systemic Disease.* Baltimore: Lippincott Williams & Wilkins;2001.) B: Canaliculitis. (From Tasman W, Jaeger E. *The Wills Eye Hospital Atlas of Clinical Ophthalmology.* 2nd ed. Lippincott Williams & Wilkins; 2001.)

Lens (and Iris)

The lens can be rapidly visualized for evidence of cataracts (opacification), as well as traumatic lens displacement. Any potential trauma to the lens capsule must be noted, as the lens may rapidly opacify, necessitating prompt surgical correction. Corneoscleral lacerations can often be noted as the pupil becomes tear shaped as

the iris plugs the laceration (Fig. 54.4). Iridodialysis refers to tearing of the iris from the sclera at its root, and may also result from trauma. Blood vessels growing on the surface of the iris (rubeosis iridis) are abnormal, and associated with proliferative retinopathies.

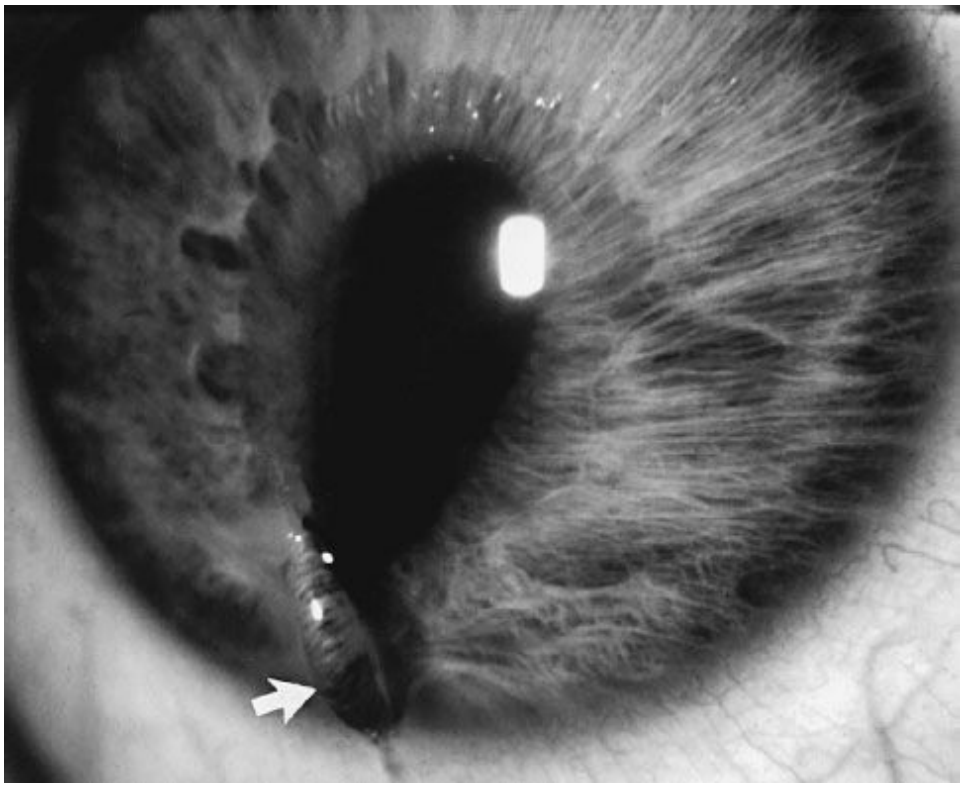

FIGURE 54.4 Tear drop pupil from corneal laceration, with iris protruding through wound (arrow). The pupil points in the direction of the laceration. (From Fleisher GR. *Textbook of Pediatric Emergency Medicine.* 5th Ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Conjunctiva (and Sclera)

The conjunctiva is a mucous membrane that covers the sclera (bulbar conjunctiva) as well as the inner surface of the lids (palpebral conjunctiva) (2). Conjunctivitis typically manifests as diffuse injection of the conjunctiva. Follicles (tiny, white lymphoid elevations of the conjunctiva) and papillae (vascularized elevations of the palpebral conjunctiva which resemble cobblestones) are commonly seen (Fig. 54.5) (13). Allergic conjunctivitis typically

shows bilateral symmetric injection, possibly associated with clear, watery discharge and slight lid swelling (14). Viral conjunctivitis is also typically bilateral, and may be associated with follicles as well as preauricular lymphadenopathy (13). Bacterial conjunctivitis typically has an abrupt onset of initially unilateral injection that is diffuse but may be more pronounced at the fornices (14). It is often associated with mucopurulent discharge with morning crusting, and will often progress to the other eye within 48 hours (14,15).

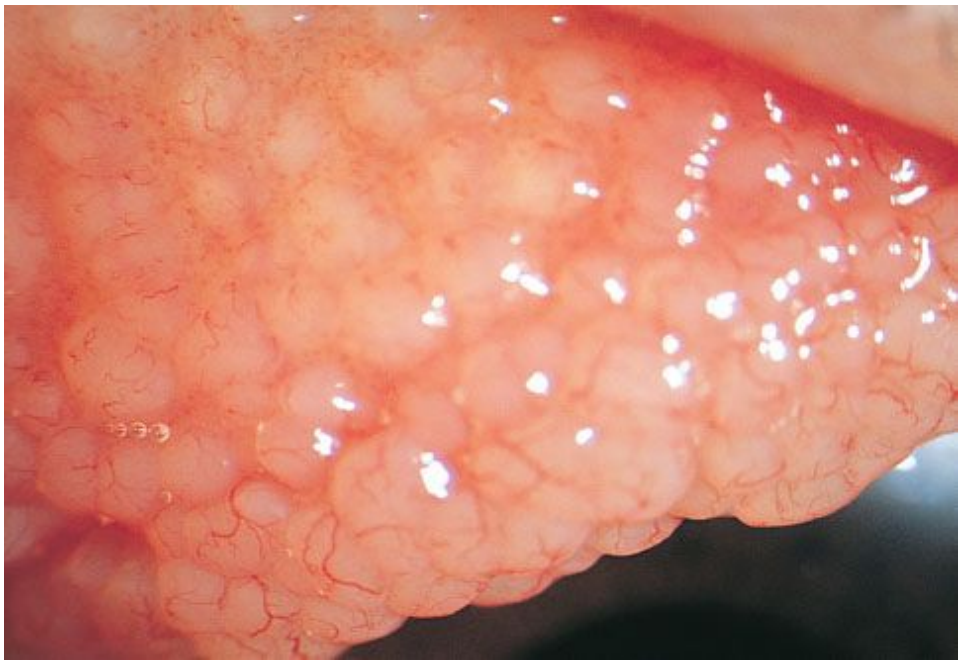

FIGURE 54.5 Follicles = may be seen in conjunctivitis. (From Tasman W, Jaeger E. *The Wills Eye Hospital Atlas of Clinical Ophthalmology*. 2nd ed. Lippincott Williams & Wilkins; 2001.)

The limbus is the area surrounding the iris, where the cornea connects to the sclera. In the patient with complaints of eye pain or redness, this area deserves special attention from the examiner. The presence or absence of injection (prominence of blood vessels) at this site can help differentiate inflammation from the conjunctiva (typically diffuse), to more serious problems such as iritis/uveitis (more prominent in the perilimbal area).

Other conjunctival findings include subconjunctival hemorrhage, which appears as a painless bright red area on the sclera, and is often

spontaneous or after Valsalva maneuvers such as coughing or straining (4). While typically benign and self-limited, severe hemorrhages covering the entire bulbar conjunctiva may signify coagulopathy or ruptured globe. Chemosis refers to edema of the conjunctiva, and is most often due to allergy, but may also be secondary to orbital venous congestion (from infection or tumor). Pterygium is a triangular growth of vascularized conjunctiva that extends to nasal aspect of cornea. It is common in patients who are chronically exposed to wind or ultraviolet light (2). A pinguecula is a common benign elevation of the conjunctiva, which can become red with allergies (2). Both can be referred for excision if they affect vision or are cosmetically bothersome.

Cornea

The cornea is the transparent anterior continuation of the sclera. It contains three layers—a superficial epithelial surface, a central stroma, and a deep endothelial layer. Corneal epithelial cells regenerate rapidly and 40% of the corneal surface can regenerate within 24 hours (2). The central stroma is a connective tissue layer with a dense collection of nerve fibers, thus explaining why corneal pathology may be extremely painful. The deep endothelial layer is responsible for pumping fluid out of the stroma and maintaining clarity of the cornea. It is only one-cell thick and cannot regenerate.

The three layers of the cornea should be visualized under the magnification of the slit lamp. With the lamp offset at 45 degrees, the practitioner should scan back and forth for any abnormalities. Foreign bodies will be obvious. Epithelial edema (translucent) and ulcers (opaque) will appear as irregularities in the contour of the cornea.

Fluorescein examination should be performed in any case of suspected abrasions, foreign bodies, or infections, and it helps to delineate the extent and often, etiology, of corneal injuries (4). The fluorescein should be instilled into the tear well, and the light source changed to cobalt blue. Defects in the corneal surface will appear bright yellow-green (6). The pattern of fluorescein uptake should be noted, as many etiologies of corneal pathology have specific

associated patterns. Circular defects often are due to foreign bodies. Abrasions are typically in the central cornea due to the limited protection from eyelids (4). Multiple vertical defects should prompt close inspection for retained foreign body under the upper lid. Herpetic lesions are classically dendritic in appearance (4). In traumatic ocular injuries, a dark blue-green stream of fluid within a bright yellow-orange area of fluorescein uptake represents leakage of aqueous humor through a corneal defect, and is known as Seidel sign (4,9).

After examining the corneal epithelium, the EP can examine the stromal layer for edema (cloudy appearance), deep ulcerations, and vascularized tissue. An advanced practitioner may also examine the single-cell width endothelial layer, and visualize keratic precipitates (white cells along the endothelium), which is highly specific for uveitis, but may only be seen with chronic inflammation (2).

Chamber (Anterior)

The anterior chamber is the aqueous-filled area between the cornea and the iris. Examination of the anterior chamber should include an evaluation of the depth of the chamber, as well as an assessment for abnormal cells within the aqueous humor.

To assess the depth of the anterior chamber, the slit lamp should be used with low magnification and the narrowest possible beamwidth, and focused on the corneal surface. Two beams will be visible on this view–-a curved beam (reflecting off the cornea) and a straight beam (reflecting off of the iris). The anterior chamber depth is the area between the two. Shallow chambers are pathologic, and may be due to acute–angle-closure glaucoma or corneal perforation (4).

A crude estimate of anterior chamber depth can be approximated with the transillumination test. To perform this test, a penlight is shone across the cornea from the temporal side, perpendicular to the line of vision. If the entire cornea illuminates, this suggests a deep anterior chamber (open angle). Shadowing of the iris on the nasal side implies a shallow anterior chamber (narrow angle) (6). It is

essential to ensure that the light is perpendicular to the line of vision, as oblique angles can give false-negative results (4).

While hyphema and hypopyon can often be seen with the naked eye, more subtle findings such as cells (white blood cells in the aqueous) and flare (cloudy/milky light scatter due to increased proteinaceous material within the aqueous) may only be visualized using the slit lamp magnification (6). These may be seen in uveitis, scleritis, or trauma. First, increase the magnification of the microscope, and make the beam as narrow as possible. Focus the beam on the cornea, and then push forward until it is focused on the lens (4). To illuminate the anterior chamber, move the light backward to a point where the beam is focused on an area midway between the cornea and the lens (4). Visualization will be improved by keeping the light centered on the pupil, to maintain a black background (4). The anterior chamber should be completely clear. Cells are seen as small particles floating within the beam, and flare looks like a "searchlight in the fog" or a "motion projector beam in a smoky room" (3,4). It should be noted that fluorescein can penetrate an abraded cornea and produce a "fluorescein flare" (4). For this reason, some practitioners recommend examining the anterior chamber prior to fluorescein staining.

Posterior Segments

The examination of the retina is another important part of the ocular examination, particularly in cases of vision loss (3). The lights of the examination room should be lowered to facilitate pupil dilation, and the patient asked to fix gaze on a distant object. The dial on the ophthalmoscope should be initially set to zero. The examiner brings the ophthalmoscope as close as possible to the patient's eye (examiner should examine patients right eye with her right eye, and vice versa), and adjusts the dial to bring the retina into focus. Impaired views of the fundus may be due to cloudy media, as can occur with hyphema, vitreous hemorrhage, cataracts, or corneal opacification.

The optic disc should be a pink-orange hue with sharp margins, and size of the cup (the pallid area within the disc) should be noted

(Fig. 54.6A). Conditions such as glaucoma will cause optic disk pallor, and increased cup:disc ratio (normal is less than one-third) (2). Papilledema can be a sign of increased intracranial pressure, and manifests as a swollen, elevated disc with blurred margins (Fig. 54.6B) (16). Absence of normal retinal venous pulsations is also seen with increased intracranial pressures (16).

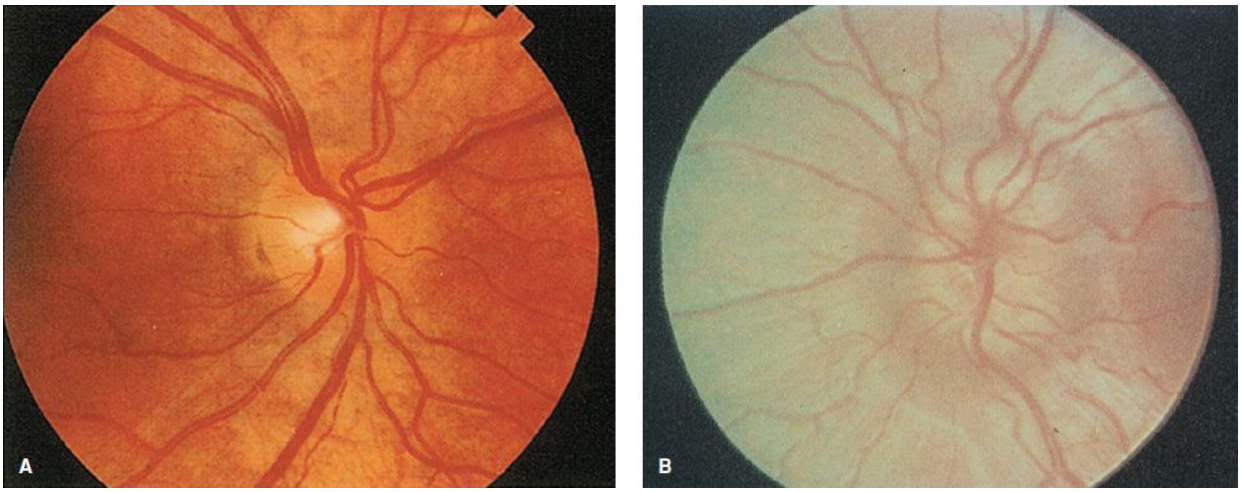

FIGURE 54.6 A: Normal optic disc. (Source of photo: Tasman W, Jaeger E (eds): *The Wills Eye Hospital Atlas of Clinical Ophthalmology*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.) B: Severe papilledema with blurred disc margins. (From Campbell WW (ed.). *DeJong's The Neurological Examination.* 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

The remainder of the retina can be evaluated for findings associated with other pathologies. Central retinal artery occlusion can classically be noted as a pale, ischemic retina with a red macula ("cherry red spot"), though this is a late finding (17). Central retinal vein occlusion may have retinal hemorrhages ("blood and thunder"), dilated and tortuous retinal veins, papilledema, and "cotton-wool" spots (small areas of yellow-white discoloration which indicate local retinal ischemia) (17). Retinal detachment often requires indirect ophthalmoscopy to visualize, although a central detachment may be evident by a white billowing retinal separation or an abnormal red reflex (17).

Intraocular Pressure Measurement

Tonometry is the determination of IOP. The main indications are to confirm a clinical diagnosis of acute–angle-closure glaucoma, and to determine a baseline IOP after a blunt eye injury (4). It should be avoided in suspected or confirmed penetrating eye injuries, as the pressure can worsen the defect and lead to extrusion of intraocular contents (18). Relative contraindications include eye infection (unless using a sterile cover) and patients with known corneal defects (4,19). Note that tonometry can rarely cause corneal abrasions (18).

Normal IOP is 10 to 21 mm Hg. IOPs greater than 30 mm Hg, especially in the context of abnormal optic disks or with visual field defects, should mandate immediate initiation of therapy for glaucoma and emergent consultation with ophthalmology (18).

There are many methods of tonometry used in the ED (Table 54.3). A complete discussion of the various modalities is beyond the scope of this chapter, but the practitioner should be familiar with the use of the instruments available to them. A simple, but insensitive, screening method is direct palpation of the globe (20). As the patient looks clinician's index finger is used to gently palpate the globe through the eyelid, with just enough pressure applied to indent the globe slightly. The amount of pressure required to indent the eye is qualitatively compared to the unaffected eye or the examiner's own eye (4).

TABLE 54.3
Methods of Tonometry

Type	Comments
Schiötz tonometer	Cumbersome, can spread infection, may create its own trauma, but is relatively easy to use
Applanation tonometer	Accurate, easy to use, mounted on most slit lamps
Tonometer pen	Electronic devices, easy to use and relatively accurate, but very expensive
Noncontact tonometers	For screening only, may be inaccurate, but does not require eye drops or corneal contact
Pneumotonometer	Effective, relatively easy to use, somewhat expensive to maintain, must be calibrated

DIAGNOSTIC TESTING

If a patient presents with a chemical exposure to the eye, immediate high-volume irrigation should be performed before any other part of the examination, as this has greatest effect on prognosis for vision (21). The pH should be measured by application of litmus paper into the tear well followed by comparison of the color with the scale on the container (18). The eye should be irrigated until the pH is normal (pH 6.8 to 7.4) (19). Once normal, the pH should be rechecked in 5 minutes, to ensure that earlier measurement was not simply sampling the pH of the irrigant fluid. Some authors recommend an additional 30 minutes of irrigation once pH is normal (22).

Bedside ocular ultrasound is a safe, noninvasive tool available to EPs who are familiar with its use. An experienced sonographer can complete an examination within 60 to 90 seconds, and make or confirm many possible diagnoses (Table 54.4) (1). It may be particularly useful in trauma or other situations where periorbital edema limits direct visualization of the eye (1). To perform the examination, ultrasound gel is placed over the closed eye, and the linear, high-frequency (7.5 to 10 Hz, “vascular”) probe is used to scan the globe in sagittal and transverse planes. Visualization may be improved by minimizing power output and gain settings, as this will decrease artifact from the eyelids. Excess pressure should be avoided, and in cases of suspected globe rupture, the transducer should only contact the gel, and not the eyelid itself (23).

TABLE 54.4
Ocular Pathology Visible with Ultrasonography

Pathology	Ultrasonographic Appearance
Retinal detachment	Band of echogenic material within vitreous body
Vitreous detachment	Collection of echogenic material between vitreous body and retina
Vitreous hemorrhage	Echogenic material within vitreous body
Retrobulbar hemorrhage	Hypoechoic lucency deep to retina
Lens dislocation	Lens in abnormal position within globe
Globe rupture	Difference in globe size between eyes; scleral folds
Intraocular foreign body	Echogenic foreign body visualized within globe
Central retinal artery/vein occlusion	Absence of Doppler flow at posterior retina
Increased intracranial pressure	Optic nerve sheath diameter >5.0 mm (adults), >4.5 mm (children 1–15)

Data from Legome E, Pancu D. Future applications for emergency ultrasound. *Emerg Med Clin North Am.* 2004;22:817–827.

Laboratory testing is rarely diagnostic in evaluation of ocular complaints. A complete blood count may be obtained in suspected orbital cellulitis. Erythrocyte sedimentation rate (ESR) may be obtained in suspected temporal arteritis, though 10% of affected patients will have an ESR <30 mm/hr. Advanced radiologic testing may be indicated in select cases. CT scan is useful for evaluation of orbital trauma or cellulitis, intraocular foreign body, or intracranial pathology. MRI may help diagnose optic neuritis, intracranial tumors, cerebrovascular accidents.

DISPOSITION

In general, consultation should be considered with unexplained impairment of vision or unexplained severe ocular pain. Emergent ophthalmologic consultation, with transfer if necessary, is indicated in cases of penetrating globe injury, retinal detachment, retinal artery or vein occlusion, or increased IOP. Most other eye complaints can be referred for urgent ophthalmologic follow-up. Ocular manifestations of neurologic disease should be referred to neurology on an emergent or urgent basis.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the contributions of the prior authors, Geoffrey Broocker and Timothy Platts-Mills, to the content of this chapter.

CHAPTER 55

Common Ophthalmic Medications

Kimberly Schertzer

This chapter provides an overview of medications used to diagnose and treat common ocular conditions.

DIAGNOSTIC MEDICATIONS

Stains

These topical solutions reveal areas of corneal and conjunctival epithelial disruption.

Fluorescein stains are by far the most commonly used stains in the emergency department (ED). These stains highlight defective epithelium within the cornea and conjunctiva, with defective areas enhancing under cobalt blue light after staining. Single-use, sterile paper strips are preferred instead of the 2% solutions for convenience and concern about contamination of multiuse containers. Evaluation must happen quickly, as the ability to see stained areas is limited, usually only 1 to 3 minutes after application.

Other stains such as *rose bengal,* are not commonly used in the ED and may be irritating. *Rose bengal* stains devitalize epithelium and is useful for differentiating a herpetic corneal ulcer from a healing corneal abrasion.

Anesthetics

By providing temporary anesthesia, topical anesthetics facilitate eye examination as well as application of diagnostic drops. Most patients cannot tolerate either the application of ocular stains or testing of intraocular pressure (IOP) without topical anesthesia. Application of a topical anesthetic to the eye of a patient with a presumed corneal epithelial defect can be both therapeutic and diagnostic. The topical anesthetic provides patients immediate pain relief and supports the diagnosis of a corneal injury. Topical anesthetics are not for repetitive use, as they suppress protective ocular blink reflexes, have been linked to delayed corneal healing, and may cause an anesthetic-induced keratitis.

Tetracaine hydrochloride (Pontocaine) (0.5% to 1% solution) may initially sting. Its effect lasts for approximately 15 minutes.

Proparacaine hydrochloride (Ophthetic, Ophthaine) (0.5% solution) is less irritating than other solutions.

Mydriatics and Cycloplegics (Red Cap)

These agents are used diagnostically or therapeutically to dilate the pupil (mydriasis) and/or to paralyze the ciliary body (cycloplegia). This effect facilitates evaluation of the internal ocular structures and blocks accommodation. In addition, these agents prevent formation of synechiae (adhesions of the iris to the lens and cornea) by reducing intraocular inflammation through stabilization of the blood–aqueous barrier and by physically pulling the iris away from greater contact with the anterior lens surface. Mydriatic agents are stored in containers capped in red. The duration of drug effects listed below are for normal, noninflamed eyes.

Phenylephrine hydrochloride (Neo-Synephrine, Mydfrin) constricts the surface vessels and dilates the pupil without causing cycloplegia. The 2.5% solution is recommended because of increased systemic (cardiovascular) side effects with 10% solution. The effect lasts approximately 3 hours.

Tropicamide (Mydriacyl 0.5% and 1%) provides short-term dilation of the pupil, plus cycloplegia (lasting 4 to 6 hours). Tropicamide is relatively easy to reverse if there is a concern about

iatrogenic angle-closure glaucoma. It is commonly used by ophthalmologists.

Cyclopentolate hydrochloride (Cyclogyl 0.5%, 1%, and 2%) is the best short-term cycloplegic for determining refractive error; it may last from 6 to 24 hours.

Homatropine hydrobromide (1%, 2%, and 5%) lasts for several days. It is a useful short-term mydriatic and cycloplegic for low-level inflammation (iritis) caused by trauma or abrasions.

Scopolamine hydrobromide (Hyoscine 0.25%) lasts between 4 and 7 days; it is more effective for long-term inflammation seen postoperatively or in severe uveitis.

Atropine sulfate (0.25% to 2% solution, 0.5% and 1% ointment) lasts for 10 to 14 days; it is most commonly used postoperatively and in severe uveitis. It carries both corneal epithelial and systemic toxicities.

THERAPEUTIC AGENTS

Lubricants

Dry eyes may be the result of decreased tear production, systemic disease, environmental factors, medication effects, or inadequate lid function. Patients with dry eyes may complain of itching, blurred vision, burning, or a foreign-body sensation. Artificial lubricants temporarily restore the precorneal tear film and provide an effective but short-term treatment for dry eye-related symptoms.

Artificial tears are often used. Most of these formulations (Table 55.1) contain "thickening" agents (such as methylcellulose or polyvinyl alcohol), which prolong retention of the tears on the ocular surface. Most formulations contain preservatives to prevent contamination, but patients who find these preservatives irritating may opt for more expensive, single-use packets. Artificial tears are generally recommended for use every 4 to 6 hours but may be used as frequently as hourly if needed.

TABLE 55.1
Artificial Tear Preparations

Agent in Solution	Trade Name (Concentration)	Preservative
Carboxymethylcellulose	Refresh tears (0.5%)	Purite
	Refresh plus (0.5%)	Preservative-free
	Thera tears (0.25%)	Preservative-free
Hydroxypropyl methylcellulose	Bion tears (0.3%)	Preservative-free
	Tears naturale free	Preservative-free
	Visine tears	Benzalkonium chloride
Polyvinyl alcohol	Hypo tears (1%)	Benzalkonium chloride
	Murine (0.5%)	Benzalkonium chloride
Glycerin	Moisture eyes (0.3%)	Benzalkonium chloride
Polycarbophil	AquaSite	Preservative free

Bland lubricating ointments (Lacri-Lube, Refresh P.M.) are more viscous than drops, making these agents useful for maximizing sleep-related lubrication or for patients with incomplete lid closure (e.g., those who have seventh cranial nerve palsy).

Antibiotics (Tan Cap)

The general principles of antibiotic therapy apply to topical antibiotics as well. See Table 55.2 for a detailed description of ocular antimicrobial agents.

TABLE 55.2
Antibiotics for Topical Use (Tan Cap)

General Principles of Administration

Administer topical antibiotics 4–6 times daily for simple infections, more frequently for more serious infections (corneal ulcers, gonorrhea). The most common infectious pathogens vary by age. In adults, they include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus* sp, and *Streptococcus pyogenes*. Children are susceptible to the same bacteria, but unlike adults, they are also at risk for *Moraxella catarrhalis* infection

Antibacterial Agents

Bacitracin. Effective only against gram-positive organisms, diphtheroids, *Haemophilus* sp, and *Actinomyces* sp. Ointment or mixture with polymyxin B (Polysporin, AK-Poly-Bac)

Ciprofloxacin. Second-generation fluoroquinolone, with broad-spectrum activity, including *Pseudomonas aeruginosa*. Allows for ambulatory treatment of most corneal ulcers. Has a lower pH than other fluoroquinolone solutions and causes corneal precipitates in up to 16% of patients. Has higher antimicrobial activity (lower MIC90) than ofloxacin. Low allergy index. Solution, ointment (0.3%) (Ciloxan)

Erythromycin. Effective only against gram-positive organisms, especially *Staphylococcus* sp. Ointment (0.5%) (generic)

Gatifloxacin. Fourth-generation quinolone with enhanced gram-positive coverage. Effective for treating coagulase-negative *Staphylococcus* sp and *Streptococcus viridans* (Zymaxid 0.5%)

Gentamicin. Effective against gram-negative organisms, especially *Pseudomonas* sp, and gram-positive organisms, including *Staphylococcus* sp. Not effective against most *Streptococcus* sp because of resistance patterns. Effective, but fairly high sensitizing and potentially toxic corneal epithelial effects. Solution and ointment (Garamycin 0.3%)

Levofloxacin. Third-generation fluoroquinolone. Approved for treatment of bacterial conjunctivitis with efficacy that parallels ciprofloxacin (Quixin 0.5%)

Moxifloxacin. Fourth-generation quinolone with improved gram-positive coverage. Kills *S. pneumoniae* faster in vitro than other antibiotics. Particular efficacious against coagulase-negative *Staphylococcus* sp and *S. viridans*. Also covers fluoroquinolone-resistant *S. aureus* (Vigamox 0.5%)

Neomycin. Broad spectrum but highly sensitizing and potentially toxic to corneal epithelium. Mixtures in solution or ointment (Neosporin)

Norfloxacin. Approved for treatment of bacterial conjunctivitis with efficacy that parallels ciprofloxacin (Chibroxin 0.3%)

Ofloxacin. Similar indications and coverage as ciprofloxacin. Has a higher solution pH than other second-generation fluoroquinolone solutions and is less likely to cause corneal precipitates (Ocuflox 0.3%)

Polymyxin B sulfate. Fairly effective against most gram-negative organisms (except *Proteus* sp or *Neisseria* sp). Ointment mixtures (Neosporin, Polysporin, others). Solution with trimethoprim (Polytrim)

Sulfacetamide sodium. Broad spectrum. Solution (10%, 15%, and 30%). Ointment (10%) (Bleph-10, Sulf-10, others). Potential for allergy is fairly high and may rarely cause Stevens–Johnson syndrome

Tobramycin sulfate. Similar to gentamicin (Tobrex, AK-Tob, others 0.3%)

Trimethoprim sulfate. Broad spectrum of activity. Is effective against some staphylococcal and streptococcal strains, including methicillin-resistant staphylococci, as well as *Haemophilus* sp. In combination with polymyxin B (Polytrim), it has a wide range of effectiveness. Its safety and effectiveness have not been determined under 2 months of age. Very low allergy index

Antifungal Agents

Natamycin. Effective against many filamentary and yeast forms. Drug of choice for most mycotic corneal injuries (and only ocular formulation commercially available). May be used in conjunction with oral antifungal agents (Natacyn, 5% suspension)

Antivirals

Trifluridine (trifluorothymidine). Drug of choice in the United States for corneal herpetic disease and penetrates the cornea fairly well. Toxic to epithelium, like others. One percent solution (Viroptic) must be initiated at an every-2-hour dosage until ulcer is healing

Anti-Inflammatories

Both steroidal and nonsteroidal anti-inflammatories are available by prescription. These agents suppress ocular inflammation and allergic reactions both inside and outside the eye. Suppression of extraocular inflammation may prevent corneal scarring and permanent abnormalities in tear film. Within the eye, these agents may prevent scarring and the later development of glaucoma.

Steroid anti-inflammatory agents (Table 55.3) (pink cap) decrease inflammation. However, their use may be associated with significant side effects, including worsening of ocular infections and permanent visual loss. Some patients experience an increase in IOP within several weeks of using topical steroids. Topical steroids should be prescribed only after consultation with an ophthalmologist and assurance of reliable follow-up.

TABLE 55.3
Ocular Steroid Preparations (Pink Cap)

Fluorometholone 0.1% (FML, others). Slightly more potent, with fewer side effects than prednisolone and dexamethasone. As fluorometholone acetate 0.1% (Flarex), potency comparable to prednisolone acetate 1% because of better penetration
Rimexolone 1% (Vexol). Similar profile to that of fluorometholone but with a lower propensity to raise IOP
Loteprednol etabonate 0.5% (Lotemax), 0.2% (Alrex). Relatively new preparations with high potency and lower propensity to raise IOP
Prednisolone acetate and phosphate 0.125% and 1% (Pred Mild, Pred Forte, others). Potent and highly effective for anterior segment inflammation. High risk for side effects (IOP and infection, especially herpes simplex facilitation)
Dexamethasone 0.1% (Decadron solution). Potent and highly effective. Very high risk for side effects

Nonsteroidal anti-inflammatory agents (gray cap) have limited systemic effects. These topical agents are useful in the treatment of pain associated with corneal abrasions or following refractive surgery.

Flurbiprofen 0.03% (Ocufen) is often used during surgery.

Diclofenac 0.1% (Voltaren) is used for postoperative inflammation following surgery. It also provides safe and effective analgesia for the initial treatment of traumatic corneal abrasions.

Ketorolac 0.5% (Acular) was developed for allergic conjunctivitis. Ketorolac may also be a useful adjunct in the treatment of corneal abrasions.

Antibiotic–Steroid Combinations

Antibiotic–steroid combinations are useful postoperatively. Multiple formulations are available that combine various concentrations of topical corticosteroids with broad-spectrum antibiotics. Antibiotic–steroid combinations should only be used with ophthalmologic consultation. They are available as both drop and ointment preparations and include these drugs:

TobraDex (Tobramycin 0.3%, Dexamethasone 0.1%)

Cortisporin (Neomycin, Polymyxin B, Hydrocortisone 1%)

Blephamide (Sulfacetamide 10%, Prednisolone acetate 0.2%)

Antiglaucoma Agents

To decrease IOP, most antiglaucoma agents (Table 55.4) either increase aqueous humor outflow or decrease its production, or both. In general, monotherapy with a prostaglandin analog or topical β-blocker is preferred, as each works effectively and results in relatively few side effects. The addition of a carbonic anhydrase inhibitor may be useful in further decreasing IOP.

TABLE 55.4
Antiglaucoma Medications

Topical	
Cholinergic agonists (**green cap**)	Pilocarpine 0.5–10%
Adrenergic agents (**purple cap**)	Epinephrine compounds 0.5–2% (Epifrin, others)
	Dipivalyl epinephrine 0.1% (Propine)
α-2 agonists	Apraclonidine 0.5% and 1% (Iopidine)
	Brimonidine tartrate (generic 0.15% and 0.2%) and 0.15% (Alphagan-P)
β-blockers (**yellow/blue cap**)	Timolol 0.25% and 0.5% (Timoptic, others)
	Betaxolol 0.25% (Betoptic-S)
	Levobunolol 0.5% (Betagan)
	Metipranolol 0.3 % (OptiPranolol)
	Carteolol 1% (generic)
Carbonic anhydrase inhibitors (**orange cap**)	Dorzolamide hydrochloride 2% (Trusopt)
	Brinzolamide 1% (Azopt)
Prostaglandin analogs (**turquoise cap**)	Bimatoprost 0.01% (Lumigan)
	Latanoprost 0.005% (Xalatan)
	Travoprost 0.004% (Travatan Z)
	Oral/parenteral
Other antiglaucoma agents	Acetazolamide (Diamox Sequels, 500-mg extended-release capsules)
	Methazolamide (Neptazane 25 and 50 mg, others)
Osmotic agents	Mannitol (Osmitrol) 20%, 1–2 g/kg IV over 30–45 min

PO, by mouth; IV, Intravenous.

Prostaglandin analogs (turquoise cap) are the preferred initial therapeutic agent. By increasing aqueous humor outflow, these drugs lower IOP by 25% to 30%, although their time to initial efficacy is somewhat longer than with *β-blockers.* Prostaglandin analogs carry some adverse effects, including lash growth, periorbital skin hyperpigmentation, and irreversible iris hyperpigmentation, seen most commonly in patients with light or mixed irides. Tafuprost has recently been approved as a preservative-free prostaglandin analog, with similar efficacy as other drugs in its class.

Topical β-blockers (yellow or blue cap) decrease aqueous humor production and are commonly used in the treatment for glaucoma.

They may cause adverse effects similar to those of systemic β-blockers (affecting the cardiopulmonary and central nervous systems) and should be avoided in patients with asthma, bradycardia, or severe chronic obstructive pulmonary disease. Betaxolol (β-1 cardioselective) is slightly less effective than nonselective β-blockers but exhibits fewer side effects because of its selectivity. As a class, topical β-blockers may have effects on libido and cause cardiac sensitivity.

Carbonic anhydrase inhibitors (orange cap) decrease aqueous humor production, but their use may be limited by potentially adverse effects. They may be oral or topical. Oral forms including acetazolamide and methazolamide decrease IOP nearly twice as much as topical forms but have significantly more adverse events, including renal calculi formation and hypokalemia. While these agents are sulfa-related, they are generally well tolerated by patients with sulfonamide allergies. In general, topical agents are less effective than oral ones, typically reducing IOP by 15% to 20%, but they have fewer adverse effects.

Topical α-2 agonists both decrease aqueous humor production and increase its outflow. Apraclonidine may cause tachyphylaxis and localized allergic reaction. Bromonide may cause respiratory depression in children younger than 2 years and should be avoided in this population. It may also cause systemic hypotension in children and infants. All ocular *α*-agonists are relatively contraindicated in patients taking monoamine oxidase inhibitors.

Adrenergic agents may be used for glaucoma. However, the rapid development of tolerance limits their use, and as a class they are less preferred than selective *α*-agonists.

Cholinergic agonists (green cap) may also be used as antiglaucoma agents. They increase outflow of aqueous humor but have no effect on its production. In general, they have been replaced by newer antiglaucoma drugs and their use is limited by local and systemic adverse effects. Cholinergic agonists may cause transient blurred vision and myopia. Still they are useful in some circumstances, such as the immediate treatment of acute angle-closure glaucoma.

Osmotic agents are not available in a topical form. In oral and parental form, they lower IOP by increasing the osmotic gradient between the blood and the eye. They can cause systemic hyperosmolarity and electrolyte imbalance. In addition, they may produce rebound IOP increases as they are eliminated from the body. The oral form is glycerol, which commonly causes nausea and vomiting, and because glycerin is gluconeogenic, should be used with caution in diabetic patients. The parenteral osmotic agent is mannitol. Both osmotic agents should be reserved for cases where acute, rapid IOP rises are not controlled by topical agents.

Allergy Medications

Environmental irritants including dust and pollen can cause redness, itching, chemosis, and increased tear production. Over-the-counter oral antihistamine–decongestant combinations often provide sufficient relief. If this conservative therapy fails, patients may find more symptomatic relief from topical antihistamines, nonsteroidal anti-inflammatory drugs (NSAIDs), and mast-cell inhibitors (Table 55.5). Topical steroids may also be considered but should be prescribed only after ophthalmologic consultation.

TABLE 55.5
Allergy Medications

Ocular Decongestants

Naphazoline hydrochloride (Naphcon, others)

Tetrahydrozoline hydrochloride (Murine, Visine, others). Available without a prescription

Antihistamines

Emedastine difumarate 0.05% (Emadine)

Epinastine 0.05% (Elestat). An antihistamine with mast-stabilizing abilities

Azelastine hydrochloride 0.05% (Optivar). Also available for inhaled use

Mast-Cell Stabilizers

Cromolyn sodium 4% (Crolom)

Nedocromil sodium 2% (Alocril)

Lodoxamide tromethamine 0.1% (Alomide)

Olopatadine hydrochloride 0.1% (Patanol)

Ketotifen fumarate 0.025% (Zaditor)

Ocular decongestants whiten eyes and reduce conjunctival congestion and eyelid edema. They do not require a prescription and are very effective. This may cause some patients to delay seeking care for serious causes of red eyes. Chronic use results in tolerance and "rebound" vascular dilation. Some ocular decongestants contain a mild topical antihistamine (antazoline or pheniramine) and are distinguished by the suffix "-A" within the name. Though these antihistamine–decongestant combinations have a short duration of action, they may be more effective than either agent used individually.

Antihistamines are primarily H1-antagonists. They have both antihistaminic and anti-inflammatory effects. Some antihistamines also possess mast-cell–stabilizing effects.

Mast-cell stabilizers may effectively treat seasonal allergies, which are usually attributed to type I (IgE-mediated) hypersensitivity. By blocking the release of histamine and other vasoactive mediators from mast cells these agents may provide relief, although their onset of action is delayed (days to weeks).

Common Pitfalls

- Topical anesthetics are not for outpatient use, as they suppress protective ocular-blink reflexes, have been linked to delayed corneal healing, and may cause a toxic chemical keratitis.
- Topical steroids can lead to worsening of ocular infections and permanent visual loss; they should only be prescribed after consultation with an ophthalmologist.
- Although most topical ocular medications act locally, certain agents (such as β-blockers) may cause serious systemic side effects.

CHAPTER 56 The Red Eye

Megann Young

The red eye is a common emergency department (ED) complaint that may present in isolation or in combination with other ocular or systemic disorders. The differential diagnosis is broad and includes causes ranging from benign to vision threatening.

CLINICAL PRESENTATION

A red eye is produced by dilated, inflamed, superficial ocular vessels and can result from infection, inflammation, allergy, or elevated intraocular pressure. Several ocular components may be involved, most commonly the conjunctiva, but also the uveal tract, episclera, and sclera.

Conjunctivitis

Conjunctivitis is the most common cause of red eye (1,2). The conjunctiva covers the inner aspect of the lids (tarsal or palpebral conjunctiva) and reflects back on itself to cover the sclera (bulbar conjunctiva), stopping at the cornea. Infection, allergy, and irritation are the most common causes of conjunctivitis.

Infectious conjunctivitis may be viral or bacterial (Chapter 60).

Allergic conjunctivitis (3) may occur seasonally, year-round (perennial conjunctivitis), or as an isolated reaction to material in the eye (often ophthalmic medications, particularly those containing neomycin), and is more common in patients with atopic diseases such as eczema, asthma, and allergic rhinitis (2). Seasonal conjunctivitis is usually caused by airborne pollens and follows the

growth cycle of the responsible plant. Perennial conjunctivitis is usually caused by allergens present in the home, particularly dust mites and animal dander. Numerous irritants may also affect the conjunctiva; common examples include dust, smoke, and chemical fumes.

Symptoms include mild irritation, itching, and watery discharge. Vision is not intrinsically affected but may be blurred by copious discharge. The conjunctivae are globally injected (both tarsal and bulbar surfaces); both eyes are equally affected (1). *Allergic conjunctivitis* may also present with significant conjunctival edema, termed *chemosis,* which appears as a marked bulging of the conjunctiva. In chronic allergic conjunctivitis, fine papillae may develop on the tarsal surface, giving a velvety appearance. Follicular hyperplasia occurs in viral or chlamydial conjunctivitis, give a cobblestone appearance.

Keratitis

Keratitis may be caused by bacterial, viral, fungal, and UV sources. *Infectious keratitis* is discussed in Chapter 60. *Photokeratitis,* caused by UV light exposure, is characterized by foreign body sensation, photophobia, and superficial punctate fluorescein uptake on slit lamp exam; management is supportive, and ophthalmology referral is only required if symptoms persist beyond 48 to 72 hours.

Uveitis

The uveal tract consists of the iris, ciliary body, and choroid. Uveitis is classified as anterior, intermediate, and posterior. Only anterior uveitis typically produces a visibly red eye; it includes iritis and iridocyclitis (inflammation involving the iris and ciliary body). Approximately 50% of cases are idiopathic; most of the remainder are immune mediated (4,5), and a few are infectious.

Typical symptoms include pain (which may radiate to the temple or worsen with extraocular movements), photophobia, consensual photophobia (light in the unaffected eye produces pain in the red eye), and decreased vision. Physical findings include decreased visual

acuity, pupillary constriction, and fine vascular dilation concentrated in the area around the cornea (perilimbal or ciliary flush). The large, dilated vessels typical of conjunctivitis are absent. On slit-lamp examination, there are cells and flare in the aqueous humor, which in severe cases may contain fibrin clot or even pus (hypopyon).

Episcleritis

The episclera is a thin, membranous layer between the conjunctiva and sclera. Inflammation is usually idiopathic but is sometimes associated with immune-mediated disorders (6,7). It occurs mainly in young adults, most commonly women. Patients have mild discomfort, tearing, and an erythematous, injected patch on the globe. The injected area is usually localized, occupying less than half of the visible globe. Episcleritis poses no threat to vision and is self-limited, usually resolving within 2 to 3 weeks (2).

Scleritis

Scleritis is an inflammation of the sclera (the thick, white connective tissue covering the anterior surface of the globe). Inflammation (7) is often idiopathic, but about 50% are associated with systemic diseases (1), often immune-mediated disorders. Scleritis is most common between ages 30 and 60 and is somewhat more common in women. Within several years of an acute attack, up to one-third of patients suffer significant loss of visual acuity. Pain is severe, deep, and typically described as “boring”; pain may be worse with extraocular movements. The pain often interferes with sleep and may radiate to the forehead or jaw. The eye is diffusely hyperemic, often violaceous; sometimes only one quadrant is involved. The palpebral conjunctiva is not inflamed. An identifying feature of scleritis is tenderness of the globe to palpation. An avascular-appearing area amid the hyperemia suggests *necrotizing scleritis,* which can progress to globe perforation.

Acute Angle-Closure Glaucoma

A rapid increase in intraocular pressure results in severe pain, hyperemia, and impaired vision with a pupil that is classically

midposition and poorly reactive (Chapter 61).

Corneal Abrasion and Foreign Body

Significant eye trauma is typically clinically obvious; patients present with complaint of injury rather than red eye. However, minor corneal abrasions and foreign bodies may be present without recognized trauma, particularly in young children and infants (Chapter 57).

DIFFERENTIAL DIAGNOSIS

The differential for the red eye may be best summarized in tabular form (Table 56.1). Other disorders that might produce scleral injection include chemical irritation or infections of the surrounding structures.

TABLE 56.1
Differential Diagnosis of Red Eye

Factor	Infectious Conjunctivitis	Allergic Conjunctivitis	Keratitis	Anterior Uveitis	Episcleritis	Scleritis	Angle-Closure Glaucoma	Corneal Abrasion, Foreign Body
Injection	Diffuse bulbar and palpebral	Diffuse bulbar and palpebral	Diffuse	Diffuse ciliary flush	Focal erythema	Diffuse erythema; may have violet hue	Diffuse bulbar	Diffuse bulbar
Discharge	Viral: Watery Bacterial: Purulent	Copious, watery	Watery	Watery	Watery	Watery	Watery	Watery
Pain	Irritation	None	Severe	Photophobia	Mild	Severe pain, tender to palpation	Severe	Moderate irritation, foreign-body sensation
Itching	Minimal	Moderate	None	None	None	None	None	None
Systemic symptoms	Occasional URI symptoms, preauricular nodes	Sneezing, rhinorrhea	None	Occasional rheumatologic or gastrointestinal	Usually none; occasional rheumatologic	Usually none; occasional rheumatologic	Headache, nausea, vomiting	None
Visual acuity	Usually normal	Normal	Decreased	Decreased	Normal	Initially normal, may become decreased	Decreased	Normal; may be decreased with central abrasion
Pupils	Normal	Normal	Normal	Constricted, poorly reactive	Normal	Normal	Midposition, poorly reactive	Normal
Cornea	Normal	Normal	Diffuse punctate lesions	Normal; anterior chamber with cells and flare	Normal	Normal	Hazy or cloudy	Abrasion visible
Intraocular pressure	Normal	Normal	Normal	Normal	Normal	Normal	Elevated	Normal

ED EVALUATION

A systematic approach to the red eye should lead one to the correct diagnosis. Key symptoms and findings that are helpful in discriminating one cause from another are listed in Table 56.1.

History should focus on the eye and relevant systemic complaints, including any changes in vision, the presence or absence and type of pain/discomfort, foreign body sensation, photophobia, history of trauma, presence and type of discharge, contact lens use, and previous occurrences. Autoimmune or rheumatologic diseases or symptoms should also be elicited (1,8).

Physical examination of the eye (Chapter 54) includes visual acuity, evaluation of pupillary response, delineation of the nature and location of vascular dilation, slit-lamp examination including fluorescein staining, lid eversion for foreign-body detection and, in most cases, ocular tonometry (1,8). A drop of topical anesthetic can provide important diagnostic information: Superficial pain from conjunctivitis, foreign body, or corneal abrasion is relieved, but the deep pain of uveitis, scleritis, or glaucoma is unaffected. Similarly, drops of phenylephrine will not affect the hyperemia of scleritis (1) but will cause blanching in other causes of red eye (phenylephrine will also cause pupillary dilation, and is contraindicated in patients with a history of glaucoma or if acute glaucoma is suspected).

Laboratory testing is usually not helpful. Serologic tests are sometimes useful when immune-mediated disease is suspected but may be coordinated with the ophthalmologist and primary care physician.

ED MANAGEMENT

The treatment options depend upon etiology. Eye trauma, corneal abrasions, ocular infections, and acute angle-closure glaucoma are discussed in Chapters 25, 57, 60, and 61, respectively.

Allergic conjunctivitis should initially be treated with either a nonprescription topical antihistamine/vasoconstrictor such as naphazoline/pheniramine or prescription agents with combination antihistamine and mast-cell–stabilizing activity such as olopatadine or ketotifen. Other agents, including topical NSAIDs and

corticosteroids, may subsequently be added as needed by consultants.

Patients with *anterior uveitis* may get relief from photophobia with a topical cycloplegic, pending ophthalmology evaluation. Definitive treatment usually involves corticosteroids and sometimes immunosuppressives (9). These should be managed by consultants.

Episcleritis is self-limited and generally requires no specific treatment. However, the duration may be shortened by oral NSAIDs or topical corticosteroids.

The discomfort of *scleritis* may be reduced by oral NSAIDs. Definitive treatment should be initiated by consultants and involves systemic as well as topical corticosteroids, with immunosuppressives for necrotizing scleritis or unresponsive disease.

CRITICAL INTERVENTIONS

- Record visual acuity in all cases.
- Measure intraocular pressure to exclude acute angle-closure glaucoma.
- Carefully evert lids to search for a foreign body.
- Perform slit-lamp examination with fluorescein staining.

DISPOSITION

Patients with suspected uveitis or scleritis should be evaluated by an ophthalmologist within 24 hours. Patients with allergic conjunctivitis, episcleritis, or photokeratitis may have either ophthalmologic or primary care follow-up within 2 to 4 days.

Common Pitfalls

- Failing to adequately explain eye pain and decreased vision; these findings almost always indicate a serious disorder.
- Assuming that all causes of red eye are infectious.
- Failing to consider angle-closure glaucoma and measure intraocular pressure.
- Failing to detect a foreign body.

- Failure to refer scleritis and uveitis to an ophthalmologist within 24 hours.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Robert S. Porter to the content of this chapter.

CHAPTER 57

Corneal Abrasion and Foreign Bodies

Lori A. Weichenthal

Corneal abrasions and foreign bodies are among the most frequent ocular conditions that present to the emergency department (ED). It is estimated that the incidence of nonpenetrating injuries to the eye is 15.7 per 100,000 persons per year (1). Although a corneal abrasion is usually a self-limited process, a persistent corneal foreign body or undiagnosed intraocular foreign body can cause unnecessary morbidity.

The emergency physician (EP) must be able to accurately diagnose and treat corneal abrasions and foreign bodies to reduce pain and prevent complications such as infection, ulceration, and vision loss. It is also important that the EP be aware of the potential for intraocular foreign body and be attentive to the historical and physical clues that suggest ocular penetration. This chapter provides an overview of the evaluation and management of corneal abrasions, corneal foreign bodies, and intraocular foreign bodies in the ED.

CLINICAL PRESENTATION

Corneal abrasions and corneal foreign bodies often present with a similar history. The patient often reports that something struck or flew into the eye, followed shortly by the development of pain. At times, the patient does not recall feeling an object entering the eye, but he or she reports being in a situation where such a possibility

exists (using a leaf blower, sawing wood, grinding metal, etc.). Contact lenses may also cause corneal abrasions, because of prolonged wear, an improper fit, foreign material under the lenses, or trauma associated with the placement or removal of the lenses. Some patients develop recurrent corneal erosions, which are characterized by pain upon awakening, usually at the site of a recent abrasion.

Whether a foreign body is present, the patient often complains of a persistent foreign body sensation. With this sensation, there is usually pain, tearing, photophobia, blepharospasm, and a minimal decrease in visual acuity. A headache may also be present but is usually mild.

An intraocular foreign body should be suspected when there is a history of a high-velocity injury to the eye. The injury may be caused by a blast effect or activities such as grinding metal or jack hammering cement without the use of protective eyewear. Patients with intraocular foreign bodies usually present with similar symptoms as patients with corneal abrasions or foreign bodies, although they often describe more visual disturbances.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses of corneal abrasion, corneal foreign body, and intraocular foreign body should include all the disease processes that present with an acute red eye. For a complete discussion of the red eye, please refer to Chapter 56. When there is no history of a foreign body or trauma, the concern for an infection, inflammatory reaction, or acute angle-closure glaucoma should be heightened.

Infections of the conjunctiva (conjunctivitis) and the cornea (keratitis) are most common and are usually viral or bacterial, but in immunocompromised patients, fungal keratitis is also possible. Patients with eye infections will have symptoms similar to those described for corneal abrasions and foreign bodies. They may also describe mucopurulent discharge and other symptoms of infection (cough, congestion, etc.). The pain associated with eye infections

also tends to be more gradual in onset or is first noticed upon awakening (2).

Autoimmune and inflammatory disorders can also cause symptoms similar to those of corneal abrasions and foreign bodies. Anterior uveitis and scleritis are two examples. Patients with these disorders often have other systemic complaints that will help the EP in differentiating them from simple abrasions and foreign bodies.

Acute angle-closure glaucoma can present with a painful red eye. This disease process, however, is usually associated with a severe, unilateral headache and decreased visual acuity, which differs from abrasions and foreign bodies.

In contact lens wearers, although corneal abrasions are common, concern for more serious injury and infection should be heightened. Corneal ulcers and infectious keratitis can occur. Chemical irritation caused by the preservatives in contact lens solutions or the enzymes used to clean some contact lenses can also lead to symptoms similar to corneal abrasions or foreign bodies.

In the setting of trauma, the differential should include corneal or scleral lacerations, hyphema, globe rupture, and traumatic iritis (see Chapter 25). Corneal or scleral lacerations range from simple partial-thickness lacerations to injuries that penetrate the eye. When the laceration is extensive and deep enough, the injury is considered a ruptured globe, which is an ophthalmic emergency. Traumatic iritis can present with symptoms very similar to corneal abrasion and foreign bodies; however, it usually occurs after significant blunt trauma and is associated with headache, photophobia, and decreased vision. If the history is of a high-velocity impact to the eye, intraocular foreign body should always be suspected.

In patients presenting with the story of multiple episodes of corneal abrasions, the diagnosis of recurrent corneal erosions should be entertained. Recurrent corneal erosions often occur in people with epithelial basement membrane dystrophy and/or a history of trauma (3).

ED EVALUATION

When a patient presents to the ED with the complaint of a foreign body sensation to the eye, the history should focus upon the preceding events and a description of all symptoms, including pain, redness, visual changes, or discharge. The time of onset and progressions of symptoms should also be elicited. If the history suggests an actual foreign body, the suspected type of foreign body (wood, metal, organic material, etc.) as well as the setting (high velocity vs. low velocity) should be determined. Previous injuries or surgeries to the eye should be documented, as should the use of glasses or contact lenses. A thorough review of systems and a general medical history should be obtained to evaluate for systemic illness. If nothing in the history suggests a possible systemic problem or multisystem trauma, the physical examination can be focused on the eye.

Visual acuity should be measured as soon as possible. In patients with corneal abrasions and foreign bodies, the visual acuity is frequently normal or mildly decreased. When an intraocular foreign body is present, the visual loss can be significant. The use of a topical anesthetic (proparacaine 0.5% solution or tetracaine 0.5% solution), one to two drops in the affected eye, will make the patient more comfortable and aid the EP in the examination. The use of topical anesthetic can also be helpful in making the correct diagnosis. If the anesthetic does not relieve the patient's pain, it suggests that the pathology is deeper than the corneal epithelium.

A complete examination of the eye should follow instillation of the topical anesthetic. For a detailed discussion of the eye examination, please refer to Chapter 54. Patients with a corneal abrasion or foreign body often have a slightly swollen eyelid, and the conjunctiva and sclera will be hyperemic. It is particularly important to search the corneal and conjunctival surfaces for a foreign body. This examination should be done under magnification with a bright light or a slit lamp. As the superior tarsal plate is a common place for foreign bodies to lodge, lid eversion should be performed in all patients when suspicion of a foreign body exists. To perform lid eversion, ask the patient to look down, grasp the eyelashes of the upper lid, pull the lid down and out, place a cotton-

tipped applicator horizontally above the tarsal plate, and fold the upper lid over the applicator to expose the underlying conjunctival surface (4).

Also of importance in evaluation of the patient with a suspected corneal abrasion or foreign body is an examination with fluorescein. Fluorescein will permanently stain soft contacts, so they should be removed before instilling fluorescein. The patient should be advised to refrain from wearing contacts for several hours. Fluorescein should be instilled in the eye, and the patient should be asked to blink several times. The eye should then be examined with a cobalt blue light or a Wood lamp. Defects of the corneal epithelium will appear green. Particular patterns of uptake can suggest specific injuries. A simple abrasion from a low-impact foreign body will often appear as a single linear uptake. Uptake of multiple linear markings perpendicular to the eyelid suggests a retained foreign body in the superior tarsal plate. A dendritic lesion viewed on fluorescein examination should suggest herpes keratitis. Corneal ulcers and infectious keratitis may appear on fluorescein examination as corneal staining with surrounding opacification (Fig. 57.1).

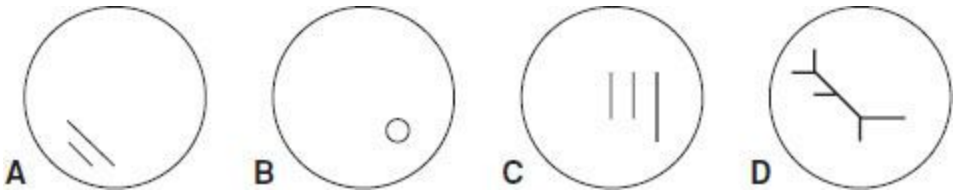

FIGURE 57.1 Corneal fluorescein uptake patterns for particular injuries. A: Typical abrasion. B: Abrasion around a corneal foreign body. C: Abrasion from a foreign body under the lid. D: Herpetic dendritic lesion.

The eye examination should be completed with examination of the anterior segment and fundus. The anterior segment is best examined using a slit lamp and is usually normal with abrasions and corneal foreign bodies. The funduscopic examination is done with an indirect ophthalmoscope and should also be normal.

Routine measurement of intraocular pressure (IOP) is not necessary in simple corneal abrasions and foreign bodies due to small and low-speed particles. Some argue that the use of a tonometer on an abraded cornea may even be harmful. In abrasions due to larger objects, or if the diagnosis is uncertain, IOP should be measured. IOP should not be measured in a suspected penetrating ocular injury, since pressure on the globe may result in extrusion of intraocular contents (4).

Some of the findings on examination of the eye that are suggestive of an intraocular foreign body or globe penetration include an irregular pupil, a prolapsed iris, a laceration to the sclera or cornea, hyphema, absence of a red reflex, significant reduction in visual acuity, and/or a positive Seidel test (5). The Seidel test involves flooding the eye with fluorescein and looking for a small stream of green using the cobalt blue light or Wood lamp, suggesting that fluid is leaking from the globe. If anything on history or physical examination is suggestive of an intraocular foreign body, imaging studies are indicated to make the diagnosis. Although plain films and ultrasonography have been used, computed tomography of the orbit is the preferred test. Magnetic resonance imaging (MRI) should not be considered if the foreign body could be metallic. Patients with suspected intraocular foreign body require immediate ophthalmologic consultation.

KEY TESTING

- Flourescein to highlight corneal epithelial defects
- Measurement of visual acuity in all cases, and IOP in selected cases
- Thorough search for foreign body, including lid eversion
- Imaging studies in case of suspected penetrating foreign body

ED MANAGEMENT

The management of the patient with suspected corneal abrasion or foreign body will be dictated by the history and findings of the eye examination. If a corneal, scleral, or conjunctival foreign body is

found, it must be removed. Frequently, removal is as easy as brushing the foreign body with a moistened cotton-tip applicator. Saline irrigation can also be used to rinse foreign bodies out of the eye. This technique is especially useful if there are multiple, small foreign bodies that are difficult to see.

If irrigation is needed, the eye should be well anesthetized. The lids should be held open with gauze pads or by the use of lid retractors. A saline stream can then be instilled in the eye. The irrigation can be done by using regular intravenous tubing attached to a bag of normal saline or a Morgan lens. The volume and duration of irrigation depends on the suspected foreign body, but at least a full liter is recommended (4).

If the foreign body is embedded in the sclera or cornea, it is best removed with a needle (25 to 27 gauge) attached to a syringe or with a commercial stud device (burr). For this to be done, the eye must be well anesthetized. The patient's head should be stabilized, and the procedure should be performed under magnification, preferably with a slit lamp. The patient is asked to focus on a distant spot. The stud device or needle is then held tangentially to the globe, and the foreign body is gently picked off. If the embedded foreign body is metallic, a rust ring may remain after removal of the metal object. The EP can attempt to remove this ring at the same time that the foreign body is removed by gently brushing it away with a stud device or needle. It is frequently easier to remove the rust ring 24 to 48 hours later when it has had a chance to mature or soften. If a patient has multiple embedded foreign bodies, as if from an explosion, they should be referred emergently to an ophthalmologist.

Once a corneal foreign body has been removed, the treatment is the same as for a corneal abrasion. Treatment for a simple abrasion consists of an antibiotic ointment or drops and oral analgesics as needed. (See Chapter 55 for a complete list of topical antibiotics.) Though there is little research supporting the use of topical antibiotics in this setting, this treatment remains the standard of care in many institutions, and the ointment itself is often soothing. Topical antibiotics are advised for corneal abrasions caused by

infected material (farm instruments, vegetable matter) or contact lens use, because these types of abrasions can rapidly progress to ulceration or keratitis. The offending agents are often gram-negative organisms. In contact lens wearers, there must be special concern about *Pseudomonas* sp. An ulcer due to *Pseudomonas* sp can destroy the cornea in as little as 24 hours. A broad-spectrum topical antibiotic, such as a fluoroquinolone, should be used in these cases.

Cycloplegics (1% cyclopentolate or 5% homatropine) have been recommended in the past because they were thought to relieve some of the pain of corneal abrasions by relaxing ciliary body spasm. A recent literature review revealed there is no evidence to support this practice (6). Similarly, patching the affected eye was once the standard of care, but studies in adults and children have failed to show any difference in the rate of healing or in the degree of pain between groups with or without a patch (1,7). Some studies even suggest that patching delays healing of corneal abrasions. In contact lens-related abrasions, the eye should never be patched, because it can lead to worsening infection and visual loss (8,9).

Traditional teaching discourages the prescribing of topical anesthetics such as tetracaine or proparacaine because of concern that home use may delay healing and enable further injury. However, one recent study suggested that prescribing dilute proparacaine 0.05% for patients with acute corneal injuries improves patient comfort and does not delay wound healing (10).

Other studies have shown that topical nonsteroidal anti-inflammatory drug (NSAID) drops may be useful to treat the pain of corneal abrasions (Table 57.1). Three studies showed a greater reduction of pain in patients using a topical NSAID compared to those receiving no topical analgesia (11–13). Topical NSAIDs can be expensive and have not been adequately tested against oral analgesics for controlling pain due to corneal abrasions and foreign bodies.

TABLE 57.1
Topical Ophthalmic NSAIDs

Ketorolac 0.5% solution
Diclofenac 0.1% solution
Indomethacin 0.1% solution

For corneal ulcers, the use of topical fluoroquinolones and topical steroids is recommended. The treatment should be done in consultation with an ophthalmologist and requires urgent follow-up. Recurrent erosions should be treated with topical lubricants, particularly at bedtime.

CRITICAL INTERVENTIONS

- Remove corneal foreign bodies.
- Treat abrasions due to infected material or contact lens use aggressively with antibiotics.
- Cycloplegics and eye patches are not routinely indicated.
- Provide adequate analgesia and close follow-up.

DISPOSITION

Patients with simple corneal abrasions, recurrent erosions, or corneal defects following foreign body removal should be followed up within 24 to 36 hours, either in the ED, by primary care, or by an ophthalmologist. Patients with abrasions caused by infected material or contact lenses or a corneal ulcer are at higher risk and need urgent ophthalmologic involvement. Patients with an intraocular foreign body need emergent ophthalmologic consultation. If an ophthalmologist is not available, a transfer should be arranged to a hospital with appropriate resources.

Return precautions should be given to all patients who are discharged home. Patients should be urged to return for any evidence of infection (drainage from the eye, increased redness, or pain) or any changes in vision. If a foreign body was the source of the patient's complaint, the use of eye protection should be urged when engaging in future activities that create the risk for injury to the eyes.

Common Pitfalls

- Failure to detect an extraocular foreign body.
- Failure to suspect an intraocular foreign body.
- Failure to provide adequate analgesia.

CHAPTER 58

Acute Vision Loss

Catherine A. Marco

Loss of vision, whether unilateral or bilateral, partial or complete, is an emergent ophthalmologic complaint and requires rapid and thorough evaluation and management. Major eye diseases are particularly common among the geriatric population with the predominant disease entities affecting this group including diabetic retinopathy, glaucoma, and macular degeneration. Approximately 50% of patients older than age 65 have a major eye disease (1). Emergent evaluation includes taking the relevant ocular history, examination of the eyes and other relevant systems, pertinent laboratory evaluation, determination of the differential diagnosis, and rapid institution of appropriate therapy. Consultation with an ophthalmologist and/or other appropriate specialists is often indicated.

CLINICAL PRESENTATION

Patients may present with complete or partial vision loss, with or without a variety of associated symptoms. Typically, any degree of visual loss is disturbing to the patient and may lead to early evaluation; however, some patients may procrastinate and not seek medical evaluation. A thorough history can be crucial and is the most efficient approach to the wide differential diagnosis of visual disturbances.

Several historic points may be particularly useful in determining the etiology of symptoms. The onset of symptoms, whether gradual or abrupt, transient or persistent, constant or waxing and waning, may be of importance. The unilateral or bilateral nature of the

disturbance, and association of pain, may be valuable in the differentiation of certain disorders. Associated symptoms, including systemic symptoms (fever, weakness, rash, etc.), previous history of similar symptoms, history of trauma, and other ocular symptoms, including eye pain, redness, discharge, and so forth, should be sought when obtaining historical information from the patient. Following is a discussion of many conditions that cause vision loss.

Inflammatory Processes

Giant Cell Arteritis

Giant cell arteritis (GCA), an inflammatory disease of medium and large arteries, typically affects patients older than 60 with a female predominance of 3:1. Peak incidence occurs between the ages of 70 and 80. GCA is often associated with polymyalgia rheumatica (2). Visual disturbances are a common presenting symptom and may include painless visual loss or cranial nerve palsies. Patients may also present with malaise, headache, neck pain, fever, night sweats, anorexia, weight loss, depression, jaw claudication, or pain over the temporal or occipital arteries (Table 58.1). Helpful diagnostic tests include an elevated erythrocyte sedimentation rate (ESR) (typically 80 to 100 mm within the first hour; elevated in 98% of documented cases), elevated C-reactive protein (CRP), and an abnormal temporal artery biopsy (3). Elevated ESR has a sensitivity of 76% to 86%, and elevated CRP has a sensitivity of 97.5%. The sensitivity of ESR and CRP together is 99% (4).

TABLE 58.1
Diagnostic Criteria for Giant Cell Arteritis (5)

At least three of the following:
Age at onset of 50 yrs or older
Onset of a new headache
Temporal artery tenderness or reduced pulsation
Raised ESR (≥50 mm/hr by the Westergren method)
Histologic evidence of necrotizing arteritis in the temporal artery

Optic Neuritis

Optic neuritis is an inflammatory disorder that often affects young women and occurs from varying etiologies, including multiple sclerosis, sarcoidosis, systemic lupus erythematosus, leukemia, syphilis, collagen vascular diseases, alcohol abuse, tumor, and infection (meningitis, syphilis, Lyme disease, viral infection). Optic neuritis is often the initial manifestation of multiple sclerosis. Acute visual loss, often occurring within 1 week, is typical. Most patients (65%) have pain with eye movement. Typically, there is unilateral involvement and an afferent pupillary defect. Elevation of the optic disc may be seen on funduscopic examination. Visual field defects may be noted. Optic neuritis often resolves spontaneously over weeks to months (6).

Uveitis

Uveitis, inflammation of the iris, ciliary body, or choroid, may cause visual impairment. Uveitis may be caused by Reiter syndrome, ankylosing spondylitis, sarcoidosis, tuberculosis, collagen vascular disorders, and other diseases. Uveitis may also present as an inflammatory response to corneal abrasion, ulcer, infection, or trauma. The presentation generally includes conjunctival injection, pain, photophobia, and blurred vision.

Vascular Events

Central Retinal Artery Occlusion

Central retinal artery occlusion (CRAO) often presents with sudden, painless visual loss (Fig. 58.1). There may be a history of transient visual loss prior to this event. The cause is often due to emboli from carotid plaques, cardiac valves, fat emboli, arteriosclerosis, or a host of other underlying disorders (such as systemic lupus erythematosus), hypotension, coagulopathy, migraine, smoking, hypercholesterolemia, procedures such as cardiac catheterization, sickle cell disease, cocaine, certain medications (sildenafil, oral contraceptives, epinephrine, etc.), amniotic fluid embolism, and GCA. Elderly patients are more commonly affected, and men are more commonly affected than women. Visual loss is typically

profound, with 90% of patients sustaining losses that range from counting fingers to light perception. An afferent pupillary defect may be present. Physical findings include “cherry-red spot” of the fovea, retinal opacity in the posterior pole, “boxcars” of the arterioles, pallor of the involved retina, and optic disc edema (7). Ultrasound, including color Doppler imaging, may be helpful in elucidating the diagnosis (8). Echocardiography and carotid artery studies may reveal sources of emboli. Branch retinal artery occlusion (RVO) may occur and may present with sudden loss of visual field and reduction in visual acuity. The long-term prognosis is related to the duration of symptoms prior to resolution. Improved outcomes are seen if the condition is reversed within 90 minutes of onset of symptoms.

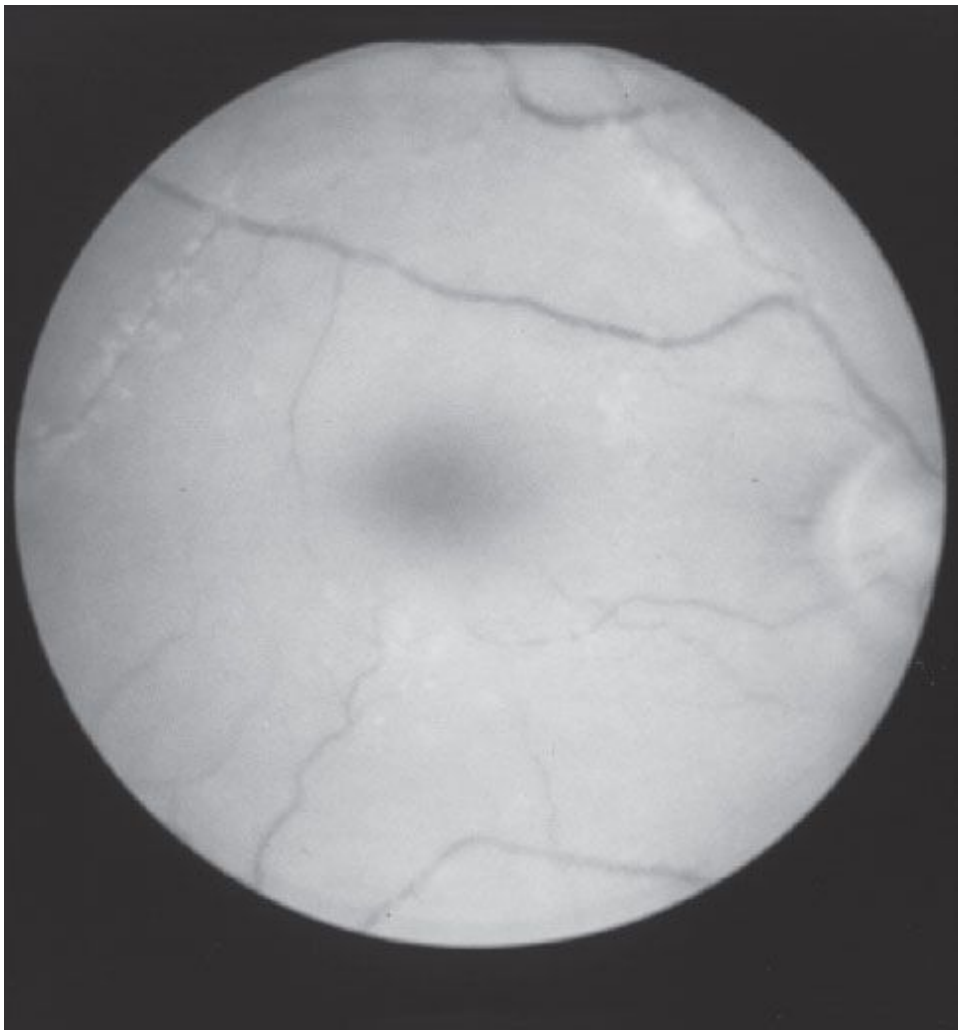

FIGURE 58.1 Central retinal artery occlusion.

Central Retinal Vein Occlusion

Patients with central retinal vein occlusion (CRVO) typically present with painless, sudden loss of vision (Fig. 58.2). Most patients are older than age 50, and many also have significant cardiovascular disease. Other associated disorders include hypertension, glaucoma, venous stasis, diabetes mellitus, tobacco use, vasculitis, and collagen vascular disorders. Physical findings may include retinal hemorrhage, which may be pronounced and diffuse, venous dilatation, cotton wool spots, and optic disc edema. Branch RVO may occur and may have segments of intraretinal hemorrhage. Complications may include macular edema, ischemia, and neovascularization with associated vitreous hemorrhage. The natural history of CRVO is often favorable even without specific intervention.

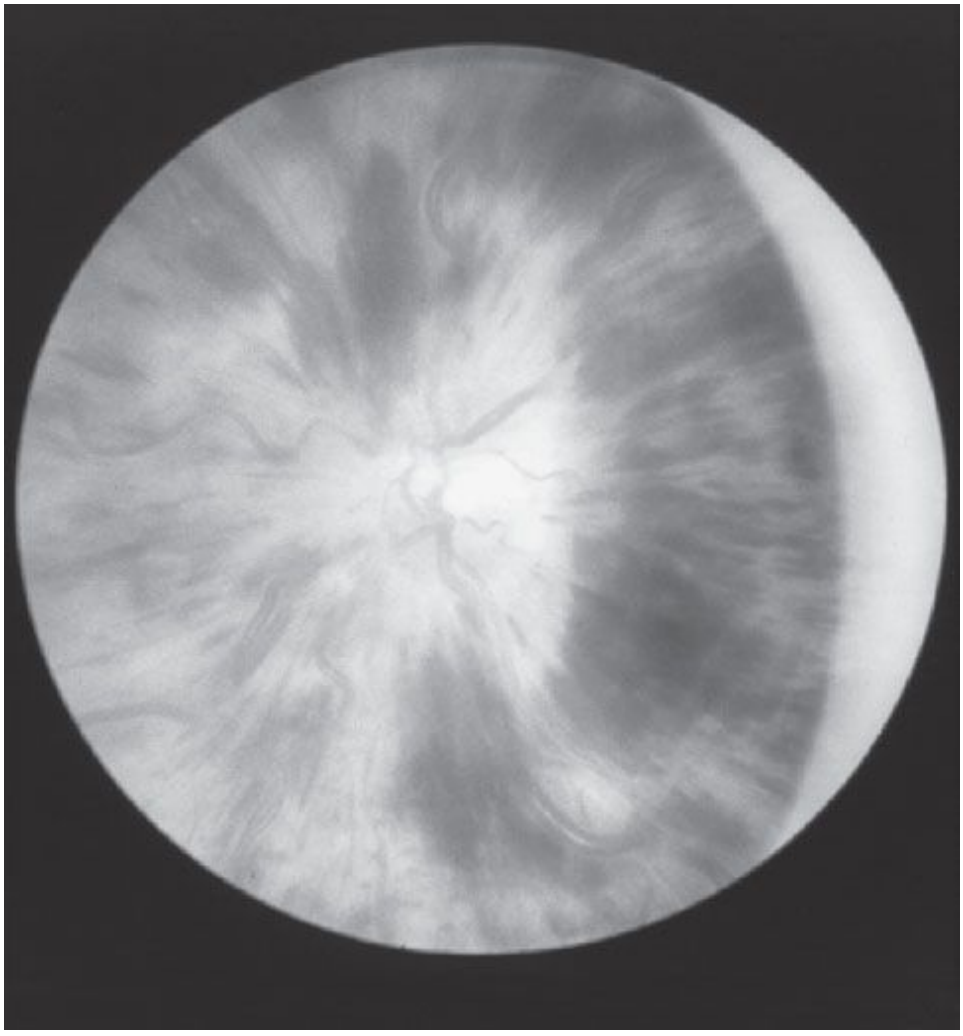

FIGURE 58.2 Central retinal vein occlusion.

Amaurosis Fugax

Amaurosis fugax, a unilateral transient obstruction of a retinal artery, may cause temporary loss of vision (up to 15 minutes). The visual loss is often described by the patient as a curtain being drawn across the visual field. Amaurosis fugax is usually caused by cholesterol emboli or fibrin-platelet emboli and may be associated with carotid artery disease, cardiac arrhythmias, anemia, sickle cell disease, hypertension, or episodic hypotension. Carotid and cardiac studies may be indicated to determine the source of the emboli.

Ischemic Optic Neuropathy

Ischemic optic neuropathy is typically found in patients older than 50 and often presents with painless decreased visual acuity. This disorder may result from an infarction of the optic nerve (90% of cases) or from GCA (10% of cases). An afferent pupillary defect may be found as well as a pale, elevated optic disc.

Vitreous and Retinal Disorders

Vitreous Hemorrhage

Vitreous hemorrhage typically presents with acute unilateral painless loss of vision and may be accompanied by symptoms of “floaters” or “cobwebs.” Associated visual disturbances may be mild or severe, depending on the extent of the hemorrhage. The normal red reflex of the fundus is absent. Diffuse, dark, particulate opacities may be seen. If severe, a black uniform reflex (“eight-ball hemorrhage”) will be seen instead of the normal retinal red reflex. Vitreous hemorrhage may be associated with numerous disorders including diabetes, trauma, malignancy, vitamin K deficiency, CRVO, leukemia, anemia, and thrombocytopenia.

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of visual loss among retinal vascular disorders and may be divided into proliferative and nonproliferative disorders. This disorder may occur in type I or type II diabetes mellitus. Nonproliferative diabetic retinopathy is a progressive microangiopathy. Symptoms may be mild or nonexistent and may include hue discrimination abnormalities, scotomas, contrast sensitivity, or a variety of other visual complaints. Physical findings include multiple hemorrhages throughout the retina and macular edema. Proliferative retinopathy refers to ischemia as a result of microvascular occlusions and may present with cotton wool spots, retinal vein bleeding, and irregular dilation of the retinal capillary bed. Sudden visual loss may occur with massive vitreous hemorrhage from fragile neovascularization or from retinal detachment. Progressive loss of vision may be slowed or prevented by laser photocoagulation.

Retinal Detachment

Retinal detachment refers to a separation of the two layers of the retina: the pigment epithelium and neurosensory retina (Fig. 58.3). The most common type, rhegmatogenous, occurs as a result of tears, holes, or breaks in the sensory layer of the retina. Retinal detachment may be associated with advancing age, male gender, significant myopia, diabetes mellitus, sickle cell disease, or ocular contusion or penetrating injury, or it may be idiopathic. In addition, exudative or traction types of retinal detachment may be seen. Symptoms include photopsia (light flashes), floaters, or a shower of black dots in the periphery secondary to hemorrhage into vitreous humor, or a sensation of a shadow or curtain obscuring the visual field. Visual acuity may be normal if the macula is unaffected or severely impaired if involved. On examination, the detached area may appear gray, opaque, or translucent. Retinal folds may be seen, and vessels may appear dark red. Symptoms often resolve within 1 week.

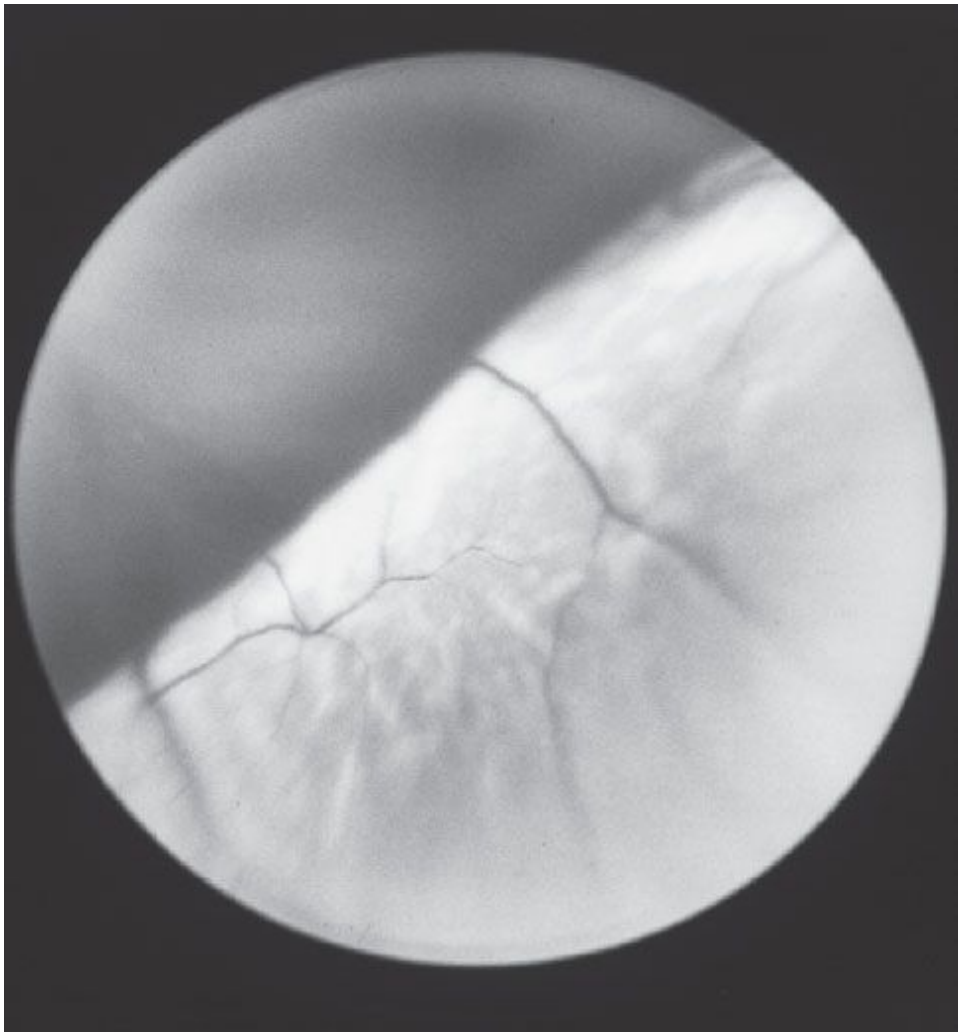

FIGURE 58.3 Retinal detachment.

Macular Degeneration

Age-related macular degeneration (ARMD) is the most common cause of permanent blindness among older patients and has an estimated incidence of up to 11.4 per 1,000. The disease can be divided into nonexudative (dry) macular degeneration, characterized by drusen (yellowish subretinal deposits) and exudative (wet) macular degeneration, characterized by submacular hemorrhage, yellowish exudates, or serous fluid. The incidence is associated with advanced age, family history, tobacco history, race (Caucasian), and gender (slight female predominance). The etiology is unknown. Symptoms include blurred vision, visual distortion, scotoma, or central visual loss. Physical findings include impaired visual acuity,

drusen (yellow–white deposits beneath the pigment epithelium), and clumps of pigment throughout the macula.

Neurologic Disorders

Cerebrovascular accidents and transient ischemic attacks may be associated with visual loss. A bilateral homonymous hemianopsia may result from involvement of the optic tract or occipital lobes. Involvement of both occipital lobes may produce complete blindness ("cortical blindness").

Cortical blindness may be caused by entities such as ischemia, mass lesions, hydrocephalus, anoxia, encephalitis, meningitis, edema, or hemorrhage into the occipital lobe(s) (9,10). Evaluation should be conducted promptly and may include computed tomography (CT), magnetic resonance imaging (MRI), and lumbar puncture.

The optic chiasm may be compressed by mass lesions such as pituitary adenomas, meningiomas, craniopharyngiomas, or aneurysms. These patients may present with bitemporal hemianopia, and advanced imaging is warranted.

Other Causes of Vision Loss

Cytomegalovirus Retinitis

Cytomegalovirus (CMV) retinitis may present with sudden or gradual visual loss when the infection invades the macula. It is seen most commonly in immunocompromised patients such as those with AIDS, on chemotherapy, or following organ transplantation. Symptoms include blurred vision, floaters, flashes of light, eye pain, and scotomas (11). Findings include retinal hemorrhagic areas combined with zones of white retinal necrosis ("tomato and cheese pizza" appearance).

Glaucoma

Patients with glaucoma may present with acute or chronic visual loss. Visual field testing may indicate a diminished perception in the nasal region. Optic nerve pallor and cupping is seen on examination. Elevated intraocular pressure (IOP) (often 50 to 70 mm Hg) is typically found. Associated symptoms often include eye pain, headache, nausea, and vomiting (Chapter 61).

Malignancies of the Eye

Although space does not permit a detailed study of ophthalmologic malignancies, it is prudent for the emergency physician to have an awareness of the spectrum of malignancies that may affect vision. Benign intraocular tumors may include retinal angiomas or astrocytic hamartomas. Malignant intraocular tumors include retinoblastoma (usually before age 1, presenting with leukocoria or strabismus) and malignant melanoma. Metastatic tumors may involve the eye, most often with choroidal metastasis (12). Complications of intraocular malignancies that affect vision include hemorrhage from tumor vascularization, retinal detachment, retinal degeneration, and retinopathy. Abnormal physical findings should alert the physician to the importance of timely ophthalmologic follow-up.

Methanol Toxicity

Methanol toxicity is associated with transient or permanent visual disturbances. Symptoms and signs usually occur within 18 to 48 hours of the ingestion. Associated symptoms include nausea, vomiting, headache, or abdominal pain. Findings include hyperemic, swollen optic discs, with retinal edema. A cherry-red spot may be observed.

Other Toxins

Numerous other toxins that may be associated with visual disturbances include carbon monoxide, lead, salicylates, sulfonamides, ergots, tin, quinine, barbiturates, chemotherapy, and nitroglycerin. Visual loss is usually bilateral, and therapy consists of the appropriate treatment of the underlying condition.

DIFFERENTIAL DIAGNOSIS

Vision loss may be caused by a variety of ophthalmologic conditions, or in association with other diseases. Some of the more common ophthalmologic causes are summarized in Table 58.2. In general, any abnormality of the cornea, lens, vitreous, retina, optic nerve, optic tract, optic radiations, or occipital cortex should be considered (13).

TABLE 58.2
Differential Diagnosis of Selected Causes of Visual Disturbance

Disease Process	Symptoms	Clinical Findings	Ancillary Tests	Management
Giant cell arteritis	Painless visual loss, sudden or gradual, HA, myalgias	Optic nerve edema, temporal artery tenderness	Elevated ESR, CRP, temporal artery biopsy	Steroids, ophthalmologic consultation
Optic neuritis	Painful visual loss, pain with EOM	APD, elevation of optic disc	MRI, consider LP	Consider steroids in MS; ophthalmologic consultation
Uveitis	Eye pain, blurred vision, photophobia	Cells in anterior or posterior chamber, flare in aqueous humor		Topical steroids, cycloplegics, ophthalmologic consultation
CRAO	Sudden, painless, profound visual loss	APD, pallor of retina, cherry-red fovea		Globe massage, paracentesis, acetazolamide, inhaled carbogen, ophthalmologic consultation
CRVO	Sudden, painless visual loss	Retinal hemorrhages, venous dilation, optic disc edema		Ophthalmologic consultation
Amaurosis fugax	Monocular visual loss (transient)		Carotid, cardiac studies	ASA, neurologic consultation
Vitreous hemorrhage	Visual floaters, cobwebs, or severe visual loss	Diminished or absent red reflex ("eight-ball" hemorrhage)		Treatment of underlying condition; ophthalmologic consultation
Retinal detachment	Acute, painless visual disturbance; filmy, cloudy vision; peripheral monocular visual loss ("veil")	Gray/translucent detached area with folds, bulging appearance		Ophthalmologic consultation
Macular degeneration	Gradual, painless disturbances; spots in visual field; distortion of straight lines	Drusen, macular pigment clumps		Ophthalmologic consultation
Diabetic retinopathy	Gradual visual disturbances, scotomas	Multiple retinal hemorrhages, macular edema		Ophthalmologic consultation
Ischemic optic neuropathy	Painless, diminished visual acuity	APD, pale, elevated optic disc		Ophthalmologic consultation
TIA	Transient binocular visual loss	Normal	Carotid, cardiac studies	Neurologic consultation, ASA
Cortical blindness	Sudden or gradual, complete visual loss or homonymous hemianopia, HA	Papilledema, other neurologic findings	CT, MRI, LP	Neurologic consultation, therapy of underlying disorder
Migraine HA	Transient visual loss	Normal		Neurologic consultation
Glaucoma	Sudden, painful visual disturbance, abd pain, N/V	Optic nerve pallor and cupping	Elevated IOP	Topical β-blocker; acetazolamide; ophthalmologic consultation; see Chapter 61
CMV retinitis	Sudden or gradual visual disturbance	Retinal hemorrhages, areas of pale retinal necrosis ("tomato and cheese pizza" appearance)	Consider CT/MRI	Foscarnet or ganciclovir, ophthalmologic consultation
Cavernous sinus thrombosis	Fever, visual loss, headache	Chemosis, proptosis, CN abnormalities	CT/MRI	IV antibiotics, admission
Methanol	Transient visual disturbance, N/V, HA	Hyperemic, swollen optic discs, cherry-red spot		EtOH, fomepizole, dialysis, see Chapter 302
Functional visual loss	Variable symptoms	Normal	Optokinetic nystagmus	Psychiatric consultation

This table represents only a summary of certain disorders, and is not an exhaustive information source for the above disease states.
HA, headache; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; EOM, external otitis media; APD, afferent pupillary defect; MRI, magnetic resonance imaging; LP, lumbar puncture; MS, multiple sclerosis; CRAO, central retinal artery occlusion; CRVO, central retinal vein occlusion; ASA, aspirin; TIA, transient ischemic attack; CT, computed tomography; abd, abdominal; IOP, intraocular pressure; CMV, cytomegalovirus; CN, cranial nerve; N/V, nausea/vomiting; EtOH, ethyl alcohol.

Patients with vascular disease may develop vision loss due to hemorrhages of various types, including preretinal, linear, punctate, subretinal, and white central hemorrhages (Roth spots). In addition, there may be acute ocular ischemia due to infarction of the optic disc (ischemic optic neuropathy), which presents with sudden visual loss and a pale, swollen optic disc. Causes of ocular ischemia include hypertension, atherosclerosis, choroidal infarction, retinal infarction,

and transient retinal ischemia (amaurosis fugax). Patients with AIDS may present with toxoplasmosis, candidal endophthalmitis, herpes zoster ophthalmicus, or optic neuropathy.

The diagnosis of functional visual loss, as seen in conversion disorder, should always be one of exclusion. There may be a variety of complaints, but no abnormalities are seen on examination. Optokinetic responses may be tested in a cursory fashion in the emergency department (ED) by passing a tape measure, or sheet of paper with prominent vertical lines, rapidly before the affected eye(s). Another simple test involves placing a mirror before the patient's face and rocking the mirror from side to side. The presence of optokinetic nystagmus (following movements with rapid returns to the primary position of the eye) indicates that vision is present. In addition, patients feigning blindness may demonstrate an inability to oppose outstretched forefingers while bringing outstretched arms together. This ability would not ordinarily be affected by blindness. Additional tests to differentiate organic from functional visual loss may be suggested by ophthalmologic or psychiatric evaluation.

ED EVALUATION

Complete details of the ophthalmologic examination are included in Chapter 54. Specifically, when evaluating the patient with loss of vision, visual acuity and visual field testing are of primary importance.

Visual acuity is an essential element of the physical examination and can be measured with a Snellen eye chart. For patients unable to adequately read from the eye chart, their ability to count fingers, detect movement, color, and perceive light should be evaluated. Visual field testing can be useful in determining the extent of visual loss and in developing the appropriate differential diagnosis. Eyes should be tested independently. In addition, the examiner should perform a slit-lamp examination and measurement of IOP.

Pupils should be evaluated utilizing the swinging flashlight test to detect an afferent pupillary defect. Funduscopic examination should be performed using a handheld ophthalmoscope. Pupillary dilation may be required to perform an adequate examination of the retina.

The fundus should be examined for evidence of papilledema, disc edema, pallor, hemorrhage, or exudates (14).

Ultrasound of the eye may be helpful in elucidating certain diagnoses such as retinal detachment and vitreous hemorrhage. Radiographic evaluation (including MRI or CT) may be indicated in cases where intracranial pathology or mass lesions involving the optic nerve or globe are suspected.

KEY TESTING

- Visual acuity, slit-lamp and funduscopic examination
- ESR and CRP (for suspected GCA)
- IOP (for suspected glaucoma)
- CT or MRI of brain
- Ultrasound of eye (for suspected retinal detachment)

ED MANAGEMENT

Many of the diseases that produce acute vision loss mandate immediate ophthalmologic consultation, intervention, or admission. The unique features of some of the causes are discussed here.

GCA should be treated expeditiously with early administration of corticosteroids (e.g., intravenous [IV] methylprednisolone, 2 to 4 mg/kg initial dose), to prevent blindness and other long-term visual defects, as well as contralateral eye involvement (common within 10 days without treatment) and may provide dramatic pain relief (15–19). Patients may have a 34% chance of improvement in visual function after steroid therapy. Aspirin may have additional protective effects when instituted in conjunction with steroid therapy. A biopsy should be performed within 7 to 10 days of steroid initiation, although most biopsies will remain positive up to 4 weeks after initiation of therapy. A negative biopsy does not exclude GCA.

Although the treatment of optic neuritis with steroids is not universally beneficial, IV methylprednisolone is indicated for patients with suspected multiple sclerosis (12,20). Interferon has also been suggested as a possible therapeutic adjunct. Investigation for an underlying predisposing condition, in consultation with the primary

care physician, is essential. Consultation with an ophthalmologist is indicated for patients with suspected optic neuritis.

Uveitis may be treated effectively with topical corticosteroids and cycloplegic agents. Systemic steroids may be indicated in severe cases. For cases resistant to steroid therapy, other therapies may include immunosuppressants such as antimetabolites or T-cell inhibitors. Therapy of the underlying disorder should be initiated.

Treatment for CRAO is often unsatisfactory but should be attempted if diagnosed within 90 minutes of onset of symptoms. Supplemental oxygen should be administered. Intermittent globe massage should be attempted to dislodge an embolus (moderate pressure for 5 seconds and release for 5 seconds). Other treatment modalities may include anterior chamber paracentesis (to decrease IOP and increase retinal perfusion), IV acetazolamide (to decrease IOP), topical timolol 0.5% or topical levobunolol 0.5%, inhaled carbogen (oxygen–carbon dioxide mixture of 95% to 5%) to induce retinal vasodilation and increase retinal PO_2. Hyperbaric oxygen and nifedipine have also been reported as successful therapies (21,22). Other treatments may include ophthalmic artery infusion of urokinase or tissue plasminogen activator, isovolemic hemodilution, oral acetylsalicylate, or oral pentoxifylline (23).

CRVO is difficult to treat successfully, but treatment should include a careful evaluation of the probable etiology to prevent contralateral eye involvement. Spontaneous resolution may occur in some cases. Treatment offered by an ophthalmologist may include intravitreal injection with vascular endothelial growth factor (VEGF) antibodies, intravitreal steroids, isovolemic hemodilution, retinal laser photocoagulation, or vitrectomy (24,25).

Amaurosis fugax should be treated with antiplatelet therapy such as aspirin, and ophthalmologic consultation should be obtained. Ischemic optic neuropathy should be treated with systemic steroids (methylprednisolone, 250 mg IV q6h) to prevent contralateral eye involvement.

Retinal detachment should be treated by an ophthalmologist, with options including diathermy, laser photocoagulation, or other intraocular surgical therapies. Treatment for macular degeneration

includes photodynamic therapy with verteporfin or intravitreal injection of pegaptanib. The use of low vision aids may be recommended.

CMV retinitis may be treated with IV or intravitreous antiviral therapy (fomivirsen, foscarnet, or ganciclovir) in consultation with an ophthalmologist.

Glaucoma may be treated with a miotic (e.g., pilocarpine), topical β-blocker (e.g., timolol), a carbonic anhydrase inhibitor (e.g., acetazolamide), mannitol or glycerin, and topical steroids (see Chapter 61).

Methanol toxicity may be treated with ethanol or dialysis and is discussed in Chapter 302.

CRITICAL INTERVENTIONS

- Rapidly recognize and obtain ophthalmologic consultation for patients with CRAO and amaurosis fugax
- Initiate steroids for patients with GCA or optic neuritis associated with suspected multiple sclerosis

DISPOSITION

For the majority of patients with acute visual loss, consultation with an ophthalmologist is indicated. The severity and nature of the disease process will dictate whether emergent or urgent consultation is necessary. Patients considered for hospital admission should be those patients who require IV medications, surgery, or other invasive procedures, or for whom serious worsening of vision is imminent.

Common Pitfalls

- Failure to measure visual acuity
- Failure to measure IOP and consider the diagnosis of glaucoma
- Failure to test visual fields adequately
- Failure to administer steroids rapidly to patients with GCA
- Delay in treatment of CRAO

CHAPTER 59

Diplopia

Kurt Brueggemann and James A. Comes

Diplopia is an uncommon and frightening emergency department (ED) complaint. The differential diagnosis is complex and evaluation may require neuroimaging or consultation with subspecialists who may not be immediately available. Diplopia can be the sentinel finding of an insidious neurologic or metabolic disease, the sole symptom of a benign and self-limited microvascular (diabetic) mononeuropathy, or the lone warning sign of an impending intracranial aneurysm rupture. Diplopia can result from a unilateral ocular problem or binocular misalignment. It may present in isolation or as part of a constellation of findings.

Management varies from expectant to emergent depending on the presumed etiology. A comprehensive emergent management strategy has not been thoroughly established. Guiding principles and available evidence favor a meticulous, systematic, and conservative approach.

CLINICAL PRESENTATION

Diplopia has a wide variety of presentations, depending upon the neuroanatomic location of the lesion (if present) (1,2). Diplopia can be categorized as horizontal, vertical, or oblique/diagonal, and it may be noted to be worse with a particular direction of gaze. Strabismus may be evident at rest (*-tropia*) or upon provocation (*-phoria*). For example a medial deviation of the eye at rest is termed an esotropia.

Diplopia can be confused with a variety of other symptoms, including dizziness, lightheadedness, blurry vision, ghost-like images, and partial or full vision loss (3).

Diplopia, colloquially “double vision,” is the result of an inability to integrate the signals received by two retinas into a single sensible visual perception. This can result from a refractive error of an individual eye (monocular diplopia) or an extraocular cause producing misalignment of the eyes (binocular diplopia).

Monocular diplopia is almost invariably due to a problem with the single involved eye, and rarely requires emergent management. It can be distinguished from binocular diplopia by having the patient alternately close one eye and then the other. If diplopia persists with monocular vision, misalignment of the eyes is not the problem (3) and further attention should be directed to the affected eye. The focus of the remainder of this chapter is binocular diplopia.

During normal vision the brain integrates the sensory input from each eye into a single stereoscopic worldview (visual acuity and depth perception). The two eyes are normally entrained and aligned to place any object of interest over the fovea (central vision) of each retina. The inability of one eye to accurately “acquire the target” produces two distinct retinal projections which cannot be fused by the visual cortex, resulting in “double vision.”

Diplopia (pathologic binocular diplopia) results from dysfunction of the extraocular muscles (EOMs), also called ophthalmoplegia. This dysfunction can result from disorders and diseases anywhere from the orbit to the CNS including the muscles, their neuromuscular junctions, cranial nerve(s) or nuclei up through their respective interneurons. These neurons make possible the complex coordination of head and eye movements involving cortical, vestibular, proprioceptive, and cerebellar circuits.

Extraocular motility is provided by six EOMs; the medial rectus (EOM-MR) and lateral rectus (EOM-LR) adduct and abduct the eye, the superior rectus (EOM-SR) and inferior oblique (EOM-IO) elevate the eye while the inferior rectus (EOM-IR) and superior oblique (EOM-SO) depress the eye.

The abducens nerve (CN-VI) innervates the EOM-LR. The trochlear nerve (CN-IV) innervates the EOM-SO. The oculomotor nerve (CN-III) innervates the remainder of the EOMs, the major muscle of the eye lid, levator palpebrae superioris (LPS), and also carries autonomic parasympathetic fibers to the pupillary constrictor muscle.

Individual cranial nerve palsies present with typical clinical presentations. A patient may adopt several coping strategies to deal with the deficits. These coping strategies can help guide the identification of the palsy. If a compensatory head position is present, it mirrors the function of the inactive muscle(s).

The clinical presentation may also vary considerably secondary to the underlying cause. For example, a lesion in the cavernous sinus may involve all three extraocular cranial nerves as well as the ophthalmic and maxillary branches of the trigeminal nerve. Lesions of the carotid artery up through the cavernous sinus may produce a Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis). A lesion of the pituitary may involve a characteristic visual field deficit and endocrinologic signs and symptoms. Diseases involving the orbit may be painfully obvious (e.g., an orbital fracture with EOM entrapment) or quite subtle (e.g., thyroid myopathy). Brainstem or other central lesions often involve other neurologic deficits including hemiparesis, anesthesia, discoordination or vertigo, facial weakness or anesthesia, dysphonia, dysphagia, or visual field deficits. Neuromuscular junction disorders can be elusive but may exhibit historical features such as fatigability, temporal variation, dysphagia, proximal muscle weakness, and dyspnea. CNS infection may also produce fever, headache, meningismus, or altered mental status.

Oculomotor (CN-III) Palsy

A complete CN-III nerve palsy will produce a “down and out” pupil, and ipsilateral ptosis with variable but critical pupillary involvement. The patient may complain of a diagonal diplopia which is worse in near-field gaze when looking inward and upward.

The accompanying ptosis (effectively closing the "bad" eye) may minimize the associated disability by obliterating the diplopia.

The cranial nerves supplying EOMs exit the brainstem and traverse the dura, subarachnoid space, and cavernous sinus before funneling into the superior orbital fissure. CN-III travels alongside the posterior communicating artery soon after it exits the brainstem. CN-III innervates four EOMs and includes fibers supplying pupillary and palpebral muscles.

A complete CN-III palsy with pupillary involvement is a posterior circulation aneurysm until proven otherwise. Pupillary involvement is particularly worrisome because the parasympathetic fibers lie in the periphery of the nerve sheath, making them more susceptible to external compression. Aneurysm and diabetic neuropathy are the two leading causes of CN-III palsy. An isolated, unilateral, atraumatic complete CN-III palsy *sparing the pupil* is often due to diabetic neuropathy. Cavernous sinus lesions can produce CN-III palsies with a concurrent Horner syndrome which can make the pupillary findings very ambiguous.

Partial, incomplete, or inconsistent palsies of CN-III are substantially more complicated and require neuroimaging and consideration of neuromuscular disease (4). A dysfunctional EOM-MR raises several diagnostic possibilities including internuclear ophthalmoplegia (INO), myopathy, and neuromuscular disease. These last examples serve to illustrate the point that any findings not consistent with a complete unilateral cranial nerve III palsy sparing the pupil require a very meticulous appraisal.

Trochlear (CN-IV) Palsy

A complete CN-IV nerve palsy may have a more subtle presentation. The patient may complain of a vertical diplopia with a torsional (rotational) component. Owing to the inaction of the functionally denervated EOM-SO the globe may appear elevated (hypertropia) and extorted. The diplopia will worsen with nasal deviation and downgaze, thus activities like reading, descending stairs or watching TV in bed may be difficult. The patient may adopt a compensatory

head posture or tilt consisting of the head tilted forward and away from the affected eye (mirroring the depression and intorsion action of the EOM-SO).

CN-IV exits the brainstem dorsally and passes alongside the edge of the cerebellar tentorium making it vulnerable in the setting of closed head injury. It has a long intracranial course, so diseases affecting the subarachnoid space should be strongly considered. CN-IV palsies are very unlikely to be aneurysmal.

The critical diagnostic consideration in patients presenting with vertical diplopia is skew deviation. Skew deviation results from a central lesion and can mimic a CN-IV palsy but is often distinguished by the presence of other neurologic findings. It results from a supranuclear lesion of the interneurons connecting the vestibular and ocular circuits and frequently presents with vertical diplopia present in all gaze directions.

Abducens (CN-VI) Palsy

Although the abducens nerve (CN-VI) innervates only a single muscle, EOM-LR, the associated diplopia is often the most severe. Horizontal diplopia is the rule and a compensatory head rotation (toward the affected side) may be present. The patient may close the eye "pseudoptosis" or cover it to minimize the symptoms.

CN-VI travels near the cavernous portion of the internal carotid artery and may be the first cranial nerve involved in vascular disease in this area. The abducens nerve ascends the clivus in a near vertical fashion and is tethered at the apex across the sharp ridge of the petrous portion of the temporal bone. This anatomic anchoring makes the abducens nerve very susceptible to increased intracranial pressure (ICP). Thus the examiner should look for headache and papilledema and have a low threshold for obtaining imaging to exclude obstructive hydrocephalus, mass lesions, idiopathic intracranial hypertension, or sagittal venous thrombosis.

Internuclear Ophthalmoplegia

Internuclear ophthalmoplegia (INO) clinically presents as an EOM-MR palsy. In normal abduction the medial longitudinal fasciculus (MLF) activates the contralateral EOM-MR to keep the eyes aligned. A lesion of the MLF manifests as an inability to adduct the eye on attempted contralateral abduction. The abducting eye will exhibit nystagmus as a response to the divergence. INO is by definition a central lesion requiring neuroimaging and consideration of neuromuscular disease. Bilateral INO is a hallmark of multiple sclerosis (MS). As the EOM-MR itself is not impaired, convergence should remain intact in an INO and be impaired in a neuromuscular disease affecting the EOM-MR.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of binocular diplopia can be simplified based on whether the findings suggest an isolated cranial nerve palsy. If an isolated unilateral cranial nerve palsy is present, and there is no history of antecedent trauma or orbital findings, the differential diagnosis can be narrowed considerably. CN-III palsy is most likely due to a posterior circulation aneurysm or diabetic neuropathy. CN-IV palsy must be differentiated from central causes of vertical diplopia and the physical examination may not be adequate to do so (5,6). The patient with CN-VI palsy must be evaluated for disease processes producing elevated ICP.

If the diplopia is not attributable to an individual cranial nerve palsy, the diagnostic considerations include myopathy or myositis (7), neuromuscular disease, demyelinating disease, descending paralytic disorders, or a CNS lesion including infection, inflammation, neoplasm, ischemia, thrombosis, aneurysm, hemorrhage, dissection, or demyelination.

Some selected diseases which can mimic or aggregate extraocular cranial nerve dysfunction include:

Cavernous Sinus Thrombosis: May involve all three extraocular cranial nerves as well as the ophthalmic and maxillary branches of the trigeminal nerve. It should be strongly considered in the thrombophilic or immunocompromised patient as the associated

infection can be bacterial or fungal. Diseases of the cavernous internal carotid artery including aneurysm or rupture may present similarly.

Giant Cell/Temporal Arteritis: Should be considered in any elderly patient complaining of unilateral headache and vacillating vision abnormalities (including diplopia). *Ophthalmoplegic migraine* must be considered a diagnosis of exclusion in all age groups.

Miller–Fisher Syndrome (MFS): Is a descending demyelinating inflammatory polyneuropathy which typically begins with diplopia and then progresses to ataxia, areflexia and potentially proximal muscle weakness, paresthesias, and respiratory failure from diaphragmatic insufficiency (8).

Botulism: Often begins with bilateral ophthalmoplegia but it can potentially involve any cranial nerve (e.g., dysphagia may be the presenting complaint). It progresses to symmetric descending weakness.

Myasthenia Gravis (MG): Can initially present with ocular symptoms of diplopia and ptosis. The ophthalmoplegia producing diplopia can involve any combination of EOMs and mimic any of the CN palsies described above. The pupils, however, are never affected in ocular myasthenia.

Multiple Sclerosis (MS): Patients may present with ophthalmoplegia resulting from cranial nerve palsies or INO.

Idiopathic Intracranial Hypertension (IIH): (Formerly pseudotumor cerebri) is an important diagnostic consideration as it can result in vision loss if left untreated. Since CN-VI is sensitive to increased ICP it is the EOM palsy associated with this condition. Funduscopic examination reveals papilledema and nonpulsatile distended retinal veins. Emergent neuroimaging is warranted to exclude obstructive hydrocephalus, venous sinus thrombosis or mass lesion.

Thyroid Extraocular Myopathy: It can produce diplopia in clinically euthyroid patients without alarming signs of an orbital process. The inferior rectus is most commonly the first muscle involved in this restrictive myopathy. Orbital findings can include

exophthalmos, ptosis, periocular inflammation, lid lag, and lid retraction.

Wernicke Encephalopathy: Must be considered in any patient presenting with altered mental status, ataxia, and oculomotor aberrations from ophthalmoplegia to nystagmus (9).

ED EVALUATION

The diagnostic approach must be guided by the overall condition of the patient and the associated signs and symptoms. Thus, if the patient is strongly suspected to have meningitis, the diagnostic and management process is governed by the preliminary diagnosis, regardless of diplopia.

The history and physical examination can be critical in lesion localization and establishing the diagnostic approach. In a stable and cooperative patient the examiner should first focus on the eyes, including tests of visual acuity, visual field integrity, pupillary reactivity, afferent defects and appearance (size and symmetry), extraocular movements, and alignment (looking for strabismus, gaze deviation, or nystagmus). The patient should be asked to report any changes in their symptoms with these maneuvers. Visual acuity and EOM testing should be performed with each eye individually and together. The examiner should then proceed to consideration of the face, looking for ptosis (if not already noted) and facial, orbital or ocular asymmetry (e.g., unilateral conjunctival injection). The presence of pain at rest or pain with movement should be noted (7,10–12). A full cranial nerve examination must be performed, as well as a complete cerebellar examination, gait testing, and evaluation of deep tendon reflexes, and extremity motor or sensory function.

Even with a careful physical examination in a cooperative patient the localization of the lesion may prove difficult (1,2). Consequently, consider broad neuroimaging and early subspeciality consultation if available. Patients with binocular diplopia without clinically evident ophthalmoplegia require careful evaluation as this can be a sign of MS.

Monocular diplopia, once identified, should prompt a thorough examination of the eye including cornea, lens, anterior/posterior chambers, retina, and possibly the optic nerve. Consideration should be given to disease processes producing monocular vision impairment or loss (13), monocular visual field deficits, and a monocular painful red eye. Ophthalmologic consultation is recommended.

In the setting of trauma, computed tomography (CT) should be the first choice for diagnostic imaging. In the absence of trauma, CT can be performed initially as it is often the most accessible, though a negative result may be falsely reassuring (14–16). If resources are available patients should be evaluated with magnetic resonance imaging, with angiography or venography, depending on the clinical picture.

Neurologic findings attributable to more than one cranial nerve (II to XII) or any other neurologic findings should prompt neuroimaging and consideration of neuromuscular disease, restrictive myopathy, demyelinating disease, or other causes of descending weakness (17). If aneurysm is strongly suspected, some authorities consider that a negative CT or MR angiogram is inadequate to exclude aneurysmal disease and thus suggest formal angiography in this setting (3).

Some authors have argued that all patients presenting with binocular diplopia require advanced neuroimaging because the potential etiologies may be life-threatening and there are no established clinical criteria for safely identifying the subset of patients who do not require an extensive workup.

KEY TESTING

- Careful neurologic examination
- MRI is indicated in most patients with binocular diplopia

ED MANAGEMENT

The most important goal is to rapidly identify patients with a serious underlying cause of diplopia, initiate therapy as appropriate,

and involve necessary specialists. Depending on the nature and severity of the underlying cause, appropriate initial actions may include intubation and respiratory support, hemodynamic support, ICP management, seizure and/or vasospasm prophylaxis, anticoagulation correction, thrombolytic consideration, or broad-spectrum antibiotics. Isolated cranial nerve palsies should undergo neuroimaging and early subspeciality consultation.

CRITICAL INTERVENTIONS

- Supportive care as needed with attention to the underlying pathology

DISPOSITION

Admission or transfer decisions largely rest on the condition of the patient, the presumed diagnosis, and the capabilities of the institution. Most patients presenting to the ED with binocular diplopia will require hospitalization, advanced neuroimaging, and subspecialty consultation. Patients with negative neuroimaging studies and histories suggestive of progressive or descending weakness require hospitalization for definitive diagnosis and close observation. As no clinical criteria exist for safely and effectively risk-stratifying potential expectant management patients, clinical judgment and the availability of specialty consultation and follow-up play a role in the disposition of these patients.

Common Pitfalls

- Failure to distinguish monocular from binocular diplopia
- Failure to identify diplopia in the patient complaining of dizziness or blurry vision
- Performing unenhanced CT in the patient with diplopia and regarding it as a definitive study
- Failure to perform lumbar puncture or opening pressure measurement in CN-VI palsy patients with a normal head CT to exclude IIH

- Failure to consider myopathy, neuromuscular or demyelinating diseases in the differential
- Failure to involve subspecialists in the diagnostic decision making

CHAPTER 60 Acute Eye Infections

Tricia C. Loo

Eye infections are encountered in the ED in a broad spectrum ranging from minor to severe. The majority of infections seen in the ED are minor, but it is very important that the emergency physician learn to recognize the signs and symptoms of severe infections which, if missed, could lead to compromise of vision and be devastating to the patient. This chapter addresses a variety of eye infections, including conjunctivitis, keratitis, keratoconjunctivitis, endophthalmitis, and orbital and periorbital cellulitis (see Chapter 255).

CLINICAL PRESENTATION

Conjunctivitis refers to inflammation of the mucous membranes that line the eyelids and sclera. Causes of conjunctivitis include viral, bacterial, fungal, or parasitic (rare) infections, allergic, chemical exposure, and contact lens wear. The main bacterial pathogens include *Haemophilus Influenzae* and *Streptococcus pneumoniae* species in both children and adults, and *Moraxella catarrhalis* in children. The most common cause of viral conjunctivitis is adenovirus. Contact lens wearers are at risk for gram negative infections, including *Pseudomonas*. Most patients presenting to the ED with conjunctivitis have a self-limited condition, but the emergency physician must be wary of patients presenting with serious etiologies (i.e., bacterial or herpetic conjunctivitis) that could result in vision loss if left untreated.

Patients with bacterial conjunctivitis may present with symptoms of eye redness, mucopurulent discharge, and itching. Patients with

viral conjunctivitis present with bilateral watery discharge and foreign body sensation. Upper respiratory infection typically precedes viral conjunctivitis. Discharge from either cause can result in crusting and sticking of the eyelids, which is especially notable after sleep. The quality of discharge or associated findings such as an enlarged ipsilateral preauricular lymph node, are commonly used to differentiate between viral and bacterial conjunctivitis, but there appears to be little evidence of these associations or of any specific factors aiding this differentiation (1).

Keratitis refers to inflammation of the cornea. Infectious keratitis frequently involves the conjunctiva as well and is referred to as keratoconjunctivitis. This condition usually causes significant pain for the patient and may have viral or bacterial etiologies as well. Patients with keratitis usually present with intense eye pain, tearing, redness, and sometimes photosensitivity. Herpes keratitis may produce severe pain and a corneal dendritic lesion.

Blepharitis refers to inflammation of the eyelids and is one of the causes of a persistent red eye. Chronic inflammation can lead to the meibomian glands getting clogged. If the glands get infected, a painful lump forms, and this is known as a hordeolum/sty. A chalazion is not truly an infection but a chronic inflammatory process leading to granuloma formation surrounding blocked sebaceous or meibomian glands.

Blepharitis may result in red, swollen eyelids, a foreign body sensation, tearing, crusting of the eyelid margins, eye pain, or photophobia. With hordeolum, similar symptoms are often present, but typically a focal area of erythema and swelling of the eyelid is noticed. Similarly, a chalazion usually causes a focal area of inflammation that is usually subacute in onset and most times occurs proximal to the eyelid margin.

Endophthalmitis is inflammation of the intraocular structures (vitreous and/or aqueous humor). It most frequently results from exogenous causes (i.e., ocular surgery or penetrating trauma), but can also rarely occur from endogenous causes (i.e., bacteremic seeding of the eye). Patients with endophthalmitis often exhibit more significant clinical findings, including eye pain, vision loss,

headache, discharge, and photophobia. Acute endophthalmitis is a medical emergency and requires aggressive antibiotic therapy (both systemic and intravitreal) and urgent ophthalmology consultation.

Preseptal and *orbital cellulitis* are relatively uncommon and affect children more frequently than adults. Preseptal cellulitis refers to infections of the soft tissues anterior to the orbital septum (Fig. 60.1). Orbital cellulitis refers to infections posterior to the septum (fat and ocular muscles). Preseptal cellulitis is more common than orbital cellulitis, and most frequently arises from external sources (trauma, bites, foreign bodies). Orbital cellulitis most frequently arises from rhinosinusitis. Periorbital cellulitis typically involves erythema, edema, and warmth of the periorbital tissues and also may involve closure of the palpebral fissures. Fever may be present. There should be no complaints of ocular pain, pain with movement of the globe, nor any limitation of globe mobility, all of which suggest the more serious diagnosis of orbital cellulitis.

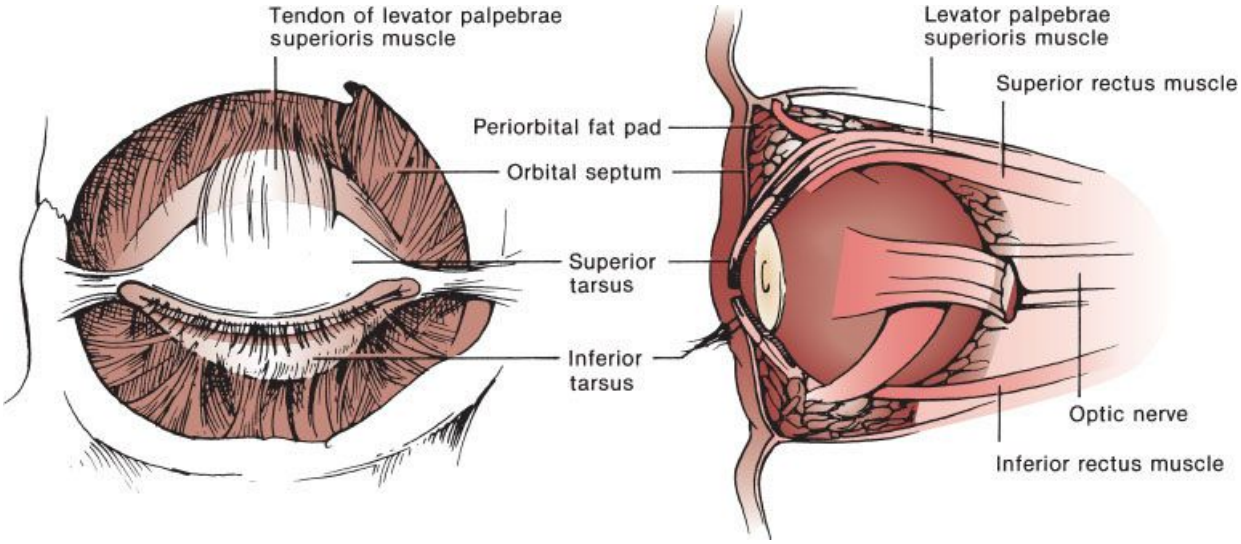

FIGURE 60.1 View of orbit–orbital septum.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the red or painful eye is broad (Chapter 56). Infection is a relatively common cause of these symptoms, but a variety of other causes must be considered, including allergic reactions, irritant causes, foreign body, chemical or thermal burns,

trauma, medication reactions, orbital disease related to other medical problems (e.g., thyroid disorders), glaucoma, uveitis, mucocutaneous syndromes (e.g., Kawasaki disease, Stevens–Johnson syndrome, etc.), and cancer (2). The differential diagnosis of periorbital cellulitis includes orbital cellulitis, insect bite, allergic response, and hordeolum. The differential for orbital cellulitis includes cavernous sinus thrombosis, endophthalmitis, and tumor.

ED EVALUATION

A thorough but focused history and a careful ocular examination are the keys to ED management of the painful or red eye. The relevant physical examination is described in more detail in Chapters 54 and 56. History should include documentation of previous visual problems or surgeries, current vision complaints, use of glasses or contact lenses, use of general or ophthalmic medications, other general medical problems, trauma, contact with other people who may have ocular infections, contact with or exposure to chemicals or toxins, symptoms of systemic illness (e.g., fever, tachycardia, etc.), history of immunocompromised state from medical conditions or medications, and the pattern of development of symptoms (one eye, both eyes, etc.). Visual acuity should always be documented, as visual acuity is the "vital sign" of the eye. This examination should take place before use of any ophthalmologic medications (e.g., topical anesthetics, mydriatics, etc.). Focused examination of the eye and periorbital areas should then be performed.

Lids

Examination of the eyelids is important to evaluate for crusting or other signs of infectious or dermatologic conditions. Any general or focal erythema or swelling of the lids should be noted. Eversion of the lids and inspection of the fornices for foreign body should also be performed.

Conjunctiva

Examination should identify chemosis or discharge. Membranes may be present in infections involving adenovirus but may be due to *S. pneumoniae,* diphtheria, or rarely, herpetic disease. Conjunctival hemorrhage may be present and is often petechial when caused by adenovirus. Copious discharge may be present in gonococcal conjunctivitis. Hemorrhage may also be secondary to other organisms such as *S. pneumoniae.* Follicular reaction, creating a "cobblestone" appearance in the lower palpebral conjunctiva, is typically seen with adenovirus infection but may be secondary to allergic or toxic causes (3).

Cornea

The cornea should be specifically examined for signs of ulceration. Most ulcers are centrally located, and fluorescein staining may reveal spots or specks of increased uptake over areas of corneal epithelial damage. Larger areas of corneal epithelial injury signify ulceration and require ophthalmologic consultation for further management because the possible complications include corneal scarring and vision loss. Fluorescein staining may also reveal the typical dendritic pattern associated with herpes simplex virus (HSV) infections. Varicella zoster virus (VZV) may also cause corneal ulcers. Care must be taken to examine the nose for involvement with the typical zoster lesions. Herpetic eruptions involving the nose may signify that the nasociliary branch of the ophthalmic nerve is involved. Corneal involvement is likely in this scenario and is referred to as the Hutchinson's sign. Corneal ulcers associated with blue or greenish discharge are often associated with *Pseudomonas aeruginosa* infection. Urgent (next-day) ophthalmology referral is often adequate for small corneal ulcerations, but larger or more extensive ulcerations require ophthalmologic consultation in the ED. Fungal ulcers are often caused by *Candida, Aspergillus,* or *Fusarium* species. The incidence of fungal infections is increasing secondary to the increasing number of patients with AIDS and because of the increasing use of immunosuppressive medications. Contact lens use also predisposes to corneal ulceration.

Anterior Chamber

Slit-lamp examination for evaluation of the anterior chamber is important to evaluate for signs of iritis (uveitis). White blood cells ("cell and flare") visualized in the anterior chamber are the key finding with iritis. Iritis may be related to significant corneal surface infections or ulcerations. A hypopyon, the layering of the white blood cells in the anterior chamber, may be seen and represents a true ocular emergency. Presence of a hypopyon requires immediate ophthalmology consultation.

Periorbital Areas and Skin

Erythema and swelling in the periorbital area may be secondary to local inflammatory causes or infection, but underlying preseptal or orbital cellulitis should be considered. There are a number of key points to remember when performing the physical examination of this area:

- Preseptal cellulitis may present with sufficient swelling to affect visual acuity and ocular motility.
- Fever is absent in as many as 24% of all patients with preseptal and orbital infections.
- Unilateral involvement is the rule rather than the exception for both preseptal and orbital cellulitis.
- Examination should be performed with the assumption that the patient has orbital cellulitis until proven otherwise.
- Proptosis and painful eye movements or extraocular movement impairment are more often associated with orbital cellulitis, although subperiosteal or orbital abscesses may cause similar findings (4).

The bacterial pathogens in orbital and preseptal cellulitis are typically the same organisms causing the predisposing condition: sinusitis, upper respiratory infection, local skin infection, dental infections, or postsurgical infections. Most commonly, *Staphylococcus aureus, Staphylococcus epidermidis, S. pneumoniae,* or other streptococcal species are causative agents, but many others have been implicated. *H. influenzae* type b vaccine has dramatically

decreased this organism's role as a pathogen in children with preseptal or orbital cellulitis (5). *Staphylococcus* sp are now seen most commonly in children with these infections. The prevalence of methicillin-resistant *S. aureus* (MRSA) continues to increase with rapidly growing numbers of ophthalmologic-related *S. aureus* isolates being reported as methicillin-resistant (6).

When preseptal or orbital cellulitis is considered, further diagnostic testing may be indicated. For the systemically ill patient, particularly pediatric patients, blood cultures may be useful. With orbital cellulitis, blood cultures are negative in two-thirds of children and 90% to 95% of adults (3). Cultures of eyelid aspirates and eye secretions are rarely helpful and are not recommended, unless there is a clear source of cutaneous infection. Cultures of cerebrospinal fluid are recommended only for infants in whom meningeal signs are evident.

Computed tomography (CT) scanning of the orbit is the preferred method of imaging for orbital infections. CT scanning of the orbit is advocated in all children in whom orbital cellulitis cannot be clearly ruled out by examination (7). Many authors recommend obtaining axial and coronal CT views to improve diagnostic yield in regard to subperiosteal or orbital abscesses that may be missed if only axial views are obtained (8–10). There is no advantage to using contrast-enhanced versus noncontrast CT scans. Orbital or subperiosteal abscesses are identified on CT scans in only 80% of cases (11), and diagnosis of orbital infection remains primarily a clinical one. Ultrasound has been used in some centers for diagnosis, and magnetic resonance imaging (MRI) may be a useful alternative for patients requiring surgical treatment.

KEY TESTING

- CT of the orbits, if orbital cellulitis is suspected

ED MANAGEMENT

Examination and other testing should allow somewhat focused treatment of eye infections. If bacterial conjunctivitis or keratitis is

suspected, topical antibiotics are generally appropriate. Although these infections are generally self-limited and rarely associated with sight-threatening complications, evidence suggests that the use of topical antibiotics may improve clinical remission rates (12,13).

Treatment of Ocular Surface and Lid Infections

Recent reviews have evaluated the antibiotic resistance of commonly used ophthalmic antibiotic preparations (14). In general, the narrow-spectrum antibiotics bacitracin, vancomycin, and cefazolin have retained their effectiveness against gram-positive infections. The broad-spectrum antibiotics include the aminoglycosides gentamicin, tobramycin, neomycin, trimethoprim, and the sulfacetamides. The aminoglycosides continue to have excellent activity against gram-negative bacteria and good activity against *Staphylococcus* sp but are less effective for *Streptococcus* sp. Trimethoprim provides excellent coverage for *Haemophilus* sp but poor coverage against *Moraxella* sp and other gram-negative bacteria. The sulfacetamides have excellent efficacy against *Streptococcus* sp and *S. aureus* conjunctival infections but less activity in cases of *S. aureus* keratitis.

Erythromycin has exhibited increased bacterial resistance rates, particularly with *Staphylococcus* sp infections. The fluoroquinolones have good activity against most gram-negative organisms and *S. pneumoniae,* but increased resistance has been seen for *Pseudomonas aeruginosa* and *S. aureus* (15,16). Failing to reach adequate concentrations of fluoroquinolones will inadequately treat infections and likely will increase bacterial resistance; therefore, frequent topical dosing is recommended. MRSA is increasing in prevalence, and initial antibiotic choices should be made with consideration of local resistance patterns. Vancomycin remains the drug of choice for serious MRSA infections (17).

Ophthalmic drops are generally well tolerated by adults, but ointment may be useful at bedtime. Ointments may be useful in children because of inherent difficulties in instilling ophthalmic drops in children. Care must be used to avoid complications caused by the topical antibiotics themselves. Neomycin is very sensitizing and can cause reactions with symptoms similar to the patient's initial

presenting complaints, thus confusing further management. Aminoglycosides, sulfa agents, and bacitracin may cause similar reactions, although less often. Cross contamination of ophthalmologic medications also occurs frequently during patients' use of these medications and highlights the importance of appropriate handwashing practices for the patient and for health care personnel. This practice should decrease the possibility of contracting or spreading the infectious agent.

Patients with herpetic corneal lesions may be treated with both a topical antiviral agent such as trifluridine (Viroptic 1%) and an oral antiviral (acyclovir, famciclovir, valacyclovir) with ophthalmologic consultation and follow-up. Gonococcal conjunctivitis should be treated with intramuscular (IM) ceftriaxone. If the infection involves the cornea or deep structures, ophthalmologic consultation and admission are recommended.

Some infections of the corneal surface may be complicated by iritis and may require treatment with cycloplegics for symptomatic relief. Steroid medications may also be indicated for patients with iritis, but use of these medications is generally deferred to the treating ophthalmologist. Topical steroids are usually not prescribed by emergency physicians without consultation with an ophthalmologist.

Initial treatment of uncomplicated blepharitis and hordeolum usually involves use of warm compresses several times daily. Typically, this is the only treatment required for hordeolum, although topical antibiotics may be indicated if there are signs of infection spreading from the area involving the hordeolum. Systemic antibiotics may be needed if there is evidence of a more significant infection.

The key to treatment of blepharitis is an adequate regimen of cleansing the eyelid margins. Topical combination preparations containing an antibiotic and a steroid (e.g., sulfacetamide and prednisolone) may also be useful but only for a short duration of treatment. Conservative management predominates in the early treatment of chalazion. Surgical excision by an ophthalmologist may be necessary, if improvement does not occur with initial treatment.

Treatment of Periorbital and Orbital Cellulitis

Outpatient treatment with oral antibiotics may be acceptable for the management of periorbital cellulitis in adults, if there is no evidence of orbital infection, and the infection is not severe. Antibiotics should cover *S. aureus,* group A *Streptococcus* sp, and Enterobacteriaceae. First-generation cephalosporins (cephalexin) or penicillinase-resistant synthetic penicillins (dicloxacillin) are appropriate choices for initial treatment. As with the treatment of conjunctivitis, local patterns of resistance must be taken into account when assigning initial antibiotic therapy. Treatment should generally continue for 7 to 10 days, unless the infection is suspected to be secondary to sinusitis. In these cases, treatment should continue for 2 to 3 weeks, and antibiotics should be targeted at typical organisms associated with sinusitis. Next-day ophthalmology follow-up should be arranged in patients when outpatient therapy is chosen. See Chapter 255 for orbital and periorbital cellulitis in children.

For orbital cellulitis and most cases of periorbital cellulitis, inpatient treatment with parenteral antibiotics is indicated. Common intravenous (IV) antibiotic doses are listed in Table 60.1. Combination therapy with vancomycin and a second- or third-generation cephalosporin (cefuroxime, cefotaxime, ceftriaxone, or ceftazidime) is recommended. Ticarcillin/clavulanate, piperacillin/tazobactam, and ampicillin/sulbactam are also reasonable choices.

TABLE 60.1
Common Parenteral Antibiotic Doses for Orbital or Periorbital Infections

Ampicillin/sulbactam: 3 g IV every 6 hrs (25–100 mg/kg IV every 6 hrs for children)

Ceftazidime: 1–2 g IV every 8 hrs (30–50 mg/kg IV every 8 hrs for children)

Ceftriaxone: 2 g IV once daily (50–100 mg/kg IV once daily or divided into every 12-hr dose for children)

Cefotaxime: 2 g IV every 4–6 hrs (50–180 mg/kg/d IV divided into every 6-hr dose for children)

Cefuroxime: 750–1,500 mg IV every 8 hrs (75–100 mg/kg/d IV divided into every 8-hr dose for children)

Chloramphenicol: 50–100 mg/kg/d divided into every 6-hr dose

Clindamycin: 600–900 mg IV every 8 hrs (20–40 mg/kg/d divided into every 6-hr dose for children)

Metronidazole: 500 mg IV every 8 hrs (7.5 mg/kg IV every 8 hrs for children)

Nafcillin: 500 mg–1 g IV every 6 hrs (150 mg/kg/d IV divided into every 6-hr dose for children)

Piperacillin/tazobactam: 4.5 g IV every 6–8 hrs (100–300 mg/kg/d IV divided into every 4–6-hr dose for children)

Ticarcillin/clavulanate: 3.1 g IV every 6 hrs (200 mg/kg/d IV divided into every 6-hr dose for children)

Vancomycin: 1 g IV every 12 hrs (40 mg/kg/d IV divided into every 6–8-hr dose for children)

CRITICAL INTERVENTIONS

- Practice strict handwashing policies to prevent the spread of ocular surface infections.
- Seek ophthalmology consultation for hypopyon, endophthalmitis, significant corneal ulcers, or orbital cellulitis.
- Initiate IV antibiotics for infections of the orbit.

DISPOSITION

Patients with signs of severe conjunctivitis, associated corneal ulcer or infiltrate, or with hypopyon require immediate ophthalmologic consultation. Other cases necessitating immediate consultation include severe conjunctivitis with suspected gonococcal source. Referral for early ophthalmologic consultation within 24 to 48 hours should be made for patients with conjunctivitis that does not improve within 24 to 48 hours and for patients with findings suggestive of herpetic disease.

Patients with deeper ocular infections, including endophthalmitis, severe corneal ulcers, or gonococcal conjunctivitis with corneal infiltrates, typically require hospital admission and urgent ophthalmologic consultation. It is uncommon for a patient with herpes simplex or herpes zoster infection to require admission. In-hospital care is geared primarily toward providing IV antibiotics, intravitreal injections, or very frequent topical antibiotic administration (18).

Patients with orbital cellulitis require admission, but mild cases of periorbital cellulitis may be managed in the outpatient setting in adults, if appropriate follow-up within 24 hours is available. IV antibiotics should be started in the ED when hospital admission is indicated.

Common Pitfalls

- Obtaining a culture of conjunctival or ocular secretions, which is not clinically useful for emergency physicians.
- Failure to recognize the distinction between preseptal and orbital cellulitis.
- Overreliance upon tests that are of little value in differentiating periorbital from orbital cellulitis, such as white blood cell count, sinus films, cultures of eyelid aspirates or eye secretions, and blood cultures.
- Failure to use CT scanning as the diagnostic test of choice for differentiating orbital and periorbital cellulitis and abscesses.

CHAPTER 61

Acute Angle-Closure Glaucoma

Stacy Sawtelle

Glaucoma is a group of disorders characterized by increased intraocular pressure (IOP) sufficient to cause loss of vision. This definition has recently evolved, however, and currently isolated increased IOP is not considered to constitute glaucoma; rather it is the resulting damage to the optic nerve that defines the disease (1,2). Visual change, pain, or elevated IOP without signs of injury to the optic nerve is now termed *acute angle-closure crisis* (AACC) rather than acute angle-closure glaucoma (AACG) (2,3).

The underlying pathologic mechanisms of AACG, increased aqueous humor production and decreased aqueous humor outflow, cause varying degrees of increased IOP. Patients with only mildly elevated IOP can have findings consistent with glaucoma (low-tension glaucoma) whereas patients with significantly elevated IOP may lack criteria for glaucoma (ocular hypertension) (4). Glaucoma is classified in terms of both anatomy of the anterior chamber (angle) and presence or absence of comorbid disease. The anatomic classification describes whether the angle of the anterior chamber is *open* or *closed*. Each anatomic classification may be further subdivided into *primary* or *secondary* depending on the absence or presence, respectively, of pre-existing disease (4). Primary AACG is particularly important to the emergency physician, as it carries a high rate of visual morbidity if not quickly diagnosed and treated. Glaucoma is the second most common cause of blindness worldwide (5).

ANATOMY AND PATHOPHYSIOLOGY

The eye is a complex organ controlled by opposing effects from the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS). Stimulation of the ciliary body receptors (β1) results in production of aqueous humor. The aqueous humor flows from the posterior chamber to the anterior chamber via the space between the posterior surface of the iris and the lens (Fig. 61.1). The area of this opening varies with miosis, mydriasis, and accommodation. The muscles controlling these functions also affect the trabecular meshwork in the anterior chamber angle and, thus alter the opening of the canal of Schlemm.

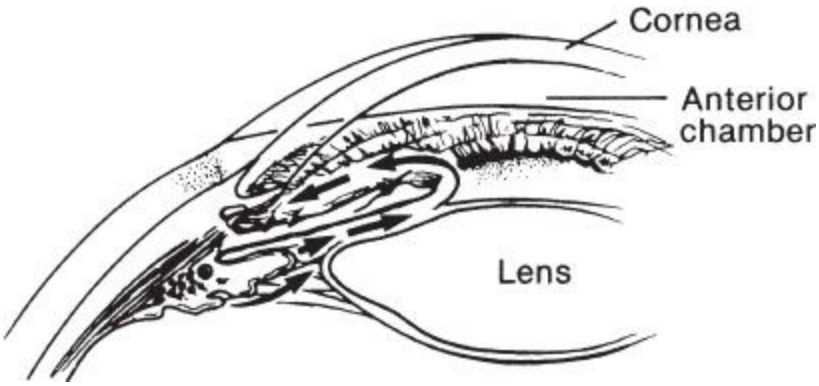

FIGURE 61.1 Normal anterior chamber angle. Aqueous passes from the posterior chamber through the pupil into the anterior chamber and out through the trabecular meshwork.

The iris contains two muscle groups, the radial and circular, whereas the ciliary body contains one group, the ciliary muscle. The radial muscle, which contains α_1-receptors, contracts when stimulated by the SNS, resulting in mydriasis. The circular muscle of the iris and the ciliary muscle both contain muscarinic receptors under the control of the PNS. Stimulation of the circular muscle causes contraction and thus miosis. Ciliary muscle contraction reduces the tension on the zonules of Zinn, thereby reducing tension on the lens. Zonule laxity allows the lens to “round up” for accommodation of near vision; however, this also increases the contact between the lens and posterior iris, potentially inhibiting

flow of aqueous humor from the posterior to the anterior chamber. Conversely, relaxed tension on the meshwork reduces resistance to outflow at the angle by enhancing the opening from the anterior chamber into the canal of Schlemm.

Elevated IOP in glaucoma most often results from an obstruction to aqueous outflow rather than excessive production (6). Obstruction to outflow from the anterior chamber occurs in both open-angle glaucoma and AACG. The location and mechanism of the resistance to outflow distinguish these two conditions. In open-angle glaucoma, the trabecular meshwork of the anterior chamber angle remains open, but the aqueous humor is unable to reach the canal. In AACG, the peripheral iris contacts the trabecular meshwork and blocks the flow of aqueous into the canal.

Several anatomic features predispose an eye to AACG, and patients may have any combination of risk factors. A shallow anterior chamber results in increased baseline narrowing of the entrance to the angle, with a greater area of contact between the lens and iris. This lens-to-iris apposition impedes the flow of aqueous from the posterior chamber to the anterior chamber through the pupil, produces a forward bowing of the peripheral iris, and effectively closes the angle (Fig. 61.2). Those with a shallow anterior chamber angle, at increased risk for the development of AACG, include the elderly, women, patients of Asian or Inuit descent, and farsighted patients (2,4,5,7). A pharmacologic or physiologic event in a susceptible person typically triggers an attack of acute angle closure by upsetting the equilibrium of aqueous humor dynamics.

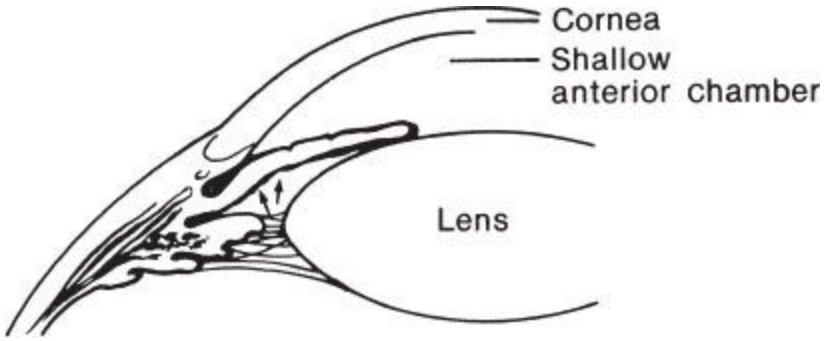

FIGURE 61.2 Angle closure with pupillary block. The angle is closed as the iris is pushed up against the trabecular meshwork.

Pupillary dilatation frequently precipitates an attack of acute angle closure. As the pupil dilates, the peripheral iris becomes more flaccid and may be pushed against the trabecular meshwork, blocking aqueous outflow. This may occur when a person is in a dimly lit environment or under emotional stress perhaps due to increased sympathetic tone. Medications that stimulate α_1- and/or β_1-receptors (sympathomimetics) and those that oppose M3 receptors (anticholinergics) cause pupillary dilatation and may precipitate AACC (Table 61.1) (3,4,8).

TABLE 61.1
Common Pharmacologic Preparations That May Precipitate AACG

Sympathomimetics
Prescription Sympathomimetics
Epinephrine compounds, norepinephrine compounds, levarterenol, terbutaline, amphetamine compounds, apraclonidine, phenylephrine, albuterol
Nonprescription Sympathomimetics
Propylhexedrine, naphazoline, tetrahydrozoline, tyzine, oxymetazoline, pseudoephedrine
Monoamine Oxidase Inhibitors
Tranylcypromine, phenelzine, isocarboxazid
Anticholinergic Activity
Mydriatic and Cycloplegic Agents
Ipratropium bromide, atropine, scopolamine, homatropine, cyclopentolate, tropicamide
Antispasmodics
Dicyclomine, oxyphencyclimine
Antipsychotics
Chlorpromazine, thioridazine, trifluoperazine, haloperidol
Antiemetics
Chlorpromazine, prochlorperazine, promethazine
Antihistamines
Diphenhydramine, dimenhydrinate, chlorpheniramine, brompheniramine, hydroxyzine, meclizine
Tricyclic Antidepressants
Imipramine, amitriptyline, doxepin, nortriptyline, desipramine
Selective Serotonin Reuptake Inhibitors
Paroxetine, venlafaxine, citalopram, escitalopram
Miscellaneous Agents
Trihexyphenidyl, topiramate, benztropine, ethopropazine

CLINICAL PRESENTATION

Most patients present with a complaint of sudden onset of severe pain localized to the orbit, or brow or more generally with a severe headache, often associated with nausea and vomiting. Occasionally, the presenting clinical picture is more systemic than ocular, leading to an erroneous or missed diagnosis (9). The physician should consider AACG in patients with headache and high-risk patients

with undifferentiated gastrointestinal illness. Blurred vision or the appearance of rainbow-colored halos around lights may occur shortly after the onset of pain (Table 61.2).

TABLE 61.2
Diagnosis of AACG

History
Acute onset of pain
Exposure to dim illumination at symptom onset (i.e., movie theater)
Emotional upset or fatigue
Precipitating medications (anticholinergics, sympathomimetics)
Symptoms
Pain
Blurred vision/halos around lights
Nausea/vomiting
Signs
Conjunctival injection
Corneal edema (light reflex irregular or steamy appearance)
Middilated, nonreactive pupil
Narrow anterior chamber (only temporal half of iris illuminated on flashlight test)
Anterior chamber cells may be present, but no keratic precipitates
Elevated IOP

The patient with AACC has a unilateral red eye with congested episcleral and conjunctival blood vessels, a nonreactive middilated pupil, corneal edema, a shallow anterior chamber, and a high IOP (Fig. 61.3). The IOP is elevated, usually ranging between 60 and 90 mm Hg (IOP <21 mm Hg is considered normal). If the attack has been prolonged, however, the IOP may be lower, due to ciliary body ischemia and decreased aqueous production. Corneal involvement varies with the duration of the attack but is often hazy or steamy appearing from epithelial edema. The anterior chamber appears shallow. Although mild anterior chamber inflammation is common, keratic precipitates (aggregates of white blood cells) on the corneal endothelium are not a typical finding.

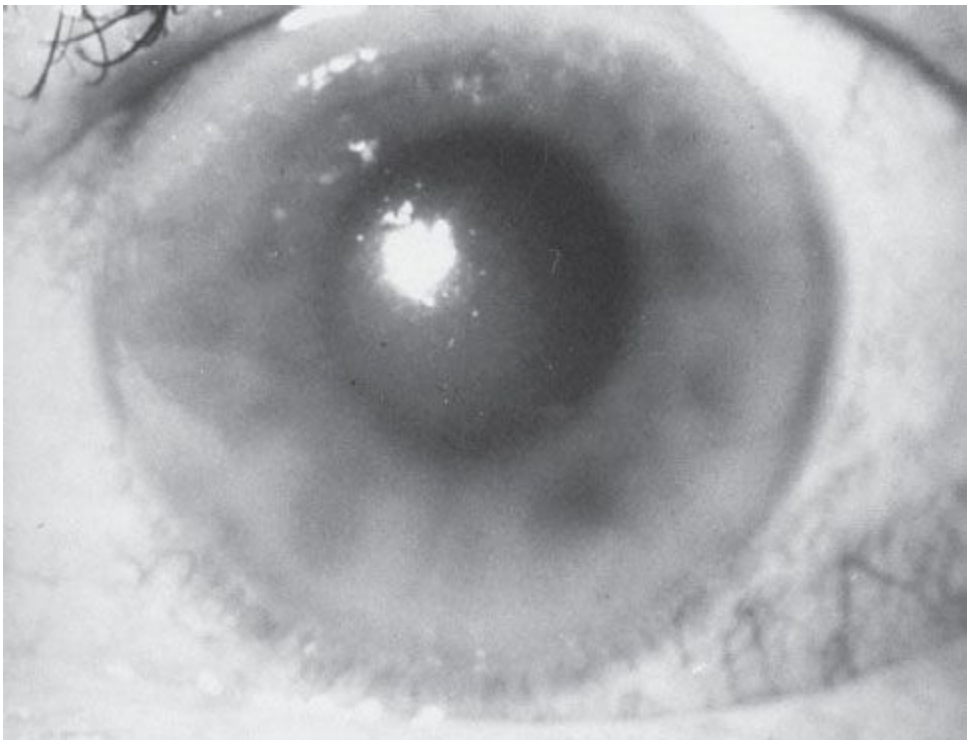

FIGURE 61.3 This eye demonstrates the hallmarks of acute angle-closure glaucoma: perilimbal injection, corneal edema, and a middilated nonreactive pupil.

The course of untreated AACG varies. An attack may damage the optic nerve as well as the corneal endothelium, lens, and retinal ganglion cell layer. In some undiagnosed patients, the attack will continue and, if untreated, can result in permanent blindness within 2 to 3 days. Visual prognosis improves with the initiation of prompt, effective treatment, but any damage to the optic nerve is irreversible.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the acutely painful red eye is extensive and is described in detail in Chapter 56. Because headache, nausea, and vomiting may be dominant symptoms in glaucoma, the differential should also include central nervous system and gastrointestinal disorders. Most conditions are readily distinguished by a careful history and physical examination. Other ophthalmic disorders that more closely mimic AACG are the secondary

glaucomas: glaucomatocyclitic crisis, neovascular glaucoma, glaucoma secondary to iritis or uveitis, and lens-induced glaucoma.

Glaucomatocyclitic crisis produces recurrent attacks of visual blurring and halos but, in contrast to AACG, pain is not a prominent feature. In addition, the anterior chamber is deep and keratic precipitates develop on the cornea after 2 to 3 days (10).

Neovascular glaucoma presents with a chief complaint of a painful red eye months after vision impairment in the affected eye. It is usually associated with disorders such as, diabetic proliferative retinopathy and retinal vascular occlusion. Retinal hypoxia serves as the underlying stimulus for neovascularization. If the condition progresses, a fibrovascular membrane may obstruct the drainage angle, leading to secondary AACG (4).

Acute iritis with secondary glaucoma presents with ocular pain, photophobia, and blurred vision. The onset is gradual in contrast to AACG. Clinical findings may mimic angle closure, with perilimbal conjunctival injection and corneal edema. However, a miotic pupil, keratic precipitates, and a deep anterior chamber differentiate acute iritis with secondary glaucoma from AACG.

Phacolytic glaucoma presents similarly to AACG, but the anterior chamber depth (ACD) is normal and there are cells in the anterior chamber. Keratic precipitates are also present, and a mature or hypermature cataract can be seen. The cause of phacolytic glaucoma is the release of soluble lens protein into the aqueous, which leads to elevated IOP when it occludes the trabecular meshwork and canal (4,11).

Lens particle glaucoma is associated with spontaneous or traumatic disruption of the lens capsule. As with acute iritis and phacolytic glaucoma, the anterior chamber is of normal depth. In addition, the pupil is often miotic, and lens cortical material is present in the anterior chamber. The particulate lens material reduces outflow in the trabecular meshwork, with resultant increased IOP (4,11).

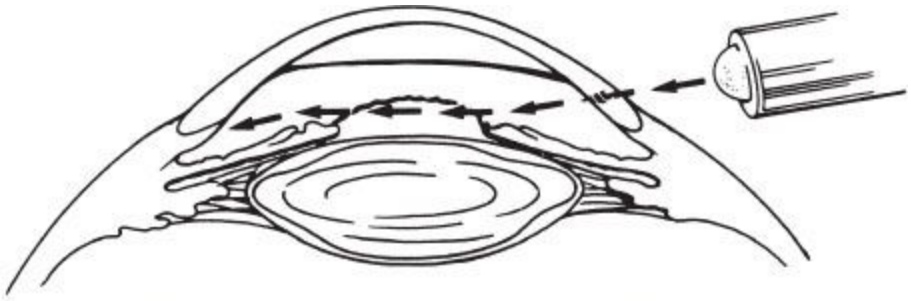
ED EVALUATION

A careful history is an essential part of the ED evaluation and should include *onset* of symptoms (sudden, gradual, subsequent to accidental or surgical trauma); history of similar symptoms previously (brief episodes of pain, blurred vision, and/or halos around lights); *visual impairment* in the affected eye and the unaffected eye; *pain* in or around the eye; *discharge* or secretions from the eye; and a detailed *medication history*.

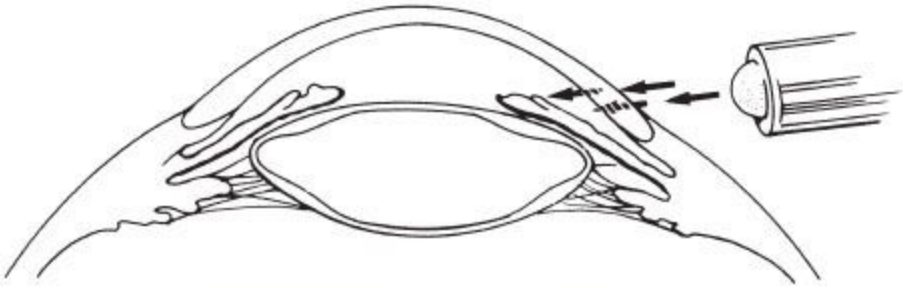
The ocular examination is described in detail in Chapter 54. The following aspects of the ocular examination deserve special emphasis in relation to AACC and glaucoma. *Visual acuity* is probably one of the most important evaluations done during any ocular examination. If a distance or near visual acuity cannot be recorded owing to inability to read the chart, the following should be recorded (including the distance at which each is tested): finger counting, and the presence or absence of perception of hand motion and light. *Conjunctival injection* is often present but is nonspecific. The pattern of injection, however, may be helpful. Perilimbal injection suggests acute iritis or angle closure. Segmental injection characterizes episcleritis; diffuse injection is typical of keratoconjunctivitis. Finally, the presence of purulent discharge suggests an infectious cause. *Corneal edema* is apparent in many cases of AACG and is due to the rapid rise of IOP. Assessment of the *ACD* is essential in the evaluation of the painful red eye and in the diagnosis of AACG. In the ED setting, an adequate estimation of the ACD can be accomplished with the oblique flashlight test and slit-lamp examination.

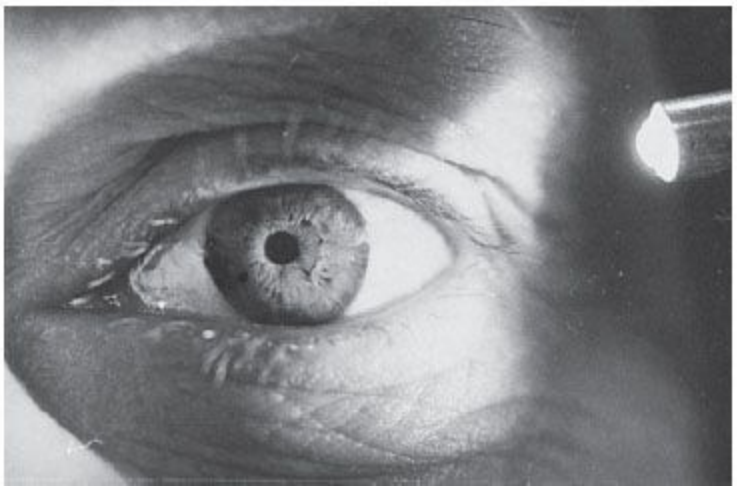
Oblique Flashlight Test

In this test (Fig. 61.4), the examiner shines the light across the eye from the temporal side toward the pupil. In an eye with a normal depth anterior chamber, the entire iris is illuminated. In an eye with a narrow angle or shallow ACD, a shadow is cast on the nasal side of the iris (12).



A





B

FIGURE 61.4 Flashlight test for wide and narrow angles. A: Wide angle: Entire iris is illuminated. B: Narrow angle: Only temporal half of iris is illuminated. (Photo courtesy of D. R. Anderson, MD.)

Slit-Lamp Examination

The ACD can also be estimated during the slit-lamp examination. A narrow beam of light is directed obliquely at the surface of the iris. The corneal thickness is estimated, as is the distance between the corneal beam and the iris beam, and the ACD is calculated. If the peripheral ACD is less than one-fourth the thickness of the adjacent cornea, the angle is narrow and at risk of occlusion (4,12,13).

The size and shape of the *pupil* and pupillary reaction to light are recorded for each eye. Unequal pupil size (anisocoria) should be noted. A middilated, nonreactive pupil is characteristic of AACC and glaucoma. In contrast, many other conditions have a miotic pupil that is minimally reactive.

A mature (opaque) or hypermature (liquid cortex) *lens* may be associated with lens-induced glaucoma. Phacodonesis, movement of the lens, indicates a dislocated or subluxed lens. This may occur secondary to trauma, or it may be part of a systemic syndrome such as Marfan syndrome. A dislocated lens can increase pupillary block and result in a secondary ACG (11).

Intraocular Pressure

The range of IOP considered normal is 10 to 21 mm Hg, although the actual range found in population studies is dependent on a number of factors and varies significantly among different ethnicities (14). Three commonly used tonometers available in the ED are the air-puff noncontact tonometer, the Schiötz tonometer, and the Tono-Pen. The Goldmann applanation tonometer is frequently used by ophthalmologists and is considered the gold standard for measurement of IOP.

Air-Puff Noncontact Tonometer

The air-puff tonometer has the advantage of measuring the IOP without the application of topical anesthesia or contact between the instrument and the eye. A puff of air is blown against the cornea and the instrument records the force needed to flatten the cornea and displays the correlated IOP (4,15).

Schiötz Tonometry

Schiötz, or indentation, tonometry determines IOP by measuring the indentation of the cornea produced by a known weight. The patient is placed in a supine position and a drop of a local anesthetic is instilled. The patient is asked to look upward and fix on some object in the distance. While separating the eyelids, the instrument is gently placed in a vertical position directly over the cornea. The plunger is allowed to rest completely on the eye. With the instrument held steady, the pointer will stay fixed at a value on the scale. Each instrument is accompanied by a conversion table that expresses the scale readings in mm Hg. Inadvertent pressure on the globe can result in a falsely elevated reading. Scleral rigidity and corneal thickness can affect the measurement (4).

Tono-Pen

A handheld electronic applanation tonometer, the Tono-Pen is frequently used in EDs. After initial calibration, the sheathed tip of the Tono-Pen is repeatedly tapped on the anesthetized cornea. The instrument calculates and displays the average of 4 to 10 readings, as well as variability percentages (4). The Tono-Pen generally correlates well with Goldmann applanation tonometry, but the Tono-Pen underestimates IOP when it is high and overestimates IOP when the pressure is low (4,16).

Goldmann Applanation Tonometry

In applanation tonometry, the cornea is flattened and the instrument measures the area flattened and the force required to do so. A local anesthetic and fluorescein are instilled. Correctly positioned at the slit lamp, the patient looks straight ahead. Illuminated by the cobalt blue light, the examiner gently contacts the anterior corneal surface

with the tip of the Goldmann tonometer (Fig. 61.5). On contact, two fluorescein semicircles are seen. A calibrated dial is then adjusted until the semicircles are aligned such that the inner borders of each semicircle match up. The IOP is estimated from the value displayed on the dial (4).

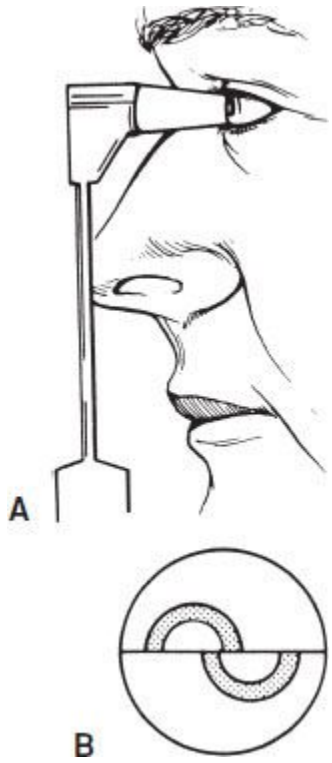


FIGURE 61.5 Applanation tonometry. A: The tonometer tip should just contact the patient's cornea. B: Viewed through the slit lamp are two fluorescent semicircles aligned edge to edge.

KEY TESTING

- Visual acuity
- ACD (use slit lamp or oblique flashlight test)
- IOP

ED MANAGEMENT

AACC, as the name suggests, is an ophthalmic emergency. Once the diagnosis has been established in the ED, the immediate goal is twofold: to obtain appropriate consultation with an ophthalmologist

and to begin treatment to decrease the IOP. The latter is directed at decreasing aqueous production, increasing aqueous outflow, and reducing vitreous volume with dehydrating agents. A combination of topical agents and systemic medications directed toward these three goals is often effective in reducing IOP and is first-line therapy (17). A number of agents can be used to acutely lower the IOP, but these medications are not without side effects and treatment should be tailored to each patient's medical status.

Topical Therapy

Timolol Maleate

Timolol maleate is a nonselective β-blocker that lowers IOP by decreasing the production of aqueous humor. It should be used with caution in patients with contraindications to β-blockers, such as asthma, heart block, and heart failure, as systemic absorption may occur. Side effects include bronchospasm, decreased pulse rate, and altered mental status. The recommended dosage is timolol 0.5% solution, one drop at 5-minute intervals initially for three doses, and then one drop every 12 hours.

Pilocarpine Hydrochloride

Pilocarpine is a direct-acting parasympathomimetic agent that causes miosis by stimulation of M3 receptors in the iris. Miosis improves the mechanical obstruction in AACG because the iris is pulled taut and away from the trabecular meshwork. Systemic side effects such as sweating, tremors, bradycardia, and hypotension, though uncommon, have been observed as a result of excessive administration of pilocarpine. Pilocarpine may be ineffective if IOP is more than 50, in which case its application can be delayed until the IOP is lowered with other agents (4). The recommended dosage is pilocarpine 2%, two drops every 5 minutes until the pupil constricts, and then one drop every 6 hours.

Apraclonidine

Apraclonidine is a topical α-2 agonist used in chronic glaucoma; it lowers IOP by reduction of aqueous humor production by an

indirect sympatholytic mechanism. Its effects are additive to those of topical β-blockers. Success in AACG treatment has also been reported, and its use should be considered (18). The recommended dosage is apraclonidine 1% solution, one drop every 5 minutes for three doses.

Prednisolone Acetate
Topical corticosteroids reduce inflammation and may be recommended by an ophthalmologist. Steroids may be used as a bridge to surgery. The recommended dosage is prednisolone acetate 1%, one drop every 30 to 60 minutes until surgical treatment is completed.

Topical Prostaglandins
Topical prostaglandin drops are thought to decrease pressure by increasing outflow of aqueous humor. The recommended dose is latanoprost 0.005% solution, one drop daily (19).

Systemic Therapy

Acetazolamide
Acetazolamide is a carbonic anhydrase inhibitor that inhibits aqueous humor formation. Because respiratory acidosis can occur with the use of carbonic anhydrase inhibitors, the drug should be avoided in patients with significant respiratory disease. Hypokalemia can also be seen with acute therapy and should be appropriately monitored. The recommended dosage for treating AACG is acetazolamide 500 mg IV every 12 hours or 500 mg PO every 6 hours.

Mannitol
Mannitol is a hyperosmotic agent that lowers IOP by increasing the serum osmolality, thus creating a gradient between the blood and the vitreous, and drawing water from the vitreous cavity. The recommended dosage is mannitol 20%, 1 to 2 g/kg IV over 30 to 60 minutes.

Glycerol and Isosorbide

Glycerol and isosorbide are hyperosmotic agents that can be administered by mouth in patients who are able to tolerate oral medications. Glycerol should be avoided in diabetic patients because it can produce hyperglycemia and ketosis. The recommended dosage is glycerol 50%, 1 to 1.5 g/kg PO (on ice with juice) or isosorbide 45%, 1.5 to 2 g/kg PO (4).

Corneal Indentation

When the IOP is higher than 50 mm Hg, topical miotics such as pilocarpine may be ineffective owing to ischemia of the iris constrictors (4). In this situation one might consider a maneuver to lower IOP known as corneal indentation. As the cornea is indented, the aqueous is displaced peripherally, temporarily opening the angle. This results in a prompt decrease in IOP. Typically, a cotton-tipped applicator, a glass rod, or an applanation prism is used, although any smooth instrument is appropriate (20). After application of a topical anesthetic, the tool is used to apply firm pressure to the inferior part of the cornea in 30-second intervals (30 seconds on 30 seconds off). The IOP is typically decreased after 3 to 4 cycles. Corneal indentation applied to the superior aspect of the cornea may result in epithelium disruption, complicating laser peripheral iridotomy (21).

Surgical Therapy

The definitive treatment of ACG is surgical release of pupillary block. Peripheral laser iridotomy has largely replaced incisional iridectomy due to its low-risk profile and ease of performance (20). In cases where the laser equipment is not readily available and the patient is refractory to medical management, the ophthalmologist may choose to perform an anterior chamber paracentesis to avoid further delays in lowering the IOP. At times, it is necessary to perform a surgical iridectomy emergently when the IOP is medically unresponsive and in which corneal clouding prevents laser iridotomy. Argon laser peripheral iridoplasty and lens extraction are other measures used in specific cases of ACG (20). The unaffected

eye should be examined for an anatomically narrow chamber and if present, prophylactic iridotomy is generally performed, since half of patients with AACG will have an attack in the other eye within 5 years (2).

CRITICAL INTERVENTIONS

- Initiate therapy to reduce the IOP.
- Consult an ophthalmologist in all cases of AACC and AACG.

DISPOSITION

AACG is an ophthalmic emergency, and an ophthalmologist should be consulted immediately.

Owing to vagal stimulation as a consequence of the rapid and severe elevation of IOP, patients with AACG are often systemically ill and require admission. Analgesic and antiemetic agents should be given if there is severe pain, nausea, or vomiting.

Parenteral administration of medications should be carried out in the hospital so that the patient can be closely observed for possible adverse reactions. Initially, IOP should be monitored every 30 minutes. If the eye is responding and IOP is decreasing, IOP can be measured every 1 to 2 hours while treatment is continued. However, if the eye is not responding well to medical maneuvers and the IOP remains elevated, laser iridotomy or iridoplasty should be performed by the ophthalmologist as soon as possible.

If emergent consultation with an ophthalmologist is unavailable at the initial hospital, therapy should be initiated and the patient should be transferred expeditiously, since delays in treatment are detrimental to the visual prognosis.

Common Pitfalls

- Failure to consider the diagnosis of AACG and to check IOP.
- Failure to obtain specialty consultation. Any patient with a painful red eye and decreased vision has an ophthalmic emergency and requires prompt consultation with an ophthalmologist.

SECTION VI
ENT and Dental Emergencies

Section Editor: GREGORY W. HENDEY

CHAPTER 62 Dental Emergencies

Rawnica L. Ruegner

Dental emergencies prompt almost 3 million emergency department (ED) visits nationally, accounting for 0.7% of all ED patients (1). Factors such as poverty, a lack of dental insurance or a primary care dentist, and difficulty finding an "off-hours" dental clinic have contributed to an increasing number of patients with dental-related complaints presenting to emergency physicians (2,3,4). Despite the common nature of dental-related complaints, many physicians receive little training on dental emergencies (5).

This chapter addresses the common nontraumatic dental emergencies. Dental trauma and odontogenic infections of the face are covered elsewhere.

DENTAL ANATOMY

Human teeth are composed of three layers. The outermost layer, enamel, is an extremely hard protective cover that contains no nerve fibers. Enamel covers the visible portion, or crown, of the tooth. The corresponding outer layer in the portion of the tooth embedded in the gum or root is known as cementum and is much softer than enamel. Under the enamel and cementum is dentin, and at the center of the tooth is the pulp chamber through which the nerves and blood vessels connect to the alveolar bone. The tooth sits in a socket with relatively long apices extending into the bone. The tooth is anchored to the bone by the periodontal ligament.

The first set of teeth, known as primary or deciduous dentition, should be completely erupted by 3 years of age. This set consists of

10 maxillary and 10 mandibular teeth. The permanent teeth begin erupting at around 5 years of age. This set consists of 32 teeth divided equally into four quadrants (right upper, right lower, left upper, left lower). In each quadrant, there is a central incisor, a lateral incisor, a canine, two premolars, and three molars. The third molar is called the *wisdom tooth* and may not be visible if it failed to erupt or has been therapeutically removed. Several numbering systems have been developed to identify a specific tooth. The most commonly used system numbers the permanent teeth consecutively beginning with the upper right third molar (tooth 1), to the upper left third molar (tooth 16), then down to the lower left third molar (tooth 17), and across to the lower right third molar (tooth 32). Other numbering systems exist, and some patients will have teeth missing, which may make numbering difficult. Generally, physicians should simply describe the tooth involved, for example, the left upper second premolar.

The biting area of a tooth is the occlusal surface for molars or incisal surface for the incisors. In the direction of the occlusal or incisal surface is coronal and in the direction of the root is apical. The medial or mesial aspect faces toward the midline of the jaw, and the distal surface faces the ramus of the mandible. The portion of the tooth facing the tongue or palate is the lingual or palatal surface. The portion facing away from the tongue is the labial or buccal surface. The portion of the tooth in contact with an adjacent tooth is the interproximal surface.

The Dental Examination

Patients with dental complaints should first be examined for possible nondental causes of their symptoms. An examination of the external facial structures and neck can detect swelling, cellulitis, or odontogenic fistulae. When performing the intraoral examination, look first for trismus (restricted opening of the mouth) and for swelling of the tongue or lips. Examine the mouth for asymmetry, swelling, or signs of cellulitis. Determine that the uvula is midline and not shifted as a result of abscess formation. Confirm that the

tongue is not elevated and that the floor of the mouth is not tender or indurated (signs of Ludwig angina). Examine the teeth looking for signs of caries. Pay particular attention to the junction of the tooth and the socket, where foreign bodies can lodge. The tissue adjacent to the tooth along the alveolar bone should be examined carefully, because odontogenic abscesses typically form in this area. The gum overlying absent molars should be examined for evidence of erupting teeth (usually the wisdom tooth). Each tooth can be gently percussed, preferably with the end of a dental mirror, though a tongue depressor will suffice.

DENTAL ANESTHESIA

Patients with severe dental pain may require anesthesia for either temporary pain relief or for painful procedures such as incision and drainage of a periodontal abscess. Topical anesthesia of the mucosa can be achieved within 2 to 3 minutes by the application of a cotton swab soaked in 20% benzocaine or 10% lidocaine. This anesthesia can lessen the pain of needle injection for further anesthesia and, in some cases, may provide adequate anesthesia for incision and drainage of a superficial abscess. An individual tooth may be anesthetized by infiltration of lidocaine (2% with 1:100,000 epinephrine) or bupivacaine (0.5% with 1:200,000 epinephrine) at the root of the tooth using a supraperiosteal injection. Mandibular teeth may be anesthetized by blocking the inferior alveolar nerve where it enters the lower mandible. Dental blocks generally last between 1 and 7 hours depending on the anesthetic and choice of procedure (6).

CLINICAL PRESENTATION

Caries and Pulpitis

Among the most common dental conditions is dental caries, or “cavities.” As oral bacteria ferment dietary carbohydrates, an acid is formed, which demineralizes the tooth enamel. This demineralization initially is asymptomatic, until the erosion intrudes on the tooth pulp, resulting in inflammation (pulpitis). Caries

appear as either a whitish gray discoloration of the enamel or as a brownish visible defect of the enamel surface. Pulpitis, or inflammation of the pulp of the tooth, causes significant pain, which depends upon the extent of inflammation. Early or reversible pulpitis causes relatively well-localized pain that is usually triggered by hot, cold, or sweet stimuli, usually lasts only a few seconds, and resolves spontaneously. Late or irreversible pulpitis results in poorly localized, severe, and persistent pain.

Periodontitis

If the inflammation of the pulp goes unabated, it will extend to the tooth apices, expand outward from the pulp, and cause apical periodontitis. The pain of periodontitis is severe, persistent, and localized to a particular tooth (unlike irreversible pulpitis, which is usually poorly localized). Periodontitis usually results in a tooth sensitive to percussion.

Peri-Implantitis

Recent advances in reconstructive dentistry may cause patients to visit the ED with problems relating to their dental implants. These patients present similarly to those with periodontitis.

Abscess and Cellulitis

Should periodontitis progress unchecked, the inflammation may extend laterally from the tooth apex to cause an apical abscess. Alternatively, an abscess can form in the absence of dental caries when inflammation begins at the junction of the tooth and gum line, extends down the tooth apices, and involves the periodontal ligament and adjacent alveolar bone. This is termed a *periodontal abscess* and results from either chronic bacterial plaque (periodontal disease) or a foreign body lodged between the tooth and gum. Clinically, both abscesses appear as a small fluctuant swelling located adjacent to the involved tooth. The swelling may appear tense and painful or it may be draining pus. Periodontal abscesses

may result in teeth that are somewhat mobile due to bone destruction. The area surrounding the abscess should be examined for evidence of cellulitis.

Pericoronitis

A partially erupted molar creates a potential space between the occlusal surface of the tooth and the gingiva through which the tooth protrudes. If plaque or food particles become lodged in this space, the overlying mucosal flap will become inflamed. Pericoronitis presents as a painful, tender area over a partially erupted tooth often accompanied by a foul taste or odor due to extruded pus.

Gingivitis

Gingivitis is inflammation of the gingiva usually caused by bacterial plaque on the tooth. Simple gingivitis does not typically prompt an ED visit, as it is painless. Gingivitis appears as redness, swelling, and pocket formation of the gingiva. If the inflammation is significant, it can produce some bleeding from the gums after brushing the teeth.

Acute Necrotizing Ulcerative Gingivitis

If bacteria actively invade the gingiva, the inflammation may produce painful, swollen gums often accompanied by fever, malaise, grayish pseudomembranes, lymphadenopathy, a foul odor, and a metallic taste. This disorder is commonly called *trench mouth* and may be facilitated by immunocompromise or physiologic stressors.

Gum Hyperplasia

Unusual gum swelling may rarely prompt an ED visit. In addition to gingivitis and acute necrotizing ulcerative gingivitis (ANUG), other conditions that may cause generalized gingival hyperplasia or swelling include acute leukemic infiltration and drug-induced hyperplasia (most commonly phenytoin and nifedipine).

Postextraction Bleeding

Teeth are commonly removed for therapeutic reasons, and postextraction bleeding is a frequent complication. Although life-threatening hemorrhage may occur, most patients present with persistent oozing from the extraction site. In patients with acquired or congenital bleeding disorders, bleeding may be persistent and difficult to stop.

Alveolar Osteitis ("Dry Socket")

Following a tooth extraction, some sockets may lose the protective clot prematurely, exposing the socket down to the bone. Typically, patients present 3 to 5 days following the extraction with severe localized pain. Some patients complain of a foul odor or taste. Physical examination shows a nontoxic-appearing patient without signs of infection. The extraction site usually is unimpressive. In contrast, postextraction osteomyelitis often is associated with fever, malaise, leukocytosis, and the surrounding teeth and bone may be sensitive to palpation. A radiograph is usually indicated to rule out retained roots or foreign bodies.

Oral Candidiasis

Candidal infections of the mouth are relatively common, especially among children and the immunocompromised. Painful white plaques are present that typically can be easily scraped off to show an erythematous underlying mucosa.

Aphthous Stomatitis

Many individuals will experience painful recurrent oral ulcers. Aphthous stomatitis is a common cause, though ulcers from hand-foot-and-mouth disease, herpangina, and herpetic gingivostomatitis may appear similar. While most aphthous ulcers are <5 mm, they may coalesce to form large lesions. These ulcers are self-limited and rarely are complicated by a localized cellulitis requiring antibiotic therapy.

Herpetic Gingivostomatitis

In children younger than 5 years old, a primary herpes virus infection (herpes simplex type 1) may present with multiple painful, ulcerated vesicles in the oropharynx. Often there is accompanying fever, lymphadenopathy, erythema, and edema. Although the primary infection lasts about 2 weeks, recurrences are common, though these usually present with a lesion at the border of the lip. Eruptions are generally self-limited.

Other Systemic Diseases

Several systemic diseases can present with oral lesions, though most are nonspecific. Systemic lupus erythematosus, scleroderma, Wegener granulomatosis, pemphigus vulgaris, Stevens–Johnson syndrome, Behçet syndrome, varicella zoster, and several neoplasms all can present with oral manifestations.

DIFFERENTIAL DIAGNOSIS

Although most patients with apparent dental complaints ultimately are diagnosed with relatively minor conditions, a few will have a serious illness. Perceived dental pain can result from sinus infections, temporomandibular joint dysfunction, otitis media, migraine headaches, neuritis, or myocardial ischemia. A dental infection can occasionally spread to the cavernous sinus, face, mouth, or throat, causing a potentially life-threatening complication.

ED EVALUATION

The evaluation of the patient with dental pain begins with a relevant history and physical examination to determine if the complaint is truly odontogenic in nature. A history of recent dental procedures, medication allergies, and anticoagulant medications is particularly important. Radiographs may be helpful in the evaluation of some patients in a search for retained roots or foreign body after a dental procedure. Computed tomography (CT) scanning

is indicated if one suspects the extension of an infection to the cavernous sinus, neck, or deep spaces.

KEY TESTING

- Consider radiographs for suspected foreign body, or CT scan for deep space infection.

ED MANAGEMENT

The treatment of asymptomatic dental caries and reversible pulpitis is a dental filling, and irreversible pulpitis requires root canal therapy. In the ED, patients with dental pain caused by pulpitis or periodontitis should receive pain medications and a referral to a dentist. Pain medications may include a nonsteroidal anti-inflammatory drug (NSAID), acetaminophen, or a mild narcotic. Antibiotics are not necessary for simple caries, but there are diverging opinions on their role in periodontitis. Treatment of peri-implantitis consists of irrigation with saline or 0.12% chlorhexidine, antibiotic therapy for 10 days, pain medication, and referral to a dentist (7).

A large apical abscess may be incised and drained following appropriate anesthesia of the area, usually accomplished with a dental block or topical anesthesia. Smaller abscesses, especially in children, may respond to antibiotics alone. The use of antibiotics for drained abscesses without accompanying cellulitis is controversial. Some authorities recommend antibiotics (4,8), and others do not (9). As many as two-thirds of dentists in one study prescribed antibiotics liberally (10). If the cellulitis is relatively minor and localized, oral medications are appropriate, typically penicillin V potassium 500 mg/qid (or erythromycin 500 mg/qid for patients with penicillin allergy). Patients who do not respond to initial treatment within 3 days should be switched to clindamycin 300 mg/qid.

Patients with apical abscesses or cellulitis treated as an outpatient should be referred to a dentist within 1 to 2 days. For cellulitis that is severe, has spread into the deep spaces of the face or neck, or is

associated with a toxic appearance or an immunocompromised patient, hospital admission and parenteral antibiotics are recommended. These antibiotics are typically clindamycin 600 to 900 mg intravenously (IV) every 6 hours or ampicillin/sulbactam 1.5 to 3 g IV every 6 hours. If significant cellulitis is present, CT scanning of the involved areas should be performed to rule out deep space infection. Remember that incision and drainage of a dental abscess may lead to transient bacteremia, so antibiotics should be given for prophylaxis against endocarditis for individuals at risk.

Pericoronitis should be treated with mechanical irrigation under the flap following appropriate anesthesia. Some sources recommend antibiotic treatment with penicillin, erythromycin, or clindamycin in the same dosing regimens as noted previously. Patients should receive pain medications and follow up with a dentist within 48 hours. Cellulitis or abscess-accompanying pericoronitis should be evaluated and treated as discussed previously.

ANUG may be treated with systemic antibiotics and rinses with warm saline or 3% hydrogen peroxide. Improved oral hygiene is mandatory and may require prescription analgesics to alleviate the pain. Viscous lidocaine may also assist with pain relief and improve oral hygiene. ANUG requires referral to a dentist.

Postextraction bleeding can usually be stopped by having the patient bite down for 10 to 15 minutes on gauze placed over the site. Arterial bleeding may require ligation of the artery, a procedure that can be difficult without proper dental equipment. Patients taking anticoagulants or with bleeding disorders may require reversal, depending on the initial indication for anticoagulation and the extent of bleeding. Oozing that does not stop with direct pressure may require the topical application of procoagulant agents including Gelfoam, Oxycel, Surgicel, or Thrombogen (11).

For alveolar osteitis, the socket should be irrigated with chlorhexidine or warmed saline (12), dried thoroughly, and packed with eugenol-soaked Gelfoam. Analgesics should be prescribed, and the patient should be referred promptly because the packing will usually need to be replaced within 24 hours.

Oral candidiasis may be treated with an oral antifungal agent such as nystatin suspension (100,000 units/mL) (13). Five milliliters is rinsed in the mouth and held as long as possible before swallowing or spitting. Aphthous stomatitis should be treated symptomatically with hydrogen peroxide rinses or diphenhydramine syrup mixed half and half with bismuth subsalicylate (Kaopectate, 2 teaspoons as a rinse as needed). Oral corticosteroids such as triamcinolone may speed healing (Kenalog in Orabase: Dispense 5 mg and apply in a thin layer to the ulcer three times a day), and topical analgesics such as 2% viscous lidocaine or amlexanox (Aphthasol) 5% paste (apply to the lesion up to four times daily) may help with pain (14). *Herpes gingivostomatitis* may also be treated with analgesics such as acetaminophen or ibuprofen, adequate hydration, and oral application of agents such as "magic mouthwash," variably described as a mixture of equal portions of diphenhydramine elixir (12.5 mg/5 mL), 2% lidocaine, and Maalox or bismuth subsalicylate (Kaopectate). For adults with a herpetic prodrome of burning or tingling, antiviral therapy with acyclovir or valacyclovir may reduce the duration or severity of the eruption. Administer acyclovir 200 mg five times a day, valacyclovir 500 to 1,000 mg bid for 5 days, or valacyclovir 2,000 mg bid for 1 day (15).

CRITICAL INTERVENTIONS

- Treat dental infections and abscesses with incision and drainage as needed and antibiotics when appropriate.
- Provide adequate analgesia by using medications and/or dental blocks.

DISPOSITION

Most patients with dental disorders may be successfully treated and discharged from the ED with appropriate dental follow-up. However, as discussed previously, some disorders may necessitate emergent dental consultation or hospital admission, such as abscesses that are large or extending over the face and neck or

postextraction bleeding that cannot be controlled by simple measures.

Common Pitfalls

- Failing to identify a systemic cause, such as myocardial infarction, for face or jaw pain.
- Failing to recognize the spread of an odontogenic infection to the face or neck.
- Failing to ascertain antibiotic allergies before prescribing penicillin or other common dental antibiotics.
- Performing dental procedures prior to antibiotic prophylaxis in a patient at risk for endocarditis.

CHAPTER 63 Head and Neck Infections

Manon Kwon

Infections of the head and neck are both common and potentially life-threatening. Knowledge of the fascial layers and the potential spaces of the neck are important to clinical practice because of the potential complications that may arise.

CLINICAL PRESENTATION

The signs, symptoms, and complications of the infectious disorders of the head and neck are determined largely by the anatomic compartment of origin. The fascial layers serve as important barriers to infection and often determine the path of the spread of infection. In addition, comorbidities frequently found in severe presentations are diabetes mellitus, old age, alcohol abuse, systemic disease, and immunosuppressed states (such as in patients with AIDS or in those undergoing chemotherapy).

Patients with deep neck infections can present in a variety of ways with the most common signs and symptoms being fever, pain, swelling, and a variable period ranging from 1 day to several weeks. Decreased oral intake can result in mild to severe dehydration, and swelling may lead to airway compromise.

Deep neck infections may occur at any age, but there appears to be a somewhat bimodal distribution. Overall there is a predominance in patients over 50 with a higher prevalence in the lower socioeconomic groups mainly due to poor oral hygiene and lack of dental care (2–4,6,7). In pediatric patients, these infections can occur at any age, but most commonly occur between 3 to 5 years of age with a slight male predominance (5).

The most common etiologic sites of infection are the teeth and tonsils. Other common causes are postsurgical and trauma that disrupts the skin and soft tissues. Intravenous drug users can present with jugular vein infections from contaminated injections. Other less common causes include foreign bodies, sialolithiasis, parotid obstruction, osteomyelitis, and epiglottitis. In patients with recurrent deep neck infections, consider underlying congenital anomalies (branchial cleft cysts, lymphangiomas, and thyroglossal duct cysts) (2–7,19).

Although mortality from head and neck infections has decreased significantly since the emergence of antibiotics, resistant organisms are spreading into the community. Most infections are polymicrobial including anaerobic and facultative oral bacteria (5). The most commonly isolated organisms in the head and neck infections are gram-positive aerobes followed by anaerobes, gram-negative aerobes and fungi. *Streptococcus viridans* and *Staphylococci* species dominate the gram positives, while *Klebsiella pneumoniae* and *Neisseria* species are frequently the gram-negative culprits (6). Emergency physicians must also be cognizant that the onset may be insidious secondary to partial treatment with antibiotics.

Facial cellulitis of odontogenic origin usually involves the upper half of the face when the maxillary teeth are the source. Involvement of the middle and lower part of the face and neck suggests a mandibular origin. These infections are generally well contained, but in a compromised host there may be rapid spread of infection, which can be fatal (24,25). Infections that affect the midface are commonly caused by a dental abscess of the anterior maxillary molar teeth and the buccal space. Infections in these areas can lead to cavernous sinus thrombosis because of the pattern of venous drainage, airway compromise, and mediastinal extension (1). Odontogenic sinusitis refers to the secondary infection of the paranasal sinuses originating from dental infection. Although most paranasal sinus infections result from an upper respiratory tract infection, direct spread of the infection from the teeth and associated oral tissues can result in secondary sinusitis. Based on proximity, the maxillary sinuses are most often involved. Symptoms include headache, foul discharge,

fever, weakness, and drainage. Osteomyelitis may complicate odontogenic infection typically involving the premolar soft tissues, maxillary sinuses, infratemporal fossa, or the periorbital region.

Ludwig Angina

Ludwig angina is defined as an infection involving the submandibular, sublingual, and submental spaces with marked elevation of the tongue (2,4,10). A characteristic brawny edema, induration, or board-like swelling is present on the floor of the mouth. Tender and firm anterior neck edema without fluctuance is appreciated on physical examination. Patients may also complain of stridor, drooling, difficulty talking, tachypnea, and tender tongue with abnormal protrusion.

Ludwig angina typically begins as an infection of the second and third mandibular molars (odontogenic), progressing rapidly into tissues that cover the small muscles between the larynx and the floor of the mouth. Hemolytic Streptococcus sp is the most commonly identified organism. Mixed flora can also cause an overgrowth of gas-producing organisms such as *Bacteroides fragilis*. Although Ludwig angina is a cellulitis with diffuse infiltration, subsequent abscess formation is not uncommon. The mode of spread is typically direct and not lymphatic. Thus the infection is classically bilateral, but not always obvious on initial presentation. Ludwig angina may result in a life-threatening airway compromise and obstruction, and these patients tend to be quite toxic.

Mediastinitis

Although the most common cause of acute mediastinitis is esophageal rupture (due to instrumentation, foreign body, or trauma), descending necrotizing fasciitis from the retropharyngeal space, prevertebral space, or other anterior visceral spaces can also spread into the mediastinum. Symptoms include increased respiratory difficulty, tachycardia, chest pain, back pain, erythema/edema of the neck and chest, crepitus, and shock. It is important to have a low threshold for further workup in patients

with these symptoms (12,13,14,16). Comorbid conditions such as diabetes and immunocompromised patients are at higher risk for this severe infection. Mediastinitis may also result from direct extension from an adjacent source of infection, including osteomyelitis of the sternoclavicular joint, pulmonary infections, and spread of granulomatous disease from mediastinal lymph nodes.

Salivary Infections

Salivary infections can develop in three ways: (a) retrograde migration into the duct from the oral cavity, (b) contagious spread of a local infection, or (c) as a suppurative complication of salivary stasis secondary to an obstructing stone. New literature suggests that the infection is polymicrobial, consisting of Streptococcus sp, Staphylococcus sp, aerobes, anaerobes, or viral etiology (mumps, AIDS, influenza, coxsackieviruses) (2,3). Sialoadenitis is a suppurative inflammation of the Stensen duct or the Wharton duct. Infectious parotiditis is often seen in elderly, dehydrated, diabetic, or patients with granulomatous disease. This entity is usually bilateral and associated with fever and a toxic appearance. Drugs with anticholinergic and diuretic properties can contribute to the development of sialoadenitis (6,25).

Lemierre Syndrome

Lemierre syndrome is a form of septic thrombophlebitis, with or without metastatic abscesses, typically involving the internal jugular vein ipsilateral to a neck or throat infection. First described in 1936, however most cases have occurred in the postantibiotic era, and it was termed in 1984 as the “forgotten disease.” However, recent reviews of the literature suggest an increasing incidence. The offending organism is most commonly a Fusobacterium anaerobic gram-negative bacillus, which is part of the normal flora of the mouth. Predisposing factors include trauma, edema, anoxia, or tissue destruction after dental disease (18,20).

Cavernous Sinus Thrombosis

The cavernous venous sinuses are bilateral structures that communicate with the pterygoid plexus as well as the superior ophthalmic vein. Because these sinuses anastomose with facial veins which have no valves, paranasal sinus, odontogenic, and facial infections may spread into the cavernous sinus. Patients with cavernous venous sinus thrombosis often have a history of midface infection for the past 5 to 10 days. Presenting signs and symptoms include headache, fevers, and cranial nerve deficits, specifically CN III to VI. The patient may have orbital pain, visual disturbances, and fullness with periorbital edema or discrete abscess. Other symptoms include confusion, drowsiness, and coma as a result of central nervous system involvement and/or sepsis.

DIFFERENTIAL DIAGNOSIS

In addition to the processes discussed above, the differential diagnosis of head and neck infections is broad and includes simple pharyngitis, dental infections, and referred pain. Tumors may present as nonspecific swelling and can be difficult to differentiate from advanced primary infections. Viral infections involving the salivary glands (e.g., mumps) can present as facial swelling. Less common infections include tuberculous cervical lymphadenitis (scrofula), cytomegalovirus, catscratch disease, and actinomycosis. Failure to respond to conventional therapy should lead the clinician to suspect a complication or an alternative diagnosis. Certain fungal infections, such as mucormycosis, although rare, are more common in the head and neck regions and should be considered in the immunocompromised patient. Autoimmune diseases such as Sjögren syndrome and Mikulicz disease can also lead to facial swelling caused by enlargement of the salivary glands. Trauma-induced swelling (vascular and nonvascular), can also mimic facial infections (4).

ED EVALUATION

The initial evaluation must focus on an assessment of the ABC’s, as some patients with a deep neck infection present in septic shock and require emergent airway management. The patient’s alertness,

posture, work of breathing, stridor, and quality of voice may be assessed in the first few seconds. Once this assessment has been made, more stable patients may have a more detailed physical examination and diagnostic testing.

Protective eyewear, mask, and gloves should be worn when evaluating the oral cavity. Positioning the patient is also important, ideally at a 45-degree angle. Consider examining children on a parent's lap for patient comfort. It is important to have the following equipment readily available: a good light source, a tongue blade, gauze, suction, and a dental mirror. Providing topical anesthesia of the oropharynx may facilitate the examination in some cases. A MacIntosh laryngoscope blade is an excellent tongue depressor and light source for examination and or procedure.

Patients with dental pain should be examined for the presence of infection and localized dental pain. Pain to percussion with a tongue blade indicates involvement at the apex of the tooth (such as a periapical abscess). Tender swelling of the gingiva adjacent to a tooth may indicate either a periodontal abscess or extension of a periapical abscess through the cortex of bone into the subperiosteal space.

The EM physician should evaluate for facial swelling which can be subtle in some cases as well as adenopathy and other signs of infection. In patients with sialoadenitis, pus may be expressed from the meatus of the salivary duct with gentle pressure to the gland or "milking" along the duct. In severe head and neck infections such as Ludwig angina, trismus, the inability to open the mouth because of involvement of the internal pterygoid or masseter muscle, may be present. Overall, this sign is present in less than 20% of patients even in advanced head and neck infections. More commonly in severe infections, patients will have a toxic presentation or appear in respiratory distress with impending upper airway obstruction or concomitant pneumonia. Other significant clinical signs include torticollis from sternocleidomastoid (SCM) inflammation, neck pain with neck movement, drooling of secretions, stridor, otalgia, headache, and vocal quality changes (2–7,19). Advanced infections may also extend down to the mediastinal area or present as facial

cellulitis with closure of the eye indicating potential spread of infection to the periorbital spaces.

Imaging studies provide important information in identifying infection, discerning abscess versus edema, mass, or lymphadenopathy, guiding drainage procedures, and diagnosing complications. Computed tomography (CT) scanning with intravenous contrast is the most helpful and readily available advanced imaging study in most hospitals. Depending on the soft tissues involved, one should consider a maxillofacial CT with 1-mm cuts and/or a neck CT with intravenous contrast. MRI may be superior to CT in assessing the origin of infection and it is less prone to interference from dental artifacts. However most studies note that CT venography seems to be superior to MR venography in the identification of the cerebral venous sinuses and at least equivalent in the diagnosis of cerebral venous sinus thrombosis (1,2,5,9,11). Overall, CT remains the advanced imaging study of choice in most instances.

A lateral soft tissue radiograph of the neck may be a helpful screening tool for deep space infections since it may reveal a thickened prevertebral stripe, enlarged epiglottis, or soft tissue gas. However it gives little information on abscess, and CT is preferred. For patients with chest symptoms, a plain chest radiograph or a chest CT may be indicated to search for evidence of mediastinitis. For patients with evidence of cellulitis or phlegmon by CT but no definitive abscess, IV antibiotics alone are effective. Patients with Ludwig angina can develop complications including internal jugular thrombophlebitis, intracranial extension, and carotid hemorrhage. Findings on CT for sinusitis may include thickening of sinus walls, sclerosis, and perforation (12–16). Since most stones are radiopaque, CT is likely to demonstrate sialolithiasis and its infectious complications if present. The salivary gland demonstrates enlargement, hypodensity on precontrast scan, and avid postcontrast enhancement, with adjacent inflammatory stranding and fascial thickening. The salivary duct may be dilated and thick walled due to a stone obstructing the duct. MR imaging can display inflammation and edema, but is poor in detecting the actual stone. In Lemierre’s,

CT scan with contrast demonstrates enlargement and thrombosis of the internal jugular vein, with enhancement of the walls of the vein and perivenular soft tissues.

KEY TESTING

Imaging studies are critical:
CT scan is the imaging study of choice in most cases
Plain films may be a useful screening tool, but should not be relied upon
Consider imaging the chest, as infections may spread to the mediastinum

ED MANAGEMENT

In the patient with a head and neck infection, the emergency physician must determine the following: (a) the potential for airway compromise, (b) the extent of involvement of contiguous structures, and (c) the potential for spread of infection to the fascial planes of the head and neck. If the patient is in need of immediate stabilization, the initial resuscitation takes precedence over further evaluation or diagnostic imaging. See Table 63.1.

TABLE 63.1
Essential Features of Odontogenic and Parapharyngeal Infections

Fascial Space/Anatomic Area	Clinical Presentation	Diagnosis and Treatment	Disposition
Periapical abscess	Acute or chronic odontalgia; pain with percussion; no visible swelling	Periapical lucency on Panorex; analgesics/ antibiotics	Dental referral
Subperiosteal	Vestibular, palatal, or sublingual swelling/ fluctuance	Stab incision to alveolar bone, irrigation and drainage, analgesics/antibiotics	Dental/oral surgery referral 24–48 hrs
Buccal space	Massive cheek swelling	Analgesics/antibiotics; fluctuance usually easy to palpate	OMFS consult for abscess drainage
Masticator Spaces; submasseteric pterygomandibular temporal	Severe trismus is the clinical hallmark	Patients are often dehydrated and may require fluid resuscitation; CT scan may confirm diagnosis	OMFS or ENT consult; hospitalize for trismus, toxicity, or severe dehydration
Sublingual, submandibular, submental space	Prominent swelling	Airway assessment; IV antibiotics; fluid resuscitation if dehydrated	OMFS or ENT consult; admission if toxic
Ludwig angina	"Brawny edema" of the neck; upper airway obstruction with stridor	Airway stabilization; broad-spectrum antibiotics	OMFS or ENT consult; admission, possible surgery
Parapharyngeal infections; lateral, retropharyngeal space	Pharyngeal bulging, dysphagia, trismus; nuchal rigidity with prevertebral involvement	CT scan defines location and extent of abscess; lateral neck x-ray may show retropharyngeal thickening	OMFS or ENT consult; admission, possible surgery
Mediastinitis	Chest pain, severe dyspnea, systemic toxicity	Wide mediastinum on CXR. Gas or fluid on CT scan. IV antibiotics	Admission, possible surgery
Cavernous sinus thrombosis	Ocular pain, orbital edema, retinal hemorrhages early; CN III, IV, V, VI deficits	Usually dramatic findings; CT scan or MRI may confirm Dx	Admission

OMFS, oral and maxillofacial surgeon; CT, computed tomography; IV, intravenous; ENT, ear, nose, and throat; OR, operating room; CXR, chest x-ray; IV, intravenous; CN, cranial nerve; MRI, magnetic resonance imaging; Dx, diagnosis.

Patients with acute airway compromise or signs of sepsis must be treated quickly and skillfully to prevent further deterioration. Securing the airway is a priority in the ED treatment and should be done in the initial resuscitation. All patients with trismus must be presumed to be difficult intubations. Trismus may be due to muscle spasm, edema, or both, and may not respond to paralytic agents. Patients with Ludwig angina, other deep space infections, postoperative swelling or bleeding present difficult challenges in airway management. Oral intubation can be attempted, although the normal anatomic relationships may be distorted because of swelling or obscured by bleeding. A "backup airway" or alternative measures such as video laryngoscopy, nasotracheal intubation, tracheostomy, cricothyroidotomy, gum elastic bougie, or fiberoptic techniques should be carefully considered before attempts are made. Consultation with the appropriate services should be obtained as time and availability permit.

Parapharyngeal space infections (sublingual, submandibular, submaxillary, lateral pharyngeal, retropharyngeal, and pretracheal) are usually polymicrobial. Appropriate antibiotic therapy includes penicillin G (high dose) plus metronidazole or cefoxitin. Alternative therapy may include ticarcillin/clavulanate (Timentin), piperacillin/tazobactam (Zosyn), or clindamycin in the penicillin-allergic patient.

Patients with suspected deep neck infections require aggressive, early, empiric broad spectrum antibiotic therapy. Most patients are given IV antibiotics targeting gram-positive cocci and anaerobes, but broader coverage for gram-negative aerobes should be considered in diabetics and immunosuppressed patients. For deeper soft tissue head and neck infections like Ludwig angina, high-dose penicillin G (12 million units/d) is required. Unasyn (Ampicillin/Sulbactam) or Clindamycin also provide excellent anaerobic coverage. Chloramphenicol is reserved for extreme situations with few other alternatives (2,4,11). If the patient does not respond to treatment with antibiotics in the first 24 hours, surgical drainage may be required. Most of these cases require admission and consultation with appropriate services. There is no consensus on duration of oral antibiotic therapy but most recommend 7 to 10 days.

Mediastinitis is a surgical emergency in which IV antibiotics, surgical debridement, drainage, and airway management are typically necessary.

Patients with simple dental-related infections can be managed as outpatients with oral antibiotics, analgesia, and rinses. A simple incision and drainage may be indicated for abscesses and follow-up should be arranged the next day with the oral and maxillofacial surgeon (OMFS) or the family dentist (2,3). Penicillin V (phenoxymethyl penicillin) is an effective and inexpensive first-line choice, and unless penicillin allergy exists, it is the antibiotic of choice for outpatient therapy. Clindamycin has become a favorite in dentistry because of its bactericidal activity and its excellent penetration into soft tissue and bone. Clindamycin covers oral pathogens and can be an alternative choice in penicillin-allergic patients (1,2,4,5,10).

Sialoadenitis may be treated on an outpatient basis with an antibiotic that has gram-positive coverage (cephalexin, dicloxacillin), oral hygiene, and a sialagogue such as lemon juice. For immunocompromised patients, consider broader coverage with antibiotics like third-generation cephalosporins, piperacillin/tazobactam (Zosyn), imipenem, or meropenem (1,2,4,5,10).

The incidence of complications from deep neck space infections has remarkably decreased since the advent of antibiotic therapy. Despite this, the potentially devastating outcomes associated with these complications remind the physician to remain vigilant for subtle signs and symptoms. Airway obstruction and asphyxia is a potential complication of any deep neck infection, but has been most commonly associated with Ludwig angina. Other complications include sepsis, internal jugular vein thrombosis, upper GI bleeding, mediastinitis, and vocal cord palsy (4,6,7,19). Carotid artery rupture, although rare, carries a mortality rate between 20% and 80%. This can occur when infection involving the carotid sheath leads to arterial wall weakening, erosion, and eventual hemorrhage. Arterial rupture may be heralded by recurrent small bleeds from the ear, nose or mouth, the onset of shock, a protracted clinical course, and hematoma in the nearby tissue, Horner syndrome or unexplained cranial neuropathies (4,19). The EM physician should be wary of patients at risk for complications (e.g., advanced age, comorbid conditions including HIV, myelodysplasia, cirrhosis, and diabetes) (6,8).

CRITICAL INTERVENTIONS

- Initiate early parenteral broad-spectrum antibiotic coverage in the patient with a suspected deep neck or parapharyngeal infection.
- Assess and manage the airway early in patients with airway compromise. Be prepared to utilize alternate “difficult airway” techniques.
- Consult appropriate services early in the management of critically ill patients.

DISPOSITION

Patients with minor infections can be discharged home with oral antibiotics and close follow-up. Patients with deep neck infections or clinical toxicity generally require admission, and some will need surgical intervention. Depending on the institution, consultants may include Dentistry, Oral Maxillofacial surgery, Ear Nose and Throat,

critical care, anesthesia, or a general surgeon. Patients with Ludwig angina or those at risk for immediate airway obstruction should be admitted to a critical care setting for close observation. If appropriate physicians and resources are not available, the patient should be transferred expeditiously to an appropriate facility. Advanced life-support personnel should be used for monitoring the airway, and consideration should be given to establishing a definitive airway prior to transfer.

Common Pitfalls

- Failure to carefully examine patients to identify the source and follow the spread of infection along the fascial planes.
- Underestimation of the potential for spread of infection to the mediastinum.
- Failure to initiate appropriate antibiotics and consultation.
- Failure to recognize the potential for airway compromise from swelling or infection, leading to delay in early airway protection.

CHAPTER 64 Temporomandibular Pain and Dislocation

Darria Long Gillespie

The temporomandibular joint (TMJ) consists of the head of the mandibular condyle as well as the articular tubercle and mandibular fossa of the temporal bone (Fig. 64.1) (1). The joint is held loosely by the TMJ capsule, which has a weak surface anteriorly—allowing the variety of movements required, but also the relative ease of dislocation (2,3). The muscles of mastication are divided into two groups: the temporalis, masseter, and internal pterygoid muscles elevate, retract, and close the mandible, while the suprahyoid, infrahyoid, and external pterygoids open and protrude (Fig. 64.2) (4).

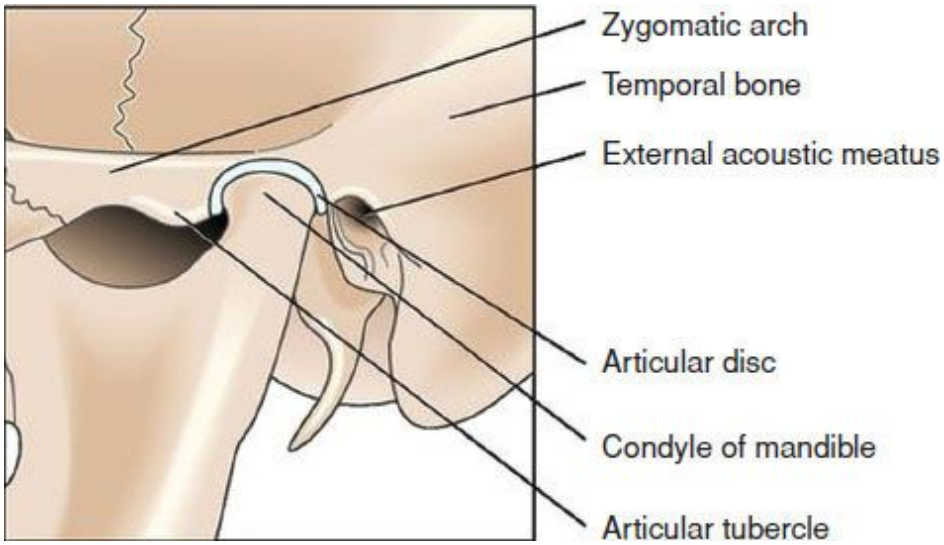

FIGURE 64.1 Bony Anatomy. (Adapted from Bickley LS, Szilagyi P. *Bates' Guide to Physical Examination and History Taking.* 8th ed.

Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

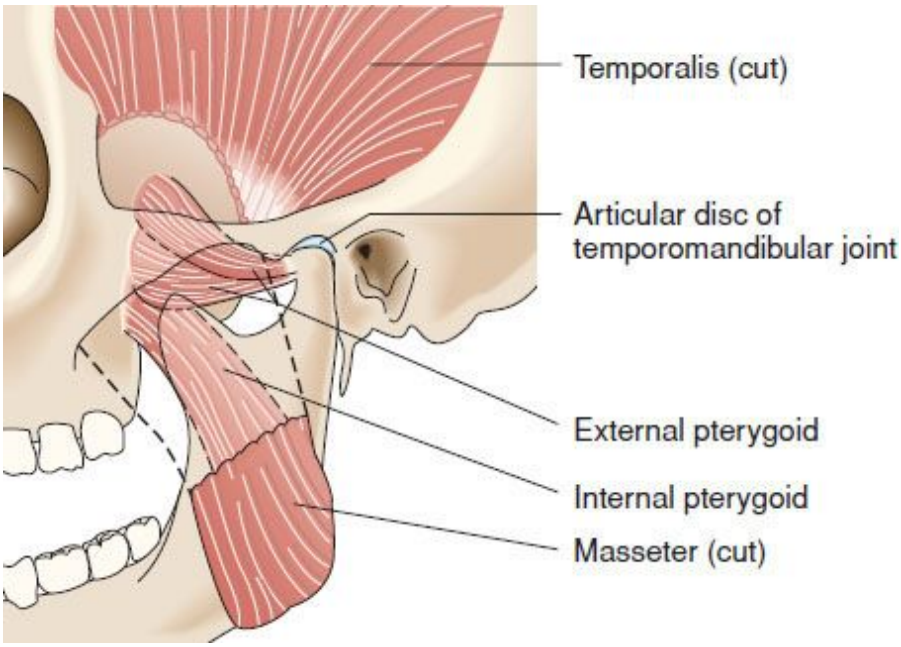

FIGURE 64.2 Muscular anatomy. (Adapted from Bickley LS, Szilagyi P. *Bates' Guide to Physical Examination and History Taking.* 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

CLINICAL PRESENTATION

Temporomandibular Myofascial Pain Dysfunction Syndrome (TMPDS): TMPDS is a neuromuscular disturbance, and its causes are debated. Contributing factors include anatomic abnormalities (congenital or traumatic), microtrauma from clenching/grinding, stress, and systemic arthritides (5,6,7,8). Recent research suggests that sleep bruxism is not a cause of TMPDS (9,10). However, increased clenching and grinding in times of stress contributes to TMPDS and triggers a cycle of muscle pain, dysfunction, and spasm (1,6). Patients who present to the ED are more commonly females in their 20s to 40s (1) and experience unilateral dull pain involving the TMJ, masseter, and temporalis muscles. Pain worsens throughout the day, as well as with chewing, and may refer to the supraorbital, cervical, and occipital regions. Patients may also complain of a "click" or sensation of catching with opening and closing of the jaw (7),

although clicking alone without pain is inadequate to make the diagnosis of TMPDS.

The TMJ is vulnerable to all conditions that affect joints in the body, including arthritis, ankylosis, and neoplasm (1). TMPDS secondary to systemic arthritides presents with pain and crepitus in periods of exacerbation and remission. Pain in secondary TMPDS typically is greatest in the morning, presents in younger patients, and has greater severity and joint erosion.

Acute mandibular dislocation: The most common dislocation direction is anterior, in which the condyle is trapped anterior to the articular tubercle due to muscle spasm, prohibiting jaw closure. Posterior, superior, and lateral dislocations are rare and usually associated with severe trauma and other injuries. Dislocations are more commonly bilateral; in unilateral dislocation, the jaw deviates away from the dislocation.

Acute dislocations can be caused by a direct blow to the jaw, seizures or dystonic reactions, and most commonly, due to maximum opening (yawning, laughing, vomiting, dental procedures). Predisposing factors include a shallow fossa and congenital or traumatic weakness of the joint capsule and ligaments (3,11). Patients present with the mouth stretched wide open, are anxious and uncomfortable, and have garbled speech and drooling due to the inability to swallow or move the tongue appropriately. They report exquisite pain due to masseter spasm.

DIFFERENTIAL DIAGNOSIS

In any patient presenting with facial, jaw, or head pain, the differential diagnosis includes deep space infections (peritonsillar abscess, retropharyngeal abscess, Ludwig angina), odontogenic pain (abscess, caries, tooth fracture), otologic referred pain, zoster, temporal arteritis, trigeminal neuralgia, or parotid gland pathology. Neck and shoulder pain are often reported with TMPDS, and the differential may include other disorders such as referred pain from cardiac ischemia.

Although most cases of TMJ dislocation are clinically obvious, some may be confused with mandibular fracture or acute dystonia.

Dislocations and fractures may coexist.

ED EVALUATION

The emergency physician should thoroughly examine the head and neck to evaluate the airway and rule out non-TMJ causes. Examination frequently reveals spasm and tenderness of the masseter externally and internal pterygoid intraorally. The joint itself can be palpated by placing a finger just anterior to the tragus, or in the external auditory meatus and pulling forward on the tragus (Fig. 64.3). Both muscle and joint examinations should be performed while the patient opens and closes the mouth. If this completely reproduces the patient's pain or demonstrates clicking or crepitus, a TMJ disorder is the likely cause. In severe cases, the jaw deviates toward the affected side, with myofascial spasm and trismus limiting full mouth opening. Examination may show facial asymmetry (12).

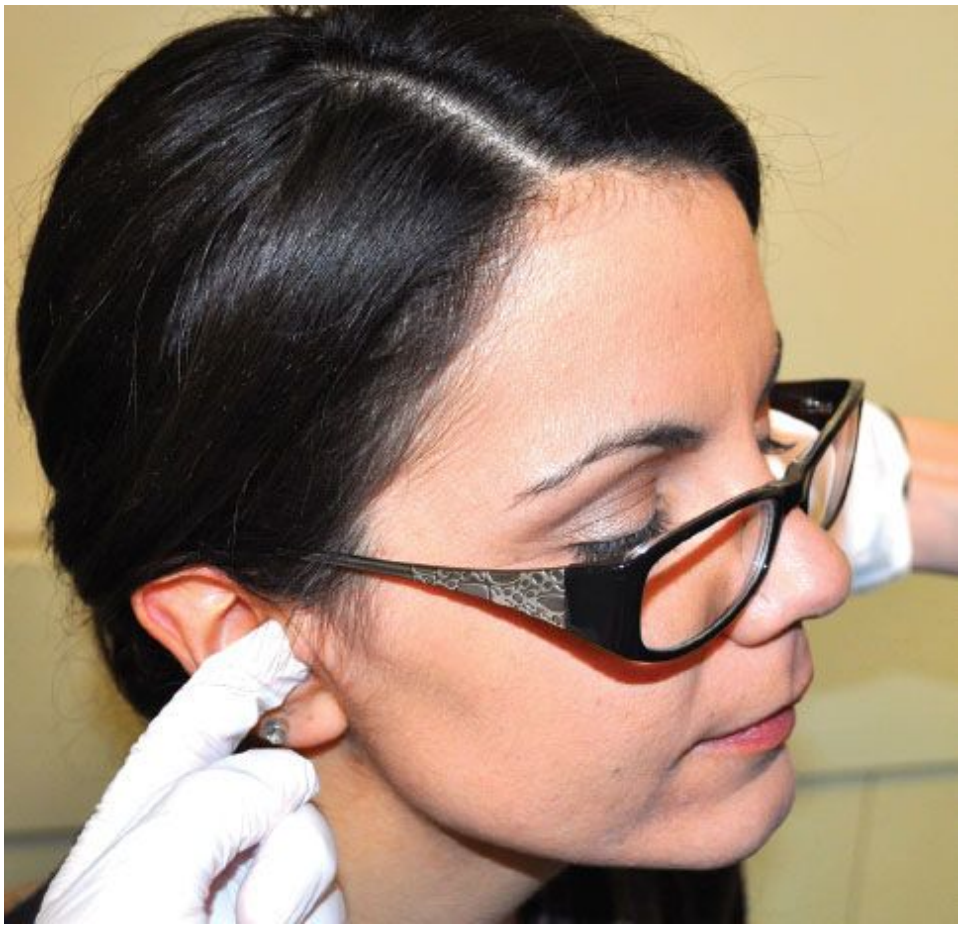

FIGURE 64.3 Palpation of the TMJ via pressure on tragus from external auditory canal.

For patients with a question of mandibular dislocation, evaluate for signs of trauma, including mandibular deformity or missing teeth, and for sensory deficit at the chin or mouth. With anterior dislocation, there is often a prominent-appearing lower jaw, as well as a depression in the preauricular area representing the empty temporal fossa.

Imaging

Atraumatic, subacute, or chronic TMJ pain: In the absence of trauma, signs of dislocation, acute change in bite, or asymmetry, emergent imaging is rarely required (7).

Mandibular dislocation: Spontaneous anterior mandibular dislocations that have no history of trauma, no atypical findings, nor evidence of fracture may be reduced without imaging (13). Otherwise, a mandibular x-ray or panorex view should be taken to exclude fracture (14). If these are unavailable, or there is high suspicion of fracture or internal derangement, a CT scan should be obtained (15).

KEY TESTING

- Obtain mandibular x-ray, panorex, or CT in cases of suspected fracture, trauma, or atypical or non-anterior dislocation

ED MANAGEMENT

TMJ pain or dysfunction: Regardless of cause, TMJ syndrome is initially treated with a combination of 1 to 2 weeks of physiotherapy, moist heated compresses, a soft/pureed diet, and nonsteroidal pain medication (5). Prescription pain medication or muscle relaxants may be of use acutely.

Acute TMJ dislocation: Anterior TMJ dislocation can be reduced in the ED.

1. Relief of anxiety, pain, and spasm is crucial (14,3), and procedural sedation or adequate analgesia is required. The physician may consider intra-articular anesthetic injection into the TMJ (3).
2. The patient should sit upright with a firm support behind his head, putting the mandible at the height of the physician's elbow (14).
3. Facing the patient, place both thumbs intraorally (Fig. 64.4) on either the mandibular ridge or over the occlusal surface of the molars, with fingers gripping the mandible. (CAUTION: Muscle spasm will cause the jaw to snap into place quickly, and thumbs should be protected with gauze wrapping and possibly tongue depressors). Alternative methods include standing behind the patient, using an external approach (16), or positioning the patient supine with the physician at the head of the bed.

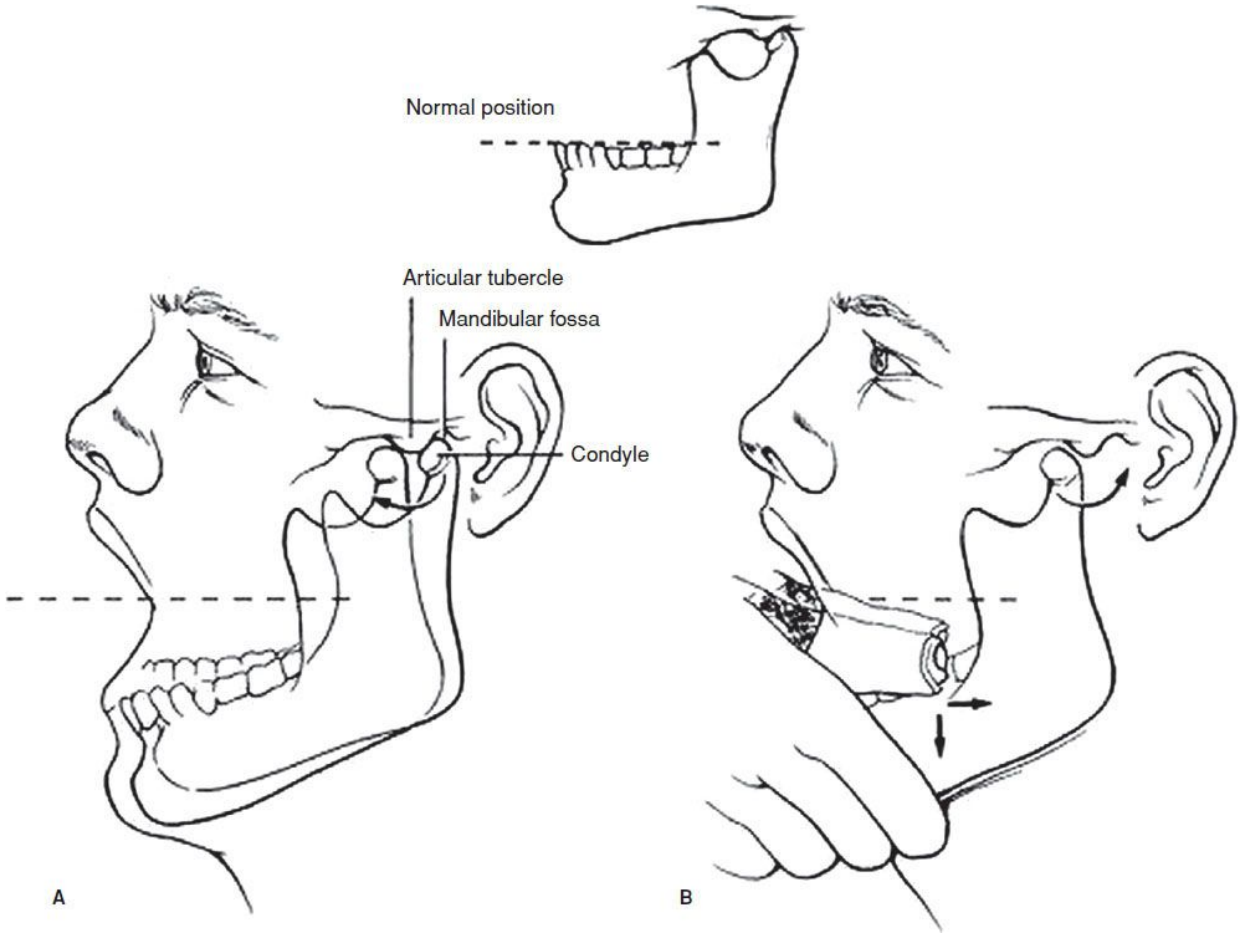

FIGURE 64.4 Anterior dislocation and reduction technique. (From Fleisher GR, Ludwig S, Henretig FM, et al. *Textbook of Pediatric Emergency Medicine.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

4. Apply downward pressure to free the condyles from the tubercle. Consider gently rocking from one side to another instead of bilateral pressure, or tilting the chin up while pushing down on the posterior mandible (3,2). Once freed from the tubercle, the mandible quickly snaps posteriorly in a C-shaped direction. Success is followed by an immediate ability to close the mouth, reduced pain, and sense of relief (3).

Complications of reduction are rare and include fracture, cartilage injury, or operator bite injury. Postreduction imaging is only necessary in a difficult reduction or in cases of severe pain during/after the reduction (13).

Posterior, lateral, superior, or open dislocations, as well as those with associated fractures or that the emergency physician cannot reduce will likely require further intervention and the emergent evaluation by an oral/maxillofacial surgeon.

CRITICAL INTERVENTIONS

- Rule out non-TMJ etiologies of pain and any signs of potential airway compromise.
- Provide adequate sedation and analgesia to facilitate reduction of TMJ dislocation.

DISPOSITION

Patients with TMPDS should be referred to a general dentist or periodontist for occlusive therapy or intra-articular steroid injections. Many patients will improve with supportive measures (5); most tend to have periods of exacerbation and remission.

After successful reduction of an anterior dislocation, patients should use nonsteroidal analgesic for pain control. For the 2 weeks following a TMJ dislocation, patients must be instructed to avoid

opening of the mouth beyond 2 cm, eat a soft/pureed diet, apply warm compresses, and follow up with a dentist or maxillofacial surgeon.

Special attention should be paid to children with posttraumatic internal abnormalities of the TMJ, as they are at higher risk of asymmetry in facial growth (2,14,17).

Common Pitfalls

- Failure to carefully examine for infection or referred etiology of pain.
- Failure to identify mandibular fracture.
- Failure to provide adequate sedation and analgesia to facilitate TMJ reduction.

CHAPTER 65 Upper Airway Obstruction

Louisa S. Canham and Jonathan Fisher

Upper airway obstruction occurs from a variety of causes including foreign-body obstruction, infection, swelling, and bleeding. Airway obstruction from choking on a piece of food can occur rapidly, although conditions such as epiglottitis may occur more insidiously. Early recognition and treatment of impending complete airway obstruction is essential to avoid catastrophic results. Evaluation, differential diagnosis, and emergency intervention all must occur simultaneously. Although not every patient with upper airway obstruction will require emergency airway management, for a subset of patients there is only a small window of opportunity to intervene before the airway is completely lost.

The major determinant of airway resistance is the radius of the airway, resistance being proportional to the fourth power of the radius. Therefore, a small decrease in diameter can have an extreme impact on the airway. Identification of high-risk presentations and clinical situations is the key to successful outcomes.

CLINICAL PRESENTATION

Nontraumatic airway obstruction can occur rapidly in a manner of seconds or through a period of days to months. The process may progress gradually or suddenly with little warning. The emergency physician must understand the disease processes at work and be prepared to intervene quickly.

The site of the obstruction, the size of the obstructing agent, and associated spasm and edema are important determinants of the

presentation. Historical factors may aid in arriving at the diagnosis. Physical findings may be nonspecific but can help to separate patients into a category of obstruction.

Increasing airway obstruction is first evidenced by subjective complaints of respiratory distress by the patient. Patients may complain of a sensation of “throat closing” or “something stuck in their throat.” Objective findings include the presence of respiratory sounds such as stridor or wheezing. Inspiratory noises tend to indicate an upper airway source of obstruction. In general, stridor is produced in large, upper airways during inspiration, while wheezing occurs in smaller, lower airways during expiration. However, the distinction may not always be so clear. Inability to swallow or handle one’s secretions can be an ominous finding. The patient’s positioning is important to note. An upright posture with the neck extended in the sniffing position is characteristic of the patient with supraglottic obstruction, such as epiglottitis. Forcing the patient to become supine can cause complete airway obstruction.

Although airway obstruction by a foreign body, such as food, occurs suddenly, obstruction by an expanding mass effect within the upper airway is more insidious. Abscesses may obstruct the airway by their location or can rupture into the airway, causing acute obstruction. Expanding hematomas behave similarly. Edema and soft tissue swelling owing to infection or allergy have a more diffuse mass effect.

DIFFERENTIAL DIAGNOSIS

Foreign-body obstruction, infection, hypersensitivity, hemorrhagic disorders, extrinsic mass, and neoplasia all may result in the syndrome of upper airway obstruction. Paradoxical vocal cord motion is a psychogenic form of stridor that mimics true airway obstruction. It is a diagnosis of exclusion, but it is an important entity to recognize to avoid harmful unnecessary interventions, such as intubation (1).

Foreign-Body Obstruction

The classic example of upper airway obstruction by a foreign body is the “cafe coronary” (2). Food that causes an obstruction has often been poorly masticated. The victim may have painful or poorly fitting dentures or otherwise poor dentition that hampers chewing. Alcohol consumption has been associated with an increased risk of choking. This type of obstruction is usually supraglottic and responds to the maneuvers prescribed by the American Heart Association, such as abdominal thrusts (3).

Aspirated toys or smaller pieces of food may pass the vocal cords and produce obstruction in the subglottic area. These obstructions may be intermittent and aggravated by the head-down position, which allows the object to move an obstructing position. Back blows and the head-down position may actually worsen these obstructions. The clinical presentation of a subglottic foreign body may be one of localized wheezing and atelectasis as the foreign body becomes lodged in a bronchus (4).

Infection

Infection of the upper airway structures may produce airway compromise within hours. Patients often present with fever, pain, hoarseness, and decreased ability to open the mouth or move the neck. *Ludwig angina* (cellulitis of the sublingual space) can quickly obstruct the airway. The condition is a true otolaryngologic emergency that requires airway maintenance and antibiotic therapy (5). Retropharyngeal or parapharyngeal abscess can cause gradual obstruction as it expands and then catastrophic deterioration if it suddenly ruptures into the airway (6). Epiglottitis may produce sufficient swelling to produce airway obstruction in the adult or child.

Hypersensitivity

Anaphylaxis presents suddenly after exposure to an antigenic stimulus. When there is laryngeal edema, prompt intervention is needed (see Chapter 175), and a delay in the initiation of medical therapy may make immediate surgical intervention necessary. Food,

drug, and insect sting allergies are the commonly encountered causes of anaphylactic airway emergencies. Severely ill patients may not be able to speak and therefore unable to relate a history of exposure.

Hereditary angioedema (HAE) is an autosomal dominant inherited condition that is manifested by sudden edema of the face, hands, abdominal viscera, and airway. Airway obstruction is the most dramatic and life-threatening complication of the disease (7). Episodes may be triggered by minor trauma, emotional distress, or surgery. There is no race or sex predilection. Despite the inherited nature of the disease (see Chapter 176), there is often no known family history.

Angiotensin-converting enzyme (ACE) inhibitor agents have also been associated with the development of angioedema (8,9). Moderate to complete airway obstruction may occur. It is important to note that this reaction may occur even in patients who have been taking ACE inhibitors for years.

Hemorrhagic Disorders

The widespread use of anticoagulants for the treatment of cardiac and cerebrovascular disease has increased the population who are at risk for the development of spontaneous hematoma. These hematomas may develop anywhere in the body, but when the pharynx, tongue, or soft tissues surrounding these structures are involved, airway compromise is a predictable consequence.

Airway compromise has been reported because of hematoma of the sublingual space, retropharynx, and hypopharynx (10,11). There is rapid, unexpected deterioration of a patient who, in most cases, was previously healthy. Pain is often noted early, frequently preceding other symptoms. Signs of airway obstruction may develop before the examiner's eyes. Physical examination often reveals an area of swelling, with or without ecchymosis. Close observation is essential to avoid an adverse outcome from unrecognized abrupt deterioration.

Extrinsic Mass

Airway obstruction owing to an extrinsic mass is occasionally seen. An example is the development of an obstruction in the esophagus caused by achalasia (12). The distended esophagus impinges on the airway in the neck and produces recurrent airway obstruction that resolves when the esophageal obstruction is cleared. Cystic lesions of various types may produce a similar syndrome that may require temporary airway support until the lesion is removed.

Neoplasia

Tumors located anywhere along the airway may cause respiratory distress via extrinsic compression or internal infiltration of the airway. Common culprits include mediastinal tumors, lung cancer, and Kaposi sarcoma. Patients present with dyspnea and noisy respirations, and may be misdiagnosed as having asthma or an airway infection. Some clues to the diagnosis of neoplastic etiology include hemoptysis and worsening of symptoms with lying flat (13,14).

Congenital tumors of the oropharynx or neck may present immediate and unexpected airway emergencies at birth. These conditions require the immediate availability of neonatal resuscitation capabilities and surgical resources (15).

ED EVALUATION

Regardless of the cause of the obstruction, the emergency physician must first gauge its severity by quickly placing the patient in one of four categories:

1. Stable airway, deterioration risk low
2. Stable airway, deterioration risk high
3. Compromised airway and respiration
4. Obstructed airway and agonal respirations

The evaluation and therapy process can then proceed with the appropriate degree of urgency.

The history should include questions about previous allergic reactions, medications, cancer, fever, pain with swallowing, and

hoarse voice. The vital signs, presence or absence of stridor, and degree of respiratory distress should be quickly assessed. The neck should be palpated for masses and lymphadenopathy, and the larynx and trachea should be moved from side to side to check if this "tracheal rock" elicits pain with gentle movement. Examination of the throat may reveal a partial view of a supraglottic foreign body, an abscess, or swelling of the tongue or pharynx.

A patient placed in the stable category with low risk of deterioration is in some ways the most hazardous for the emergency physician. It implies that the patient can be evaluated at a leisurely pace with a minimal degree of observation. However, airway obstructing lesions can deteriorate quickly and unexpectedly.

The second category reflects the appropriate degree of concern during the initial evaluation of any patient in whom airway obstruction is suspected. The risk of deterioration calls for constant observation and readiness to intervene if necessary. Measures intended to correct the underlying obstructive process should be instituted as soon as possible. Laboratory studies may be helpful in confirming an infectious or hemorrhagic etiology. A lateral cervical spine radiograph may reveal a thick epiglottis or signs of a retropharyngeal abscess, such as prevertebral thickening or gas. Computed tomography (CT) scan may further delineate a mass or abscess impinging upon the airway but must be used carefully in the patient who may not tolerate the time and positioning necessary to obtain this study.

The third category, with established airway compromise, calls for immediate decisions regarding airway intervention. The emergency physician must quickly assess the likelihood of success with a medical approach before intubation or surgical intervention is required. The decision to intubate is a clinical one. An arterial blood–gas analysis may add more supporting data, but such testing usually only delays needed therapy, with potentially catastrophic results.

The last category, with the patient in an agonal state, represents the most straightforward situation. The airway must be established emergently.

KEY TESTING

- Advanced imaging (usually CT scan), if the patient can tolerate the study

ED MANAGEMENT

The patient who is stable is a candidate for treatment that might obviate the need for airway intervention. Oxygen supplementation should be initiated in all cases. Consideration needs to be given to nebulization therapy with racemic epinephrine and steroids to decrease edema in hypersensitivity or croup syndromes. If infection is a possibility, appropriate antibiotic therapy should be initiated. Bleeding disorders require replacement of clotting factors.

A mixture of 80% helium and 20% oxygen (heliox) has been suggested as a temporizing measure in patients with airway obstruction caused by tumors (16). The density of the mixture is one-third that of air, and the less turbulent air flow may improve oxygenation in selected patients with a narrowed upper airway. Heliox may not be suitable for hypoxic patients, given the relatively low concentration of oxygen delivered.

When foreign-body obstruction is suspected, airway clearing maneuvers should be implemented promptly according to widely accepted protocols described by the American Heart Association (3). Failure to clear the airway should lead to more aggressive maneuvers to establish an airway. A supraglottic obstruction that is not removable may be bypassed by tracheal intubation or establishment of a surgical airway. With subglottic obstruction, intubation or a surgical airway may not solve the problem as the obstruction is beyond the part of the airway bypassed by the insertion of a tube. Magill forceps may allow removal of foreign bodies under direct vision (17). An aspiration technique uses a blunted (tip cut off) endotracheal tube, wall suction, and a meconium aspirator or “Y” connector attached to the tube (18). If the obstruction is in the lower trachea, attempts to remove the object have failed, and the patient’s condition continues to deteriorate it may be possible to push the obstruction into a

mainstem bronchus, so the other lung can be ventilated as a temporizing measure.

The incidence of acute epiglottitis in children under age 5 years has dramatically decreased with the use of *Haemophilus influenzae* type b vaccine. In 2000, the incidence was only 0.3 per 100,000 children (4). Adult epiglottitis can also lead to complete obstruction, but this is less likely because the adult airway is larger. However, patients may deteriorate unexpectedly and should be continuously monitored until the infection recedes. Preparations for immediate surgical airway placement must be made. Antibiotics should provide coverage against *Staphylococcus aureus, Pneumococcus* sp, group A streptococci, and *H. influenzae.* A standard regimen is ceftriaxone 1 g intravenously (IV) and vancomycin 1 g IV in an area where there is a high prevalence of methicillin-resistant *S. aureus.* Patients with other deep-space infections such as Ludwig angina and retropharyngeal abscess should receive antibiotics that also cover anaerobes, such as clindamycin 900 mg IV or metronidazole 500 mg IV. Steroids may be considered to help reduce swelling and potentially avoid the need for intubation (19). Emergent ENT consult should be obtained to determine the need for drainage.

The most common infectious cause of airway obstruction in children is croup, which is almost always viral in etiology. Standard treatment involves the use of nebulized racemic epinephrine, which provides fast relief but does not have a sustained effect. Steroids, given as a one-time dose, have become more widespread in the treatment of croup in recent years (6,20).

The patient with a hemorrhagic disorder associated with warfarin therapy requires aggressive therapy to reverse the coagulopathy. Correction is most rapid with administration of fresh frozen plasma (FFP) or prothrombin complex concentrates (10,11). FFP should be supplemented with vitamin K, which enhances the synthesis of clotting factors in the liver. Levels of the vitamin K–dependent factors II, VII, IX, and X begin to increase 2 hours after vitamin K administration with significant elevation in 6 to 8 hours, and vitamin K levels are frequently normal in 24 hours. Hemophiliacs should be treated with the appropriate factor concentrate.

The patient with hypersensitivity or anaphylaxis should be treated emergently with epinephrine (0.3 mL 1:1,000 subcutaneous [SC]), antihistamines (diphenhydramine 50 mg IV and ranitidine 50 mg IV), and steroids (methylprednisolone 125 mg IV) (see Chapter 175). There are no randomized controlled trials evaluating the use of these medications in nonallergic angioedema, but if the etiology of the edema is unclear the risks of empiric treatment are low (8). Patients with known HAE can be treated with FFP to supply the missing C1 esterase inhibitor (21); in addition, a plasma-derived C1 esterase inhibitor product was approved by the FDA in 2009 for use in patients with HAE (8).

Airway Opening Maneuvers

Airway opening maneuvers such as chin lift, head tilt, and oral and nasal airways are most useful in patients with a decreased level of consciousness (3). The situation is quite different if the comatose state is a result of hypoxia caused by airway obstruction and specific medical therapy and more aggressive airway intervention therapy are indicated.

Nonsurgical Management

A patient with significant airway compromise who does not improve with medical intervention often requires tracheal intubation. Blind nasotracheal or orotracheal intubation will suffice in many cases in which the decision is made before the airway is completely obstructed. Rapid sequence orotracheal intubation can often be accomplished, but the physician must weigh the risks of paralysis against its potential benefit in each case.

Useful adjuncts for difficult intubation include the gum-elastic bougie, video laryngoscopes, flexible video-optic devices, and the intubating laryngeal mask airway (ILMA). Inability to remove an obstructing object or to secure the airway with tracheal intubation is an indication to pursue surgical approaches to the airway. Nasal flexible endoscopic intubation performed by the emergency physician, anesthesiologist, or otolaryngologist may be extremely

helpful when the practitioner is comfortable with the technique. The nasal approach may allow passage behind a very proximal supraglottic obstruction. If the obstruction is in the lower trachea, standard tube placement will not relieve the obstruction. In such cases, the tube may need to be advanced further to the carina or into a mainstem bronchus.

Surgical Management

Transtracheal needle ventilation using a high-pressure oxygen source can temporarily provide oxygenation and minimal ventilation, provided that upper airway obstruction is not complete, so that exhalation can still occur through the upper airway. The technique is a temporizing measure that allows time to secure the airway by other, more definitive means. Cricothyrotomy is the emergency surgical airway of choice for most obstructing lesions in the upper airway. For subglottic obstructions, such as a laryngeal abscess, hematoma, or tumor, tracheostomy is preferred (22).

CRITICAL INTERVENTIONS

- Plan and prepare for airway management in the patient with impending airway obstruction before it occurs.
- Proceed with rapid assessment and treatment simultaneously.
- Administer appropriate specific therapies (epinephrine, FFP, antibiotics, steroids) in an effort to avoid the need for direct airway intervention.

DISPOSITION

The development of protocols for the treatment of acute upper airway obstruction should be initiated by the emergency physician. A cooperative team effort should be organized between the emergency, anesthesia, otolaryngology, pediatric, and internal medicine personnel who will be dealing with these patients.

The patient with airway obstruction needs to be under constant observation in an intensive care unit until the risk of airway obstruction has passed. Whenever there is doubt as to the

immediate future course of a patient with airway obstruction, intensive care unit admission is mandatory.

Common Pitfalls

- Underestimation of the potential for sudden deterioration
- Assumption that a sore throat is caused by simple pharyngitis when pharyngeal findings are absent
- Inadequate preparation of equipment and personnel

CHAPTER 66 Sore Throat

Michael F. Murphy

Sore throat is a common presenting complaint in emergency medicine, particularly the acute variety. Although most causes of sore throat are not life threatening, some are life threatening.

The pharynx is a U-shaped fibromuscular tube extending from the base of the skull to the lower border of the cricoid cartilage, where it is continuous with the esophagus at the level of the sixth cervical vertebra. Posteriorly, the pharynx rests against the fascia covering the prevertebral muscles and the cervical spine. Anteriorly, the pharynx opens into the nasal cavity (the nasopharynx), the mouth (the oropharynx), and the larynx (the laryngo- or hypopharynx).

The oropharyngeal musculature has a normal tone similar to any other skeletal musculature. This tone serves to keep the upper airway open during quiet respiration. Respiratory distress is associated with pharyngeal muscular activity that attempts to open the airway further. Benzodiazepines and other sedative hypnotic agents may attenuate some of this tone. This fact explains why sedation may lead to total airway obstruction in patients presenting with partial airway obstruction.

The glossopharyngeal nerve (IX) supplies sensation to the posterior one-third of the tongue, lingual and faucial tonsils, the valleculae, the free edge of the soft palate, the superior surface of the epiglottis, and most of the posterior pharynx. This nerve also supplies sensation to a portion of the tympanic membrane, the carotid sheath, sinus and body, and the stylopharyngeus muscle. The innervation patterns, as they relate to the carotid sheath, and the epiglottis are important in identifying occult but potentially

lethal causes of sore throat. Stimulation of the glossopharyngeal nerve at any of these locations may be interpreted by the patient as a “sore throat.”

CLINICAL PRESENTATION

Most patients with sore throat are nontoxic appearing, have a clear voice, and have no difficulty with respirations. Since most causes of sore throat are infectious in origin the patient may experience fever, significant pain, and become dehydrated. The challenge for the clinician is to provide symptomatic relief and to identify those patients with serious pathology requiring specific treatment. Four conditions comprise the vast majority of adults that present to the ED with a chief complaint of sore throat: retropharyngeal abscess (RPA), peritonsillar cellulitis and peritonsillar abscess (PTA), epiglottitis, and acute pharyngitis.

The patient with RPA presents with fever, neck pain, and sore throat out of proportion to the oropharyngeal findings. Other symptoms and signs may include odynophagia, neck swelling, drooling, torticollis, meningismus, cervical adenopathy, and stridor. The voice may be normal, though if the abscess is high in the neck, nasal obstruction and a hyponasal voice result. A “hot potato” voice may be present if the swelling is above the level of the larynx (see Chapter 1). Chest pain associated with these symptoms strongly suggests mediastinal extension.

PTA is part of a continuum of illness from tonsillitis, through peritonsillar cellulitis (inflammation without fluid collection) to PTA. The patient may present at any point along this continuum, and symptoms and treatment vary accordingly though severe unilateral throat pain is typical.

Supraglottitis (epiglottitis), because of its occult nature and potential lethality, merits special discussion. The clinical presentation may be categorized into a spectrum that varies from a fulminating course developing over hours to a subacute form smoldering for days to weeks.

- Category 1: severe respiratory distress, imminent or actual respiratory arrest. Patients in category 1 typically report a history of a brief but rapidly progressive illness. Blood culture often reveals *Haemophilus influenzae* type b.
- Category 2: moderate to severe symptoms and signs of potential airway compromise. Symptoms and signs include inability to swallow or lie supine, dyspnea, severe sore throat, muffled voice, stridor, and the use of accessory muscles. The emergency physician should prepare to intervene if the airway should suddenly deteriorate, then undertake further evaluation of the airway.
- Category 3: mild to moderate illness without signs of airway compromise. Patients may report a 3- to 14-day history of a sore throat and pain on swallowing with minimal physical findings on examination. A patient can rapidly worsen with little warning.

DIFFERENTIAL DIAGNOSIS

Throat pain (pharyngalgia), has many causes and may be acute, subacute, or chronic. The most common cause of all forms of sore throat is pharyngitis, meaning "inflammation of the pharyngeal mucous membrane." "Sore throat" and "pharyngitis" are not identical, because many noninflammatory disorders (e.g., oropharyngeal carcinomas) can also cause pharyngeal pain. Local infection is the most common cause of inflammation of pharyngeal structures or acute pharyngitis. The most common and serious causes are discussed in more detail (Table 66.1).

TABLE 66.1
Differential Diagnosis of Sore Throat

Acute Pharyngitis
Bacterial Infections
• GABHS
• N. gonorrhoeae
• C. diphtheriae
Viral Infections
• Epstein–Barr virus
• Herpes virus
• Influenza virus
• Rhinovirus
• Coxsackievirus A
Noninfectious
• Stevens–Johnson syndrome
• Pemphigus
• Angioedema
Chronic Pharyngitis
• GERD
• Obstructive sleep apnea
• Fungal infections (e.g., *Candida albicans*)
• Chronic sinusitis with postnasal drip
• Inhalation of irritants (pyrethrins, chlorine gas, heavy smoking)
• Breathing dry air
• Glossopharyngeal neuralgia
• Carcinomas: pharyngeal, lingual, and tonsillar
• Monomyelocytic leukemia
• Thyroiditis
Retropharyngeal Abscess
Peritonsillar Abscess/Cellulitis
Supraglottitis/Epiglottitis

Acute Pharyngitis

Acute pharyngitis and tonsillopharyngitis are the most common causes of sore throat. Acute pharyngitis usually presents as the rather abrupt onset of pharyngeal pain, particularly with swallowing (odynophagia). The severity of the pain is variable, usually being worse in the morning. Odynophagia that is so severe as to preclude

swallowing is uncommon and should prompt one to consider conditions such as epiglottitis, and RPA or PTA. Important causes of acute pharyngitis include the following.

Group *A β-hemolytic streptococcus* (GABHS): GABHS is the most common cause of bacterial pharyngitis in children (see Chapter 260). The typical age range is 3 to 25 years, though sore throat can occur at all ages. Some historical and physical features favor a diagnosis of GABHS over viral etiologies of acute pharyngitis, including younger age, higher fever, absence of a cough, anterior cervical adenitis, and tonsillar exudates. However, weighted scoring systems utilizing these criteria have not demonstrated high sensitivity or specificity (Centor Criteria as modified by McIsaac) (1) though they may identify patients in whom testing is cost effective (Table 66.2) (2).

TABLE 66.2
Clinical Scoring Systems and Likelihood of Positive Throat Culture for Group A Streptococcal Pharyngitis

Criteria	Points
Fever (temp >38° C)	1
Absence of cough	1
Tender, swollen anterior cervical nodes	1
Tonsillar swelling or exudate	1
Age	
3–<15 yrs	1
15–<45 yrs	0
45+ yrs	−1

Neisseria gonorrhoeae: This sexually transmitted disease may occur independent of a genital infection and is of variable severity. Gonococcal pharyngitis is an important source of gonococcemia.

Corynebacterium diphtheriae: This bacterium is a potentially lethal cause of pharyngitis. Sore throat and dysphagia are prominent symptoms, and patients exhibit a grey–white pharyngeal mucosal membrane of varying size. Airway obstruction may follow. Despite

immunization, large portions of the adult population in the United States lack immunity to the diphtheria toxin.

Viral infections: Viruses are common infectious causes of pharyngitis in adults and children (Table 66.1).

Stevens–Johnson syndrome (SJS): SJS is an immune-mediated hypersensitivity disorder that is a severe expression of erythema multiforme. It usually involves the skin and the mucous membranes and may cause severe erythema, edema, sloughing, blistering, ulceration, and necrosis of the oropharyngeal mucous membrane. Four etiologic categories have been identified: infectious (e.g., herpes simplex virus and mycoplasma), drug induced (e.g., sulfonamides and phenytoin), malignancy related, and idiopathic. SJS may be fatal.

Pemphigus: This is a group of rare autoimmune blistering diseases of the skin and/or mucous membranes. Pemphigus vulgaris is characterized by sores and blisters that almost always start in the mouth and carries a moderate to high mortality rate if unrecognized and untreated.

Retropharyngeal Abscess

RPA is more often a disease of young children usually occurring when lymph nodes in the retropharyngeal space become infected. These lymph nodes involute by puberty. In adults, RPA may be caused by direct trauma or extension of a local infection, such as Ludwig's angina, odontogenic infections, or mycobacterial osteomyelitis of the cervical spine (Pott's disease) (3). Traumatic causes include blunt and penetrating neck wounds, which have the potential to develop the delayed complication of an abscess, and iatrogenic injuries secondary to intubation or endoscopy. Uncommon causes include sinusitis, and otitis media. RPAs tend to be polymicrobial, with *Streptococcus* sp, *Staphylococcus* sp, and anaerobes most commonly recovered when cultured.

Peritonsillar Cellulitis and Abscess

PTA is a complication of tonsillitis. It occurs more frequently in teenagers and younger adults, but it can present at any age, especially in immunocompromised or diabetic patients. The abscess forms in the potential space between the lateral aspect of the tonsillar capsule and the superior constrictor muscle of the pharynx. When tonsillitis spreads beyond the tonsil capsule, inflammation in this space results in cellulitis and abscess if left untreated. Abscess cultures tend to be polymicrobial, with the frequent presence of GABHS and anaerobes such as *Bacteroides*. *Lemierre syndrome* is septic thrombophlebitis of a neighboring internal jugular vein, usually caused by *Fusobacterium necrophorum*. It may be complicated by septic pulmonary emboli.

Supraglottitis/Epiglottitis

Supraglottitis is an acute disorder that usually produces substantial throat pain but is not generally considered a variant or a complication of acute pharyngitis. Strictly speaking, the term supraglottitis more appropriately defines the condition because the pathologic changes involve not only the epiglottis but also the aryepiglottic folds and false cords. *H. influenzae* type b was traditionally the most common bacterium found in blood cultures, but *S. pneumoniae* is also common.

ED EVALUATION

History

As with any presenting complaint, the onset, location, radiation, duration, quality, timing, and exacerbating and remitting factors of the pain or discomfort ought to be elicited. Throat pain of acute onset is common. If the diagnosis of acute infectious pharyngitis is obvious, an overly detailed evaluation is not necessary. If the etiology is not clear, a more complete evaluation is indicated and should include the following questions: Was pharyngeal trauma involved? Is a foreign body such as an impaled fish bone suspected? Has a caustic, irritative, or thermal agent been inhaled or ingested? Is this a single episode of throat pain, or recurrent? Does the pain

vary day to day, morning to evening, or is it seasonal? How long has the pain persisted? Is the pain positional? Does mouth opening or closing affect the pain? Is the pain associated with meals or certain types of foods?

The patient is often able to localize the origin of the pain (i.e., the nasopharynx, the oropharynx, or the hypopharynx). The pattern of pain radiation may indicate the location of a lesion, as painful swallowing is associated with faucial, lingual, oropharyngeal, or hypopharyngeal disorders. Pain in the throat brought on by exertion and relieved by rest may represent cardiac ischemia.

Associated symptoms such as the presence or absence of cough, fever, and coryza should be noted. Additional historical features such as earache, stiff neck, hoarseness, odynophagia, pain on protruding the tongue, trismus, facial pain, alterations in taste, or halitosis may be helpful. A history of contact with sources of infection is important, particularly in close social settings.

Physical Examination

Attention should be directed to the patient's general appearance and vital signs, including oxygen saturation. Signs suggestive of upper airway obstruction or sepsis must be quickly noted and addressed.

Patients with deep-space neck infections and epiglottitis may be much sicker and appear toxic, dehydrated, and febrile. The patient with an RPA may hold the head stiff or lean it to one side in the case of a PTA, as motion of the head and neck elicits pain. Anterior or lateral displacement of the larynx may be noted in an RPA or deep-space infection, and patients with Lemierre syndrome may present with anterolateral neck pain and swelling.

The face and anterior neck should be examined for sinus tenderness, parotid tenderness, or induration, fullness or masses in the mandibular space, lymphadenopathy, tenderness along the carotid sheath, pain on laryngeal manipulation (may indicate epiglottitis or parapharyngeal abscess), thyroid tenderness, and cervical spine mobility.

The carotids should be auscultated for bruits, and the oral cavity should be inspected. Trismus is often present with PTA but not with uncomplicated RPA or epiglottitis. Inflammation, mucosal ulcerations, purulence, and masses ought to be noted. There may be distortions of normal anatomy in patients with a deep-space abscess (e.g., palatopharyngeal arches, soft palate, posterior pharyngeal wall). In the case of RPA, the posterior pharyngeal wall may be displaced forward toward the uvula (Fig. 66.1). A PTA displaces the tonsil downward, medially, and deviates the uvula to the opposite side (Fig. 66.2). A process more caudal in the neck may show no abnormalities on oral examination.

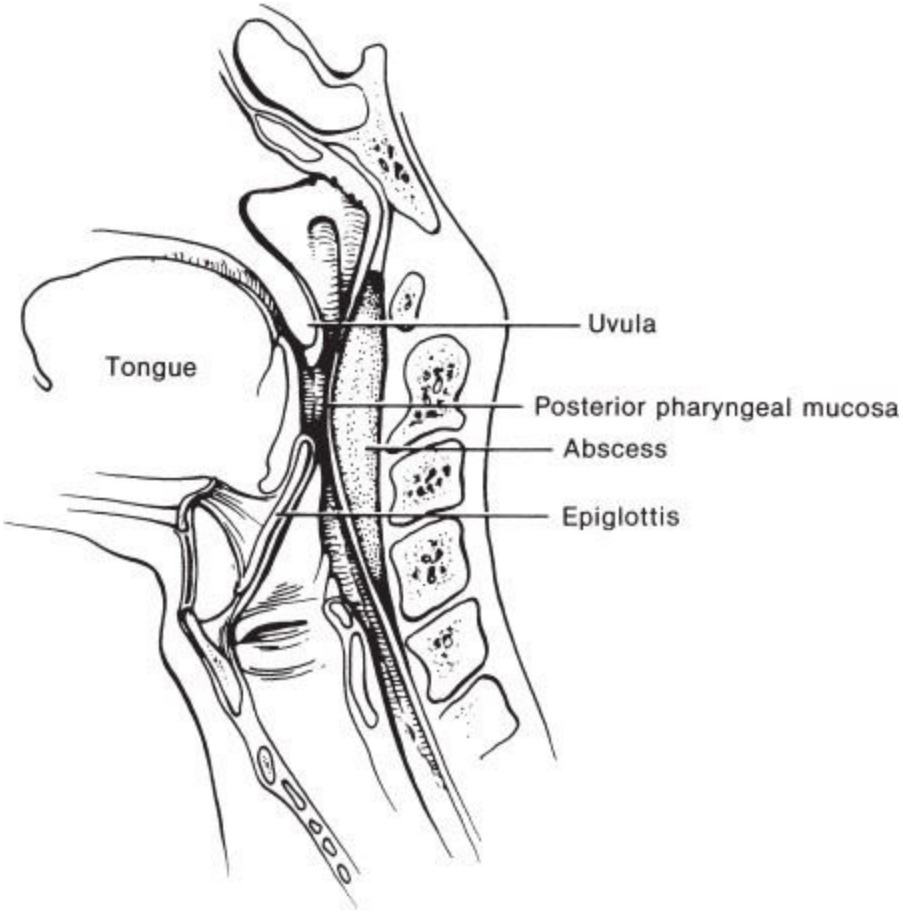

FIGURE 66.1 Retropharyngeal abscess.

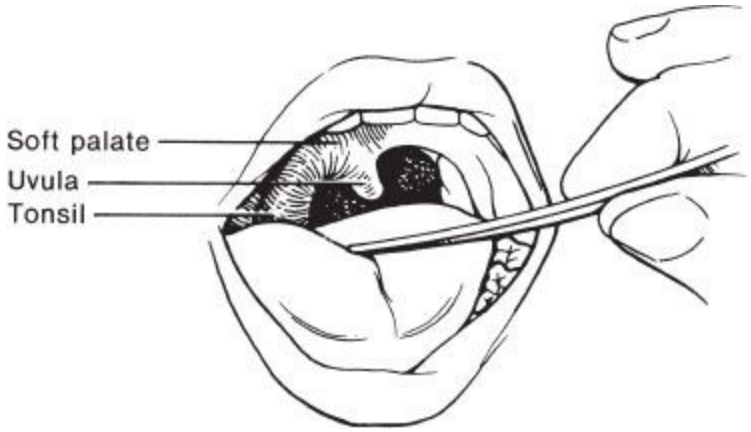

FIGURE 66.2 Peritonsillar abscess.

The use of a tongue depressor to facilitate the exposure of oral and pharyngeal structures has generated some controversy because of the prohibition placed on such a maneuver in evaluating the pediatric patient with suspected epiglottitis. With this exception, there ought to be no reluctance to utilize this maneuver. The patient is asked to protrude the tongue as part of this examination, and the presence of pain is noted.

Palpation of the floor of the mouth, the peritonsillar areas and the base of the tongue presents the risk of being bitten or provoking the gag reflex, but it may be indicated if an oral or lingual abscess or lesion is suspected. Lidocaine 5% ointment applied to the base of the tongue or lidocaine 4% aqueous to gargle prior to palpation may attenuate or eliminate these responses. Although palpation of the posterior pharyngeal wall may confirm the diagnosis of RPA, this maneuver is not recommended because of the risk of rupturing the abscess into an already compromised airway.

If a nasopharyngeal or hypopharyngeal lesion is suspected but not visible on direct examination, flexible endoscopic nasopharyngoscopy may be undertaken, particularly in the case where symptoms are ‘out of keeping’ with physical findings and supraglottitis is suspected. Preparation should include the administration of a vasoconstrictor nasal spray (e.g., 0.25% phenylephrine), topical anesthesia for the nasal mucosa (e.g.,

lidocaine 4% atomized or by pledgets), and oropharyngeal topicalization as described above.

Diagnostic Imaging

Radiologic studies are not indicated in most patients with sore throat. However, when one suspects the presence of RPA or supraglottitis, the following studies may be useful.

Lateral soft tissue x-ray: Plain films have some utility in detecting a thickened prevertebral stripe (as in RPA) or swollen epiglottis. Moderately sensitive and specific, these studies cannot be relied upon to exclude these potentially life threatening conditions (4).

Indirect endolaryngoscopy and ultrasound: Recent advances in ultrasound applications have identified this modality as effective in diagnosing upper airway conditions, particularly epiglottitis (5,6).

CT scan: Contrast-enhanced computed tomography scanning is the imaging study of choice in defining the extent of deep-space neck infection in peritonsillar, retropharyngeal, and parapharyngeal abscesses, if the patient is cooperative and sufficiently stable to lay flat for the study. Ultrasound and magnetic resonance imaging (MRI) may also be useful in some cases (5,6).

Laboratory

General laboratory studies such as complete blood count, coagulation profiles, electrolyte studies, and renal and hepatic function are not helpful unless otherwise indicated. A blood sugar determination may be useful in diagnosing an occult diabetic.

Culture of a throat swab on a sheep blood agar plate is considered the gold standard for confirmation of acute GABHS pharyngitis (7). Rapid antigen detection tests (RADTs) have supplanted throat culture in many clinical settings as they are easily done, reasonably reliable, and give immediate results. *N. gonorrhoeae* and *C. diphtheria,* if suspected, require specific collection techniques and culture media.

Guidelines promulgated by the American College of Physicians (ACP), the American Academy of Family Physicians (AAFP), and the

Centers for Disease Control and Prevention (CDC), the Infectious Diseases Society of America (IDSA), and the American Heart Association (AHA)–American Academy of Pediatrics do not recommend throat swabbing or rapid antigen detection testing when there are no clinical features suggestive of streptococcal infection as identified in Table 66.2 (2). In the event that clinical suspicion is high and RADT is negative throat swabbing has been recommended. The recent development of chemiluminescent single-stranded DNA probe that detects specific rRNA sequences unique to GABHS has been shown to be highly sensitive and specific and considered by some to be equivalent to throat culture as a confirmatory test. The IDSA recommends routine confirmation of negative RADTs by culture or DNA probe unless the patient is treated. However, the cost-effective nature and medical necessity of this practice in adults has been questioned because of its substantial cost, delay in antibiotic prescribing, and because suppurative complications are very uncommon (7).

KEY TESTING

For suspected supraglottitis:
- Video laryngoscopy (flexible, stylette, blade)

For suspected GABHS pharyngitis of intermediate suspicion, consider:
- Rapid antigen detection testing
- Throat swab or DNA probe (controversial)

For suspected RPA:
- CT scan

ED MANAGEMENT

Initial attention should be directed to the airway, breathing, and circulation (ABCs) and immediate life threats. The patient is observed for signs of airway compromise, and the vital signs are examined for evidence of cardiovascular compromise. The four cardinal signs of upper airway obstruction include muffled voice (hot potato voice), difficulty swallowing secretions, dyspnea, and

stridor. Although the first two may not herald imminent upper airway obstruction, dyspnea and stridor are much more sinister. The presence of stridor generally indicates that the airway has been reduced to 4.5 mm or less (8). Any of these findings in a patient who insists on sitting upright to breathe should prompt an immediate upgrade to an acute resuscitation area in the ED for possible airway management.

The treatment of sore throat without airway compromise is mostly symptomatic, utilizing gargles and mild analgesics. Ulcerated, extremely painful lesions may be dabbed with a cotton-tipped swab containing a solution of 4% lidocaine and bismuth subsalicylate (Kaopectate) (to make it adhere), though the efficacy of this therapy in relieving pain is anecdotal and unproven. Some have reported that adults with moderate to severe pharyngitis obtain relief of symptoms sooner if treated with IM or oral dexamethasone (9).

GABHS

A number of antibiotics have been shown to be effective in treating GABHS pharyngitis, including penicillins, cephalosporins, macrolides, and clindamycin. Penicillin remains the agent of choice because of its proven efficacy, safety, narrow spectrum, and low cost (2). Patients with acute infectious mononucleosis treated with ampicillin or amoxicillin may develop a rash.

Supraglottitis

Patients with severe airway compromise or obstruction must receive immediate airway management in the ED. Patients with mild dyspnea or respiratory complaints may be closely monitored in the intensive care setting. Indirect flexible or rigid videolaryngoscopy is helpful in evaluating the adequacy of the airway in these patients and as a guide to the aggression of therapeutic maneuvers. The antibiotic of choice on empiric grounds is cefuroxime, cefotaxime, ceftriaxone, or ampicillin–sulbactam (Unasyn). Though some

recommend the use of steroids, scientific evidence is lacking. Aerosolized epinephrine is not thought to be useful.

Retropharyngeal Abscess

Intravenous fluids and intravenous antibiotics such as high-dose penicillin (6 million units every 6 hours) and metronidazole (500 mg every 6 hours after a 1 g loading dose), or cefoxitin (2 g every 8 hours) should be started immediately. An otolaryngology consult should be obtained early. Patients should be admitted to the intensive care unit or taken directly to the operating room. Definitive management includes incision and drainage under carefully controlled circumstances. The presence of mediastinitis mandates a surgical consult.

Peritonsillar Cellulitis

Intravenous fluids should be given to correct dehydration, and intravenous antibiotics should be initiated. Penicillin (1 to 2 million units every 4 hours) or clindamycin (600 mg every 8 hours) are good choices. Early cellulitis may be treated with hydration and antibiotics alone, though it may be difficult to differentiate from abscess. Needle aspiration may provide both diagnostic information and therapeutic benefit if abscess is present. Lemierre syndrome is primarily treated with intravenous antibiotics with anaerobic coverage.

Peritonsillar Abscess

In addition to the antibiotic regimen described for peritonsillar cellulitis, diagnostic and therapeutic needle aspiration is indicated (10). With the patient in the sitting position and hunched slightly forward, topical anesthetic is applied to the posterior pharynx. The patient should be told that although an initial puncture will be felt, the procedure is likely to reduce the pain significantly. Aiming posteriorly toward the medial aspect of the enlarged tonsil, an 18- or 20-gauge needle is inserted to a depth of 2 cm, aspirating during

insertion. Insertion of the needle more than 2 cm runs the risk of puncturing the internal carotid artery.

CRITICAL INTERVENTIONS

- Provide emergency airway management for patients with impending airway obstruction, such as severe epiglottitis or RPA.
- Initiate antibiotic therapy promptly for serious throat infections.

DISPOSITION

All patients with signs of upper airway obstruction should be admitted. Immunocompromised patients may need to be admitted to hospital for aggressive intravenous antibiotic and fluid management and continuous observation.

All patients with epiglottitis or RPA, whether or not they are intubated, should be admitted to a high acuity unit for close observation.

Nonimmunocompromised patients with uncomplicated, peritonsillar cellulitis that can take fluids and medications orally may be discharged, provided they are in the company of a reliable caretaker and close follow-up is arranged.

Patients with PTA can be discharged on appropriate antibiotic therapy after successful aspiration or incision and drainage. If the treatment does not relieve severe symptoms, or if there is any suspicion of spread of infection beyond the peritonsillar area, admission for further evaluation and treatment will be required.

Almost all patients with simple pharyngitis can be treated as outpatients, with follow-up as needed.

Common Pitfalls

- Overtreatment of pharyngitis, most of which are viral in etiology, with antibiotics.
- In a patient with severe symptoms, excluding the diagnosis of supraglottitis without visualization of the epiglottis and surrounding structures.

- Underestimating the severity or potential for airway compromise in patients with RPA or PTA.

CHAPTER 67

Sinusitis and Rhinitis

Hagop M. Afarian

Upper respiratory complaints, including sinusitis, are among the most common disorders encountered by the emergency physician. It is estimated that 14% of the US population, approximately 31 million people, are treated annually for diseases of the paranasal sinuses, costing approximately 5.8 billion dollars each year (1,2). Sinus disease is usually a harmless inconvenience; however, it occasionally presents as a fulminant, life-threatening entity in the ED.

Sinusitis is an inflammatory disease of the paranasal sinuses resulting from infectious, allergic, or autoimmune processes (3). Rhinitis strictly means inflammation of the nasal mucous membranes. Rhinitis may be caused by allergic (most common), nonallergic, infectious, hormonal, occupational, and other factors (4). This chapter will focus on rhinitis as part of a broader infectious disease spectrum. Rhinosinusitis has been proposed as a more precise definition, as inflammation frequently involves the nasal passages, and sinusitis without rhinitis is rare (5).

The human sinuses are composed of four paired, sterile cavities lined with ciliated, columnar epithelium. Maxillary and ethmoid sinuses are present at birth. Frontal and sphenoid sinuses develop in the 7th and 10th year of life, respectively (6). Individual sinus anatomy is highly variable, with frontal sinuses absent in 2% to 5% of the population (7). The posterior ethmoid and sphenoid sinuses empty into the superior meatus. The frontal, anterior ethmoid, and maxillary sinuses empty into the ostiomeatal complex within the middle meatus. Obstruction of the ostiomeatal complex (OMC)

caused by inflammation, anatomic abnormality, or other pathology is the critical event in the development of acute sinusitis (6). Maxillary sinusitis is most common, followed by ethmoid, frontal, and sphenoid (1).

A practice guideline published in the 2007 *Journal of Otolaryngology: Head and Neck Surgery* classified sinusitis into acute (<4 weeks), subacute (4 to 12 weeks), chronic (>12 weeks) with or without acute exacerbations, and recurrent acute (having four episodes of sinusitis within 1 year with complete resolution of symptoms between each episode) (2).

The exact incidence and prevalence of sinusitis is difficult to determine because of a lack of rigid criteria defining sinus disease. Women are affected approximately twice as often as men (8). An estimated 0.5% to 2% of upper respiratory infections (URIs) in adults and 5% of URIs in children are complicated by acute bacterial sinusitis (8). Furthermore, up to 16% of Americans suffer from chronic sinusitis (2,9).

Most cases of sinusitis follow a viral URI. Viruses injure the sinus epithelium, resulting in ciliary dysfunction and an inflammatory cascade. Mucostasis and a damaged epithelium make the sinuses susceptible to secondary bacterial invasion. Inflammation results in occlusion of the OMC, obstructing sinus drainage and creating a hypoxic, hypercarbic, acidic environment with negative pressure, promoting bacterial growth (10).

Other factors contribute to the development of sinusitis. Five percent to 10% of acute maxillary sinusitis occurs because of contiguous spread of dental infection (9). Ciliary motility disorders, both congenital (Kartagener syndrome) and acquired, predispose to sinusitis. Inflammatory changes and anatomic abnormalities (polyps, adenoids, tumors) can result in OMC occlusion. Nasal foreign bodies also result in OMC obstruction, leading to sinusitis; 95% of nasally intubated patients develop sinusitis (9). Immunocompromised patients are more susceptible to the development of sinusitis and are more likely to have severe disease (9).

Infectious sinusitis can be of viral, bacterial, or fungal origin. Viral rhinosinusitis is 20 to 200 times more common than bacterial

sinusitis (11). Over 200 viruses have been implicated, with subtypes of rhinovirus, parainfluenza, and influenza virus being the most common (12). *Streptococcus pneumoniae* (30% to 40%), nontypeable *Haemophilus influenzae* (30% to 40%), *Moraxella catarrhalis, Staphylococcus aureus,* other streptococcal species, and anaerobes of dental origin compose the primary pathogens in acute bacterial sinusitis (8). Viral infections predominate in the first 10 days followed by a predominance of aerobic bacteria for up to 3 months and then anaerobic bacteria thereafter (10). *Pseudomonas* sp is an important pathogen in patients with cystic fibrosis and HIV and those with nasal tubes. Fungal sinusitis may present as an acute fulminant or a chronic indolent process. Mucoraceae species including *Rhizopus* sp, *Mucor* sp, and *Absida* sp cause necrotizing invasive disease, most often in patients with diabetic ketoacidosis (13). *Aspergillus* sp are becoming a more common pathogen, manifesting in one of the three chronic forms in immunocompetent adults: indolent invasive, mycetoma ("fungus ball"), and allergic fungal sinusitis, the most frequent form of fungal sinusitis in the United States (14).

CLINICAL PRESENTATION

The clinical presentation of acute sinusitis is highly variable, but usually includes purulent nasal discharge, congestion, facial pressure, dental pain, fever, headache, cough, fatigue, halitosis, or a diminished sense of smell. Many of the symptoms are indistinguishable from those of a viral URI; thus duration of symptoms becomes critical in diagnosis. A patient with cold symptoms not resolving after 7 to 10 days has a higher likelihood of acute bacterial sinusitis (11).

Systemic toxicity, mental status changes, severe headache, and fever are signs and symptoms indicative of a more serious sinus disease and its complications (7). Periorbital cellulitis is the most common complication of sinusitis, usually originating from the ethmoid sinuses (15), and must be differentiated from orbital cellulitis (see Chapter 60). Intracranial complications of sinusitis

include meningitis, osteomyelitis, cavernous sinus thrombosis, and intracranial abscesses (epidural, subdural, and intracerebral). Fifteen percent of meningitis cases may be of paranasal sinus origin (7). Extension of acute frontal sinusitis with suppurative inflammation of cortical bone results in the Pott puffy tumor, a condition requiring aggressive surgical and antimicrobial therapy (15). Cavernous sinus thrombosis presents with periorbital edema, exophthalmos, papilledema, and cranial nerve III, IV, and VI palsies. Intracranial abscesses will usually present with fever and acute neurologic signs, and 33% of patients develop long-term morbidity, including blindness, hemiparesis, seizure disorders, and cognitive impairment (7).

Special consideration must be given to the immunocompromised host with sinus complaints, as invasive fungal sinusitis is much more common in this population. Patients are typically toxic and may present with moldy smelling, thick, brown or black nasal discharge. The nasal mucosa may become gray and eventually necrotic from fungal–vascular invasion. Perforation of the palate, nasal septum, or cribriform plate may be apparent (14). The invasive organisms cause ischemic necrosis of the bone and mucosa with hematogenous invasion of the orbit, skin, and brain. Progression to coma and death can occur within hours. Interestingly, acute fungal sinusitis is relatively rare in acquired immune deficiency syndrome (AIDS) patients, presenting as a late-stage phenomenon when CD4 counts drop to $<50/mm^3$ (14). Aspergillus is the most common fungal pathogen in this group.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for sinusitis is broad, as the signs and symptoms of sinus disease are neither sensitive nor specific. Viral URI, nasal polyps, cocaine abuse, allergic rhinitis, and vasomotor rhinitis all may present with symptoms of nasal discharge and congestion. Cerebral spinal fluid rhinorrhea should be considered in a patient with a history of head trauma. Persistent unilateral nasal discharge with epistaxis is concerning for neoplasm or nasal foreign

body (1). Tension, cluster, and migraine headaches and dental disease are alternative diagnoses in the patient whose sinus disease manifests as cephalgia or facial pain.

ED EVALUATION

Acute sinusitis is a diagnosis based primarily on clinical history and physical findings (Table 67.1). Unfortunately, physical examination findings are not specific for acute sinusitis (12). Findings may include mucosal hyperemia, purulent rhinorrhea, nasal airway congestion, crusting of the anterior nares, and facial pain. However, palpable facial tenderness is a poor indicator of underlying sinus infection, and "purulent" discharge is not a reliable indicator of bacterial sinusitis (8). Transillumination has poor correlation with the presence of fluid, poor intraobserver consistency, and poor specificity. Thus, transillumination is of little use in the diagnosis of acute sinus disease (12).

TABLE 67.1
Major and Minor Factors for Diagnosis of Acute Sinusitis[a]

Major[b]	Minor
Facial pain or pressure	Headache
Facial congestion	Cough
Fever	Fatigue
Nasal congestion/obstruction	Halitosis
Purulent anterior nasal discharge	Dental pain
Purulent posterior nasal discharge	Ear pain/pressure
Hyposmia or anosmia	

[a]From the Task Force on Rhinosinusitis (11) and Chow AW, Benninger MS, Brook I, et al. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. *Clin Infect Dis.* 2012;54(8):e72–e112 (8).
[b]Diagnosis requires two major OR one major and two minor factors in a patient with symptoms for more than 7 days.

Radiographic imaging has little role in the diagnosis of acute sinus disease in the ED. Abnormal findings are common in asymptomatic individuals, and findings such as air–fluid levels, sinus opacification, or mucosal thickening have poor sensitivity

(12). Plain radiographs are often normal in patients with acute disease and abnormal in those without disease (12).

Computed tomography (CT) scan is more sensitive than plain films in the detection of sinusitis but is overly sensitive in detecting "disease" (16). Eighty-seven percent of patients with viral URIs have abnormalities consistent with sinusitis on CT (9). Use of CT in the ED should be limited to ruling out other diagnoses such as malignancy. CT is indicated when serious complications of sinusitis are suspected and in patients who are not improving after antibiotic therapy (5,8,16).

Nasal cultures are not helpful in the diagnosis of acute sinusitis, as growth correlates poorly with cultures from sinus aspirates (9). Sinus aspiration, although more specific, is excessive and impractical in the ED. Blood tests are necessary only in patients who show signs of systemic toxicity, CNS involvement, or who have significant comorbid disease or immunosuppression.

As the ED applications of ultrasound expand, it may become one more tool to help in the diagnosis of sinusitis. One study reported high sensitivity and specificity of ultrasonography for sinusitis (17). However, it is operator dependent and feasible only for the frontal and maxillary sinuses.

The lack of a simple, accurate diagnostic test means that physicians must rely on a clinical diagnosis in most cases, but this creates a tendency to label many common colds as sinusitis (1). Duration and severity of symptoms may provide clues in the diagnosis. In acute bacterial sinusitis, symptoms generally last greater than 10 days, worsen after 3 to 4 days or after a period of improvement "double sickening," and are much more severe than those associated with a viral URI (8,11).

KEY TESTING

- Laboratory tests and imaging are not indicated in most patients with rhinosinusitis. Testing should be reserved for toxic, immunocompromised patients or those with a suspected intracranial complication

ED MANAGEMENT

The goal of therapeutic intervention in acute sinusitis is threefold: to relieve obstruction of the OMC, to restore mucociliary clearance, and to reestablish sinus sterility through eradication of infection (6). As acute sinusitis is not purely an infectious process, antimicrobial therapy alone will likely fail (1). Combination treatment with antibiotics, analgesics, topical and systemic steroids, nasal and oral decongestants, mucoevacuents, antihistamines, and nonpharmacologic measures may provide the best symptomatic and therapeutic outcome.

There is some evidence to suggest that both topical and systemic corticosteroids may provide benefit to patients with acute sinusitis. The use of topical steroids in acute sinusitis is attractive, as they are a potent anti-inflammatory agent with few side effects. Some studies have demonstrated improved symptom relief, but the clinical efficacy of topical and systemic steroids remains uncertain (9,12,18). The greatest benefit to both topical and systemic corticosteroids may be when used as adjunctive therapy to antibiotics (8,18).

Topical α-adrenergic agonists, such as oxymetazoline 0.05%, have been used to decrease mucosal edema, promoting sinus drainage. These agents should not be used for more than 3 days as this may elicit *rhinitis medicamentosa* because of rebound vasodilation. α1-Agonists, such as phenylephrine, do not reduce blood flow of the nasal mucosa to the same degree as α2-agonists and therefore are preferred (5). Oral systemic decongestants (ephedrine, pseudoephedrine, phenylephrine, phenylpropanolamine) may be helpful, but side effects, including nervousness, insomnia, hypertension, and tachycardia, may limit their use. Oral decongestants have a weaker effect on the nasal mucosa, but they do not cause the rebound vasodilation noted with topical agents.

The mucoevacuent guaifenesin can be used to increase mucous flow and decrease mucous viscosity (9). Side effects are minimal but may include abdominal discomfort and emesis (12). Antihistamine use in acute sinusitis remains controversial. Although antihistamines

may decrease rhinorrhea, some argue their use is contraindicated as they may cause xerostomia, increasing mucous viscosity, leading to inspissation and outflow obstruction (8). Nonpharmacologic therapy such as steam inhalation and saline rinses provide symptomatic relief by softening crusts and moisturizing dry mucosa. Both isotonic and hypertonic solutions can be used for nasal irrigation, without significant evidence to support one over the other (19).

Although treatment of acute sinusitis requires a multifaceted regimen, the main question remains whether or not to use antibiotics. In 2012 the Infectious Diseases Society of America (IDSA) published a clinical practice guideline to provide recommendations for the treatment of bacterial sinusitis (8). Antibiotics are frequently prescribed, but great controversy exists regarding indications for use, choice of antimicrobial agent, and duration of therapy (20). Many studies suggest that in the majority of patients, acute sinusitis resolves quickly with or without antibiotics. Mild cases of rhinosinusitis with symptoms lasting less than a week are most likely viral in etiology and should not be treated with antibiotics (11). Symptoms lasting more than 10 days, worsening after 3 to 4 days, or after a period of improvement "double sickening" are more likely to be bacterial (8). Severe cases with significant pain, fever, and comorbidities should be treated with first-line antibiotics, while nonsevere cases should only be treated with antibiotics if there are no signs of improvement after 7 to 10 days (2).

Amoxicillin is still a first-line agent of choice in acute sinusitis, however, with increasing rates of resistance, there is evidence, greater in children than adults, to support use of amoxicillin–clavulanate as first-line empiric therapy (Table 67.2) (8). Most studies show no difference in efficacy between antibiotics, although high-dose therapy is recommended in areas with higher rates of penicillin-nonsusceptible *S. pneumoniae* (3,8). Empiric therapy with trimethoprim–sulfamethoxazole and macrolides are no longer recommended in the treatment of acute bacterial rhinosinusitis because of high rates of resistance, while doxycycline continues to remain effective (8). While there have been reports of acute

bacterial rhinosinusitis due to methicillin-resistant *Staphylococcus aureus* (MRSA), routine empiric treatment for MRSA is not typically indicated (8). Recommendations for duration of therapy span from 5 to 7 days to 10 to 14 days (1). A small number of studies have shown 3 days of therapy can be as effective as longer courses of treatment (21). Second-line agents should be initiated in cases that fail first-line therapy (8,11). The natural course of untreated acute sinusitis is unknown, but it is estimated that many, if not most, cases resolve without treatment (3). In the midst of the antibiotic controversy, it is important to remember the importance of basic symptomatic treatment.

TABLE 67.2
Antibiotic Therapy Alternatives in Acute Sinusitis[a]

Drug	Dose (Adult)	Dose (Pediatric)
First-Line Therapy		
Amoxicillin (high dose)	1 g PO tid × 10 d	90 mg/kg/d max of 3 g/d PO divided bid × 10–14 d
Amoxicillin/ clavulanate	875/125 mg PO bid × 10 d	45 mg/kg/d Amox + 6.4 mg/ kg/d Clav PO divided bid × 10–14 d
Second-Line Therapy		
Amoxicillin/ clavulanate	2,000/125 mg PO bid	90 mg/kg/d Amox + 6.4 mg/ kg/d Clav PO divided bid × 10–14 d
Doxycycline	100 mg PO bid or 200 mg PO qd	Not recommended for children
Cefprozil	250–500 mg PO bid × 7–14 d	7.5–15 mg/kg PO divided bid 10–14 d
Cefdinir	300 mg PO bid or 600 mg PO qd × 7–14 d	14 mg/kg PO divided qd or bid 10–14 d
Cefpodoxime proxetil	200 mg PO bid × 7–14 d	15 mg/kg PO divided bid × 10–14 d
Azithromycin	500 mg PO qd day 1 then 250 mg/d on days 2–5	10 mg/kg PO qid on day 1 followed by 5 mg/kg PO qid days 2–5
Clarithromycin	500 mg PO bid for 14 d	6 mos and older 15 mg/kg/d (divided bid) for 10 d, max 1 g/d
Third-Line Therapy		
Levofloxacin	750 mg PO qd × 5 d or 500 mg PO qd × 10 d	Safety and efficacy in children under 18 yrs of age have not been established
Moxifloxacin	400 mg PO qd × 10 d

PO, by mouth; qd, once daily; tid, three times a day; bid, twice a day; qid, four times a day.

Special consideration is needed for managing sinusitis in children, the elderly, and immunocompromised patients. Children with recurrent acute sinusitis or chronic sinusitis, despite aggressive therapy, should be referred for evaluation for cystic fibrosis or underlying immune dysfunction (6). In elderly patients, the threshold for treating acute sinusitis should be lower, as aggressive

medical intervention may be important in reducing morbidity in this group (12). In immunocompromised patients, increased alertness for fulminant sinusitis and its complications is necessary. The initial treatment of acute sinusitis is essentially the same regardless of HIV status, except for duration of antimicrobial therapy: 21 days of therapy is recommended (22). In patients with CD4 counts of $>200/mm^3$, opportunistic sinus infections are more common and are more resistant to standard therapy (23). In addition, those patients who have had a recent hospitalization within the last 5 days or who have taken antibiotics within the last month are at higher risk for failure of first-line therapy, and second-line therapy should be considered instead (8).

Patients with severe headache, altered mental status, systemic toxicity, meningeal signs, or visual complaints suggestive of intraorbital or intracranial extension require aggressive evaluation and management. Administration of broad-spectrum antibiotics, generally a third-generation cephalosporin plus vancomycin, should not be delayed by diagnostic procedures (3). This treatment should be followed by CT, lumbar puncture, and appropriate consultation (1).

CRITICAL INTERVENTIONS

- Promptly initiate antibiotic therapy for severe cases of sinusitis in elderly, immunocompromised, or toxic patients.
- Order imaging studies and initiate parenteral antibiotics early in patients with suspected intracranial complication of sinusitis.

DISPOSITION

Most patients with acute, uncomplicated sinusitis or rhinitis can be safely discharged with instructions to return to the ED or follow up with their regular doctor if symptoms are worsening or not improving within several days. Patients should be educated on the signs of potential intracranial extension (severe headache, vomiting, and confusion) and advised to return to the ED immediately. Patients with sinus symptoms lasting longer than 1 month, despite a

complete course of therapy, should be referred to an otolaryngologist for further evaluation (1).

Patients with intracranial extension of sinus disease require aggressive parenteral antibiotics and hospital admission, often to a critical care setting. Transfer to a referral center is necessary if a specialist is not readily available for these patients. Appropriate stabilization efforts and intravenous antibiotic therapy should be initiated prior to transfer, and advanced cardiac life-support-capable transport by ground or air is necessary.

Common Pitfalls

- Routine radiographic imaging in the setting of acute uncomplicated sinusitis adds little to the evaluation and is often misleading.
- Overuse of antibiotics in healthy patients with symptoms for less than 1 week.
- Failure to recognize signs of a serious complication. Patients with sinusitis and marked headache and fever must be carefully evaluated, with increased concern in the elderly or immunocompromised patient.

CHAPTER 68

Ear Infections in Adults

Michael Cole and Sukhjit S. Takhar

The vast majority of ear infections in the antibiotic era are benign and self-limited. However, there are certain life-threatening conditions that require prompt diagnosis and treatment (eTable 68.1).

TABLE 68.1
Therapeutic Options for the Management of Otitis Externa[a]

Drug	Dosage	Comments
VoSol Otic HC (2% acetic acid)	4 drops every 6 h for 7–10 d	Use only in mild disease when the tympanic membrane can easily be visualized
Ciprofloxacin otic HC Ofloxacin otic HC	4 drops every 12 h for 7–10 d	More expensive. Very high topical levels may overcome resistance.
Neomycin/polymyxin B/hydrocortisone	4 drops every 8 h for 7–10 d	Can cause contact dermatitis. Do not use if the tympanic membrane is ruptured.

[a]Note: Removal of debris from the ear canal should always be performed prior to antibiotics administration.

eTABLE 68.1
Most Common Etiologies of Ear Pain

Diagnosis	Symptoms/Signs	Typical Treatment	Example
Acute Otitis Externa	Erythema of ear canal Edema of ear canal Otorrhea	Cleaning the ear canal Topical agents (e.g., antibiotics, acetic acid)	
Acute Otitis Media	Middle ear effusion Limited TM* mobility on pneumotoscopy Erythematous TM Bulging TM	Oral antibiotics Watchful waiting in otherwise healthy patients	Mastoiditis	Inflammatory changes over the mastoid process Tenderness of the mastoid process Displacement of the auricle by inflammation and edema	Intravenous Antibiotics Consider emergent otolaryngology and/or Infectious disease consult in moderate to severe cases	 From Fleisher GR, Ludwig W, Baskin MN. *Atlas of Pediatric Emergency Medicine.* Philadelphia, PA: Lippincott Williams & Wilkins; 2004
Auricular Cellulitis	External Ear is: Erythematous Tender Warm Ear Lobule may be affected	Oral or Intravenous antibiotics depending on severity of disease	 Courtesy of Steven D. Handler, MD, MBE
Perichondritis	External Ear is: Erythematous Tender Warm Ear Lobule is spared Piercing often present	Oral or intravenous antibiotics depending on severity of disease Consider emergent otolaryngology and/or Infectious disease consult in moderate to severe cases	 Used with permission from Handler SD, Myer CM. *Atlas of ear, nose and throat disorders in children.* Ontario, Canada: BC Decker; 1998:12

Diagnosis	Symptoms/Signs	Typical Treatment	Example
Cholesteatoma	Collect of keratinized epithelial cells on TM Asymptomatic or hearing loss, dizziness	No acute treatment Otolaryngology referral	 Asset provided by Anatomical Chart Co
Bullous Myrinigitis	Painful vesicles on TM Often mycoplasma infection	Antibiotics—similar spectrum as acute otitis media	 The Wellcome Trust, National Medical Slide Bank, London, UK
Otitis media with effusion	Middle ear effusion without signs of acute inflammation	None. Self limiting	 Courtesy of Alejandro Hoberman, Children's Hospital of Pittsburgh, University of Pittsburgh

[2]TM = Tympanic Membrane.

ACUTE OTITIS EXTERNA

Acute otitis externa (AOE) is a diffuse inflammatory condition of the external ear canal. Knowledge of the anatomy helps to understand AOE and its complications. The external ear is composed of the external auditory canal (EAC) and the auricle. The outer portion of the external canal is cartilaginous with a well-developed dermal layer. The inner, or osseous, portion is lined by a thin layer of epithelium that is firmly attached to the periosteum of the temporal bone (Fig. 68.1). The narrowest part of the canal is the osseous–cartilaginous junction. Cerumen is produced by the apocrine glands and is required for a healthy ear canal. It is a thin, acidic, protective coat that is inhospitable to many microorganisms including those most commonly implicated in AOE (1).

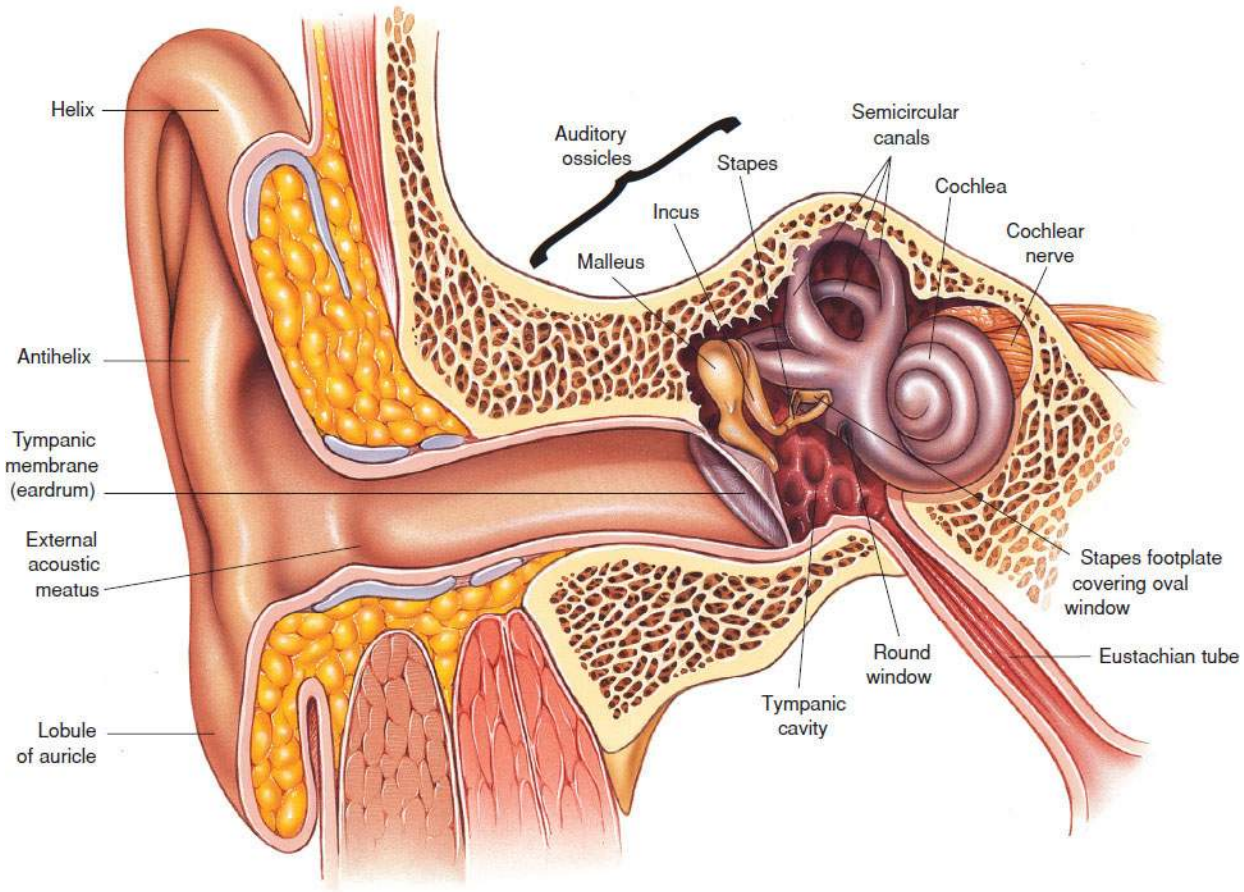

FIGURE 68.1 Anatomy of the middle ear. Asset provided by Anatomical Chart Co.

The overlying squamous epithelium of the inner portion can be disrupted by direct trauma, prolonged use of ear plugs, ear phones or hearing aids, or maceration from prolonged water exposure, providing the initial insult that leads to infection (2). A warm, humid environment promotes bacterial growth. AOE, often known as *swimmer's ear,* occurs most often in the summer months and in tropical climates with *Pseudomonas aeruginosa* and *Staphylococcus aureus* being the most common pathogens (3,4). Fungal infections are typically seen in chronic disease and occasionally cause AOE.

Invasive otitis externa, also called necrotizing otitis externa or malignant otitis externa, is a rare complication of otitis externa. Essentially it is osteomyelitis of the temporal bone, occurring when the infection spreads from the auditory canal to the temporal bone

and nearby structures, like the cranial nerves. It was originally called *malignant otitis* due to the high associated mortality. It occurs most often in the elderly diabetic patient and occasionally in other immunocompromised patients. *P. aeruginosa* is the responsible organism in up to 98% of cases (5,6).

ACUTE OTITIS MEDIA

Acute otitis media (AOM) is an inflammatory process of the middle ear. It occurs most commonly in young children. In adults, the pathophysiology and treatment are quite similar, with a few noteworthy differences.

Eustachian tube dysfunction is critical in the pathogenesis of otitis media. The tube connects the middle ear cavity to the nasopharynx and provides ventilation and drainage (see Fig. 68.1). Eustachian tube dysfunction may result from an upper respiratory tract infection, allergy, barotrauma, or nasopharyngeal tumor. These inciting factors may lead to congestion and accumulation of fluid behind the tympanic membrane (TM). If this fluid subsequently becomes infected by nasopharyngeal organisms, AOM is the result.

The most common organisms involved in AOM are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis* (7,8). Viruses are often present as coinfection agents. Patients with chronic disease can be infected with *Pseudomonas* or *S. aureus.*

Complications of otitis media occur when the infection spreads beyond the confines of the middle ear. Intracranial spread may lead to meningitis, brain abscess, or lateral sinus thrombosis, whereas extracranial spread leads to TM perforation, mastoiditis, subperiosteal abscess, facial nerve paralysis, or petrous apicitis (9,10). Complications have decreased dramatically in the antimicrobial era.

It is noteworthy that the mastoid air cells are connected to the middle ear. In uncomplicated otitis media, patients often have fluid in the mastoid air cells. Therefore the finding of fluid in the mastoid air cells on imaging is nonspecific and requires clinical correlation. Mastoiditis is clinically diagnosed when there is tenderness over the

mastoid prominence, displacement of the auricle posteriorly and inferiorly, and signs of inflammation.

AURICULAR CELLULITIS AND PERICHONDRITIS

Infections of the external ear structures are usually the result of local trauma or extension from a severe case of otitis externa. Auricular cellulitis is an infection of the dermis overlying the external ear and it is most often caused by streptococci or staphylococci.

Perichondritis is infection or inflammation of the perichondrium of the auricular cartilage. Piercing the upper third of the pinna ("high piercing") has become fashionable, and it allows the introduction of bacteria into a poorly vascularized area. Although most infections are due to staph and strep, patients with recent (<1 month) piercings appear to have an increased incidence of pseudomonal infection (11,12). Cosmetic deformity following perichondritis is common and difficult to avoid.

CLINICAL PRESENTATION

The initial symptoms of otitis externa may be pruritus and a sensation of fullness, which can progress to more severe pain, mucopurulent discharge, and hearing loss (13). Infection may spread beyond the ear canal, leading to pain in surrounding soft tissues and lymph nodes. Potential spaces, tissue planes, and fissures in the external ear canal can allow the spread of bacteria to the temporal bone, parotid gland, and the temporomandibular joint. Infection may also spread through the thin, osseous portion of the ear canal to the skull base. Patients with necrotizing external otitis complain of severe, unrelenting pain, often worse at night. Cranial nerve VII (facial) is the most commonly affected, leading to facial paralysis, although others may be involved (5,6).

Patients with AOM develop progressive pain as fluid accumulates in the middle ear, bulging the TM outward. There can also be hearing loss, vertigo, and low-grade fever. Perforation of the TM leads to drainage of pus or blood. This differs from otitis externa in that the pain improves after perforation and drainage occur.

Auricular cellulitis resembles soft tissue infections in other parts of the body. The ear is tender and erythematous in the absence of systemic complaints. Perichondritis is a deeper infection. Patients may present days to weeks after a high piercing. There is localized tenderness and possible purulent drainage and the ear may also appear deformed. The ear lobule is devoid of cartilage and is not involved in perichondritis.

DIFFERENTIAL DIAGNOSIS

A variety of conditions can mimic otitis externa. These conditions may cause otalgia, otorrhea, and/or inflammation of the external ear canal. Commonly, otitis media with a perforation of the TM is misdiagnosed as otitis externa as a result of fluid drainage into the EAC. Chronic otitis media (COM) is defined as recurrent or chronic middle ear infections in the presence of a perforated TM, which may drain either serous or purulent fluid (i.e., chronic suppurative otitis media). Patients with COM have fluid drainage with less inflammation and tenderness of the external ear canal when compared with AOE. Cholesteatoma is a keratinized collection of epithelial cells diagnosed by its distinct appearance with patients being asymptomatic or presenting with hearing loss, dizziness and otorrhea. Herpes zoster oticus (Ramsay Hunt syndrome) presents with vesicles on the TM and adjacent tissues, otalgia and, classically, facial nerve palsy. Bullous myringitis, also characterized by small vesicles on the TM, is classically a manifestation of mycoplasma infection but occurs with other organisms as well. Localized abscesses also occur in the ear canal and are most often due to *S. aureus*. Squamous cell carcinoma of the external ear canal should be considered in an older patient who fails standard therapy for otitis externa. Fungal otitis externa should be considered if the physical examination shows a white or black discharge. Contact dermatitis and seborrheic dermatitis are also mimickers of AOE.

A variety of disorders cause middle ear pain and may be confused with otitis media. Otitis media with effusion (OME) presents with a middle ear effusion without any signs or symptoms of acute inflammatory disease. Antibiotic therapy is not appropriate in these

patients. COM, as described above, may also be mistaken for AOM. Frequently a cholesteatoma is also present. These patients need otolaryngology referral.

Relapsing polychondritis is an autoimmune disease that can involve the auricular cartilage in addition to the cartilaginous tissues in the respiratory tract and aorta. These patients present with complaints and physical examination findings similar to those of infective perichondritis. However, the ear lobe lacks cartilage and thus is spared in relapsing polychondritis.

ED EVALUATION

Acute Otitis Externa

Otitis externa is diagnosed based on history and physical findings. Patients should be questioned about predisposing factors such as water exposure, instrumentation of the ear canal, and immune status. The patient should be questioned about hearing loss, vertigo, and prior infections.

A thorough examination of the head and neck should follow. Patients almost invariably complain of pain with tragal manipulation or otoscope insertion. The ear canal is edematous and narrowed and may be filled with cellular debris. If possible, the external canal should be cleaned for better visualization of the deeper structures and to aid in treatment.

Patients with systemic toxicity should be evaluated for a deeper, invasive infection. The most common organisms are *S. aureus* and *P. aeruginosa.* Patients with a chronically weeping, wet ear are more often infected with *Pseudomonas.* Staphylococcus tends to be associated with a more acute onset of symptoms. Appearance of granulation tissue on the floor of the EAC at the bony–cartilaginous junction is a typical finding in invasive disease. Although patients with invasive otitis externa may be in severe distress, they may remain afebrile with a normal white blood cell count (5,6). High-resolution, CT scan with thin cuts through the temporal bone, is generally the initial imaging study for patients with suspected invasive disease (6).

Acute Otitis Media

Patients with suspected AOM should also be asked about risk factors such as recent respiratory tract infections, a history of tobacco exposure (both primary and secondhand tobacco exposure increases risk), and barotrauma (e.g., air travel or scuba diving). To diagnose acute otitis media, the patient should have 1) acute symptoms, 2) a middle ear effusion, and 3) symptoms of middle ear inflammation. Classic findings (erythema and bulging of the TM) have been shown to be highly suggestive of disease, and a normal TM (one that is concave, gray, and translucent) is helpful in ruling out disease. To avoid overdiagnosis, pneumatic otoscopy is often recommended to confirm middle ear effusion; however this requires a cuffed speculum, and is often impractical in the emergency department. The physical examination should also focus on possible complications of otitis media. In addition to the ear itself, the mastoid process, nasopharynx, and oropharynx should be examined and a cranial nerve examination should be performed. If invasive infection or severe disease is suspected, CT scan with thin cuts through the temporal bone is the initial imaging study of choice (14). Contrast-enhanced CT scans or an MRI should be considered if one is concerned about intracranial complications. Note that fluid in the mastoid sinus found on imaging, *radiologic* mastoiditis, is a nonspecific finding and does not correlate with clinical mastoiditis since other diseases of the ear (AOM, COM, etc.) may result in fluid in the mastoid sinus (15,16). Laboratory tests are often not helpful in the initial examination.

Auricular Cellulitis and Perichondritis

The patient should be questioned about trauma and other exposures such as bites, as well as comorbid conditions. A careful inspection of the external ear is critical. One should also ask about previous history of similar episodes. The external ear structures should be palpated and any deformities or obvious abscesses noted. Early perichondritis can present as tenderness without erythema.

KEY TESTING

- Consider CT scan if invasive disease is suspected.

ED MANAGEMENT

Acute Otitis Externa

The EAC should be cleaned if possible. Purulent debris, cerumen, and desquamated skin should be removed using a wire loop or suctioning. EAC irrigation (aural toilet) using a tepid solution of dilute hydrogen peroxide is also reasonable provided the TM is intact. Cleaning of the EAC can be difficult and painful, but it is a necessary step to allow topical agents to reach the underlying infected tissue. A wick (1/4 inch ribbon gauze or a preformed cellulose sponge) should be placed in the canal if there is significant edema (17). Pain control must also be addressed, with acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or opioids being used as needed.

After cleaning the EAC, topical treatment is recommended for *uncomplicated* AOE (13,15,18–20). Topical agents are safe and effective and provide a high concentration of medication at the site of infection. Typically the active ingredient is an antibiotic or an acid, often combined with a steroid (Table 68.1). If the TM is intact, multiple agents are available to treat AOE (e.g., cortisporin otic, topical aminoglycosides, or topical fluoroquinolones). However, acidifying agents and aminoglycosides should be avoided in patients with a perforated TM owing to an increased risk of ototoxicity. In patients with AOE with a perforated TM, the drug of choice is a topical fluoroquinolone. Regardless of the type of topical agent chosen, therapy should be continued for 7 to 14 days and after each dose it is recommended that the patient lie on their side for 15 to 20 minutes (21). Of course, final antibiotic choices should be made with regards to cost and local microbiologic susceptibilities, when available (21). Although MRSA infections have been increasing, initial treatment for AOE does not need to include specific MRSA coverage (15).

Oral antibiotics for AOE are required in more severe disease and in patients that are severely immunocompromised (e.g., patients with AIDS or those on chemotherapy or immunomodulators) (Table 68.2). Ciprofloxacin 750 mg every 12 hours should be used in suspected pseudomonal infections and cephalexin or dicloxacillin 500 mg PO every 6 hours are appropriate for staphylococcal infections.

TABLE 68.2
Antibiotic Therapy for Invasive Otitis Externa

Drug	Dosage	Comments
Ciprofloxacin	400 mg IV every 12 h 750 mg PO every 12 h	High resistance. Only oral drug for pseudomonas
Piperacillin/tazobactam	4.5 g IV every 6 h	
Ceftazidime/cefipime	2 g IV every 8 h	
Aztreonam	2 g IV every 8 h	If penicillin allergic
Gentamycin/tobramycin	5 mg/kg IV every 24 h	Combine with a β-lactam

Invasive otitis externa requires intravenous antibiotics (see Table 68.2). Pseudomonas is the causative agent in more than 90% of the cases. Pseudomonas has become increasingly resistant to quinolone monotherapy (22), and thus an antipseudomonal β-lactam antibiotic (piperacillin/tazobactam, ceftazidime, imipenem) is the preferred agent in most parts of the United States. A bacterial culture of the ear canal should be sent in patients who require systemic antibiotics.

Acute Otitis Media

There are few good studies on antibiotic treatment of AOM. According to the most recent guidelines from the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) and from the National Institute for Health and Clinical Evidence (NICE) high dose of amoxicillin is currently recommended as first-line treatment (23,24). Placebo studies have demonstrated that patients are much more likely to clear infections due to *H. influenzae* and *M. catarrhalis* than those due to *S. pneumoniae.* There is increasing penicillin resistance in *S. pneumoniae,* but it can be

overcome with higher doses of amoxicillin (Table 68.3). *H. influenzae* and *M. catarrhalis* both produce β-lactamase, an enzyme that can degrade amoxicillin. Patients with more severe disease should be given amoxicillin/clavulanic acid to cover these organisms. Macrolides, cephalosporins or respiratory quinolones such as levofloxacin or moxifloxacin are appropriate for patients with penicillin allergy (23,24). The duration of treatment should be 5 to 10 days, depending on severity of disease and the antibiotic choice.

TABLE 68.3
Antimicrobial Therapy for Uncomplicated Acute Otitis Media

High-Dose Amoxicillin	1 g PO every 8 h, 7 d	First-line therapy
High-dose Amoxicillin/ clauvulanate	2,000/125 mg PO every 12 h, 7 d	Use in patients that are more ill or who fail amoxicillin
Azithromycin	500 mg PO d one then 250 mg PO daily for 4 d	If penicillin allergic
Levofloxacin	750 mg PO daily for 5 d	If penicillin allergic
Moxifloxacin	400 mg PO daily for 7 d	

Observation without antibiotics or delayed antibiotic administration is an option in the treatment of adults with uncomplicated otitis media (23,24). This is a reasonable choice in a healthy adult with mild or ambiguous signs of AOM. In delayed antibiotic administration, the patient is discharged with a prescription for the antibiotic and told to initiate use only if symptoms either worsen or do not improve in 3 to 4 days (23,24). Decongestants and antihistamines have not been shown to be helpful in the treatment of AOM, but oral analgesia should certainly be prescribed. Provided the TM is intact, topical anesthetic agents such as benzocaine may also help alleviate pain associated with AOM.

Patients with a serious complication of otitis media require IV therapy (Table 68.4). Pneumococcus is the most common organism in acute complicated disease. Patients with mastoiditis should have broad-spectrum antibiotics, specialty consultation, and be admitted to the hospital.

TABLE 68.4
Antimicrobial Therapy for Complications from Otitis Media

Cerebral abscess	Vancomycin + ceftriaxone + metronidazole	Pneumococcus, polymicrobial	Use meningitis dosing of antibiotics
Meningitis	Vancomycin + ceftriaxone	Pneumococcus, *H. Influenza*	Use meningitis dosing of antibiotics
Acute mastoiditis	Ceftriaxone ± vancomycin	Pneumococcus, *H. Influenza*, Staphylococcus, Group A streptococcus	Use osteomyelitis dosing of antibiotics
Chronic mastoiditis	Piperacillin/tazobactam ± vancomycin	Polymicrobial, staphylococcus, pseudomonas	

Auricular Cellulitis and Perichondritis

The management of external ear infections is determined by the severity. Auricular cellulitis may be treated with cephalexin, dicloxacillin, or clindamycin. More severe disease, however, requires admission and treatment with intravenous antibiotics. Severe infection or infected bite wounds receive broader antibiotic coverage such as amoxicillin/clavulanate. In penicillin-allergic patients, combination therapy with clindamycin and ciprofloxacin is appropriate.

It is important to recognize that infections involving cartilage can spread quickly and are difficult to cure. Earrings or other foreign bodies must be removed. Consultation with an otolaryngologist and/or an infectious disease specialist is often needed.

In mild cases of perichondritis, treatment consists of oral antibiotics. Patients with a recent upper ear piercing should be treated with ciprofloxacin 750 mg PO q12 hours for 10 to 14 days to cover pseudomonas and should have close follow-up. More severe cases should be treated aggressively with intravenous antibiotics covering both staphylococcus and pseudomonas. Patients often need surgical intervention for subperichondrial abscesses.

CRITICAL INTERVENTION

- Initiate broad-spectrum IV antibiotics in patients with invasive otitis externa, complications of otitis media, or perichondritis.

DISPOSITION

Patients with simple otitis externa can be discharged with topical antibiotics and follow-up in 2 to 3 days to ensure clearance of the infection. They should also be instructed to avoid water immersion

for several days. Patients who do not respond to topical antibiotics may have either resistant organisms or involvement of the bony structures. Those with invasive otitis externa need admission or transfer to a hospital with urgent otolaryngology and infectious disease consultation.

The majority of patients with otitis media may be discharged home on oral antibiotics with follow-up. Patients with complications from otitis media should be admitted for intravenous antibiotics and specialty consultation.

The disposition of patients with auricular cellulitis depends on the severity. Patients with minor infections can be discharged with oral antibiotics and an early recheck. Those with more severe disease should be admitted for intravenous therapy. Most patients with perichondritis should be admitted for IV antibiotics, except in mild cases.

Common Pitfalls

- Using systemic antibiotics in uncomplicated otitis externa.
- Failing to use a wick in patients with otitis externa and significant canal edema.
- Using ototoxic agents in patients with a perforated TM.
- Failing to adequately visualize the TM.
- Not removing a foreign body (e.g., earrings) in patients with perichondritis.
- Underestimating the potential severity of cartilage infections.
- Failing to obtain specialty consultation in complicated cases.

CHAPTER 69

Epistaxis

Trevor J. Lewis

Epistaxis is a frequent problem encountered by the emergency physician, accounting for approximately 1 in 200 emergency department (ED) visits in the United States (1). The incidence is bimodal, with peaks at ages younger than 10 and between 70 and 79 years of age (2). The higher incidence in children is attributed to local digital trauma in combination with reduced humidity during winter months (1,3). Pediatric epistaxis is usually benign and treated with local measures (4). Elderly patients are more likely to require invasive therapy and admission, because of both systemic causes of epistaxis and increased endothelial degeneration (3). Epistaxis is rarely life-threatening, and a majority of patients can be managed definitively by the emergency physician. When bleeding is not controlled by local measures, the source is usually posterior, and urgent otolaryngology consultation is required. Most posterior bleeds occur in older patients with the mean age of occurrence reported as 64 years of age (5).

The vascular supply to the nose is extensive, consistent with its function of warming and humidifying air. The blood supply to the nasal mucosa arises from the internal maxillary and facial arteries via the external carotid as well as from the posterior and anterior ethmoidal arteries via the internal carotid (6). The sphenopalatine artery, the terminal branch of the maxillary artery, supplies the lateral nasal wall below the middle turbinates and is the vessel responsible for most posterior epistaxis (7). The superior labial artery and greater palatine artery, terminal braches of the facial and maxillary arteries, respectively, supply the anterior portions of the

septum and floor of the nasal cavity. The anterior and posterior ethmoidal arteries supply both the septum and the lateral aspect of the nose superiorly. The confluence of these terminal arteries is referred to as *Kiesselbach plexus* or Little area. The majority of anterior nosebleeds occur in this area (Fig. 69.1).

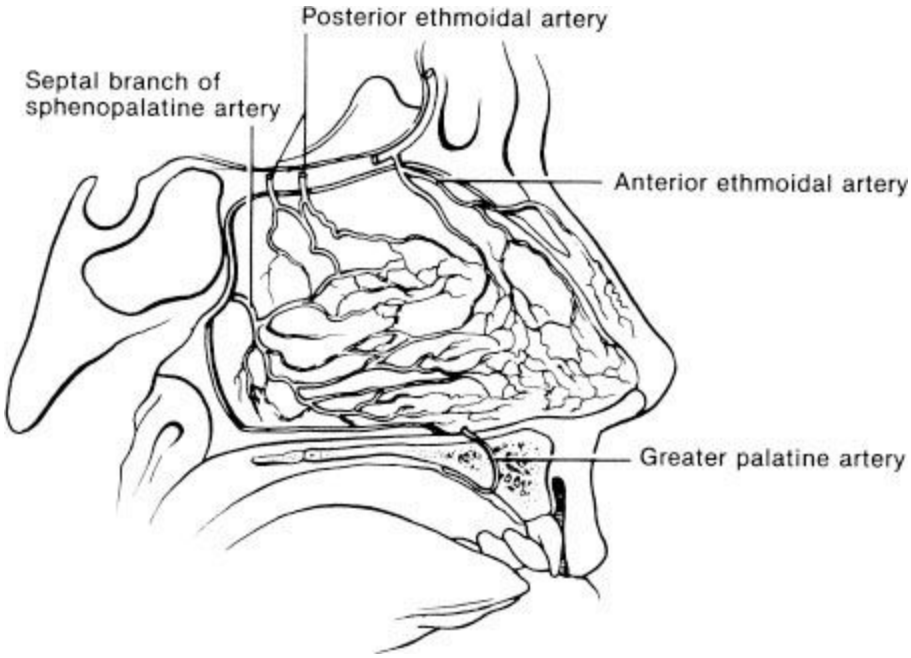

FIGURE 69.1 Blood supply to Kiesselbach plexus.

CLINICAL PRESENTATION

Epistaxis usually presents as spontaneous unilateral bleeding from a discrete lesion. Bilateral epistaxis is more commonly due to trauma or a posterior source of bleeding. Approximately 90% of nosebleeds are anterior, which means the bleeding source can be visualized in the anterior portion of the nasopharynx. The remaining 10% are posterior hemorrhages, in which a bleeding source is not directly visible. Posterior bleeds may present with nausea, hematemesis, anemia, hemoptysis, or melena (7) or may present with sudden copious bleeding due to involvement of larger vessels.

Patients with an underlying coagulopathy may present with other manifestations of bleeding such as bruising, petechiae, bleeding gums, hematuria, or gastrointestinal bleeding. Patients with a significant amount of blood loss may present with signs and

symptoms of hypovolemia such as lightheadedness, fatigue, tachycardia, or hypotension.

DIFFERENTIAL DIAGNOSIS

Epistaxis usually occurs from an interaction of factors that damage the superficial blood vessels of the nasal mucosa. The differential diagnosis includes both local and systemic causes, although the majority of cases are idiopathic (8). Local causes include direct facial trauma, nose picking (epistaxis digitorum), and chemical nasal irritants such as cigarette smoke, cocaine, and steroid nasal sprays. Epistaxis may be due to inflammatory disorders such as upper-respiratory infection, sinusitis, and allergic rhinitis. Environmental causes such as dry air during the winter months have been correlated with higher rates of admission for epistaxis (9). Other causes include foreign bodies (especially in children, the developmentally delayed, and elderly institutionalized patients), iatrogenic causes such as nasogastric and nasotracheal intubation, surgical complications, and overzealous treatment of self-limited hemorrhage.

Hypertension has been cited as a cause of epistaxis, but the relationship is controversial. Although studies have shown a higher prevalence of hypertension in epistaxis it is postulated that the sight of blood may cause a hypertensive or “white coat” response (8). Many hereditary bleeding disorders can present with epistaxis, including hemophilia, von Willebrand disease, and thrombocytopenia. Heavy alcohol use and a history of renal failure also increase the risk of epistaxis.

Numerous medications increase the risk of epistaxis via inhibition of normal clotting mechanisms. The most common class is nonsteroidal agents (including aspirin), which interfere with the cyclooxygenase pathway and inhibit platelet aggregation (6). Other commonly implicated medications include warfarin and other antithrombotic agents as well as antiplatelet medications. Many herbal supplements have anticoagulant properties including those that contain garlic, gingko, ginseng, and vitamin E (9).

Occasionally, patients present with massive epistaxis that is initially confused with hemoptysis or hematemesis. Blood from an episode of epistaxis that is swallowed or aspirated may further confuse the issue. If blood is coming from the nose and mouth and the source is unclear, the patient should be asked to sit upright, blow the nose, and rinse the mouth with water, and the oropharynx should be examined under suitable light. Blood dripping from the posterior nasopharynx confirms nasal hemorrhage. Table 69.1 lists some causes of epistaxis.

TABLE 69.1
Causes of Epistaxis

Spontaneous or idiopathic
Trauma
Digital trauma
Facial fractures
Foreign body
Infection
Bacterial rhinitis or sinusitis
Nasal diphtheria
Tumors
Juvenile angiofibroma
Paranasal sinus tumors
Surgery
Chemical irritants
Systemic toxins
Medications
Aspirin
Nonsteroidal anti-inflammatory drugs
Warfarin
Heparin
Dipyridamole
Clopidogrel, Ticlopidine
Thrombolytics
Coagulopathy
Thrombocytopenia
Disseminated intravascular coagulation
Hemophilia
von Willebrand disease
Hepatic failure
Leukemia
Venous congestion
Congestive heart failure
Mitral stenosis
Forceful coughing or nose-blowing
Other
Osler–Weber–Rendu syndrome
Barotrauma
Endometriosis
Allergic rhinitis

ED EVALUATION

Initial evaluation of the patient with epistaxis should focus on control of the bleeding to facilitate a directed history and physical examination and to alleviate the patient's anxiety. These measures should be initiated in triage and include the direct application of pressure by the thumb and index finger to the nasal alar area and the anterior septal area. The patient should be instructed to bend forward at the waist and spit out any blood that may pool in the throat. Swimmer's clips may be applied to the nasal area to control hemorrhage (10). Patients presenting with massive epistaxis or unstable vital signs require immediate resuscitation and airway management as well as direct control of the bleeding site. This precludes a lengthy history and physical examination. Once the patient has been stabilized, a more detailed history and examination can be obtained.

The history should focus on the initial site, duration, and amount of bleeding. One should inquire about precipitating events, including trauma and intranasal medications (illicit or otherwise) (3) as well as previous episodes of bleeding and whether control was achieved at home or in the hospital. Episodes of hematemesis may suggest a posterior source of epistaxis. Easy bruising or prolonged bleeding after minor surgical procedures suggests the possibility of coagulopathy, and recurrent episodes of epistaxis, even if self-limited, should raise suspicion for intranasal tumors. Use of alcohol and medications, especially aspirin, nonsteroidal anti-inflammatory agents, warfarin, or other antithrombotic or antiplatelet agents, should be noted, as these not only predispose to epistaxis but make treatment more difficult.

KEY TESTING

- Clotting studies (PT [INR], PTT): only for suspected bleeding diathesis, liver disease, or the anticoagulated patient (11,12).
- CBC, Platelets: if the patient relates a history of easy bruising, platelet disorder, neoplasia, or recent chemotherapy.

ED MANAGEMENT

The first priority in the management of epistaxis is to address the airway, breathing, and circulation (*ABC*s). Patients with unstable vital signs or severe hemorrhage should have intravenous access, as well as continuous cardiac monitoring and pulse oximetry. Massive hemorrhage may require endotracheal intubation to protect the airway and facilitate nasal packing. Elderly patients with massive bleeding may deteriorate rapidly, so aggressive resuscitation is vital (8). Rapid control of epistaxis that is associated with multiple trauma or significant facial injuries is best secured immediately with epistaxis balloons (13). This allows other life-threatening injuries to be addressed expeditiously. In patients with nontraumatic massive epistaxis, rather than making lengthy attempts at locating a bleeding source, the physician should proceed directly to packing with nasal balloons or tampons.

Most cases of epistaxis, however, are minor, and the episode frequently terminates with the proper application of pressure. When simple compression fails to stop the bleeding, the source of epistaxis must be located and then treated appropriately. Available treatments include topical vasoconstrictors, chemical or electrical cautery, nasal packing using prefabricated nasal tampons or epistaxis balloons, or traditional nasal packing. Every ED should have a prepackaged epistaxis tray or have key materials readily available (Table 69.2).

TABLE 69.2
Equipment Used for Management of Epistaxis

ENT chair
Headlamp
Nasal speculum (short and long)
Bayonet forceps
Frazier suction tips (No. 7 and 9)
Yankauer suction tip
Emesis or kidney basin
Gown, gloves, mask
Silver nitrate sticks
Electrocautery (optional)
Cotton balls
Dental roll
4- × 4-in gauze
Facial tissue
0.5- × 72-in petrolatum gauze
Antibacterial ointment (Neosporin, Polysporin, or Bacitracin)
0-silk sutures (straight needle)
Silk tape
Tongue depressors
Small plastic cups
Foley catheters (16 or 18Fr with 30-mL balloon)
Red rubber catheters (two 8Fr)
Umbilical clamps
Topical anesthetics (Cocaine 4%, Lidocaine 4%)
Topical vasoconstrictors (Phenylephrine 0.25%, Oxymetazoline [Afrin], Epinephrine 1:1,000)
Prepackaged nasal tampons (Rhino rocket and Rapid Rhino)
Prepackaged nasal balloons (Epistat, Simpson, Brighton)
Merocel nasal sponges
Avitene, Fibrin Glue, Surgicel, Oxycel, or Gelfoam

Preparation is the key to successful management. The physician should wear gown, gloves, and protective eyewear in anticipation of droplet spread of blood. The patient should be seated in an adjustable examination chair and draped from the neck down. A headlamp or mirror provides an excellent light source for optimal visualization.

The patient should be sitting upright or leaning slightly forward to prevent blood from tracking into the pharynx. The chair should

be adjusted so that the patient is just below eye level and the patient's head comfortably positioned against the headrest to prevent sudden movements during treatment. The patient should hold an emesis basin under the chin to catch blood running from the nose or mouth.

The patient should be instructed to blow the nose to clear the nasopharynx of blood and clots, even if bleeding has ceased, as local fibrinolysis of clots can result in persistent oozing or recurrence of epistaxis. This also allows for improved access for topical anesthesia (8). An initial attempt to locate the bleeding site should then be undertaken. The nasal speculum is used to spread the nares vertically, with the instrument held in such a manner that the index finger rests on the bridge of the nose for stabilization. The examination begins at Kiesselbach plexus, moving superiorly and posteriorly along the nasal septum, and concludes with the turbinates and lateral wall. Particular attention should be directed to common sites of bleeding: Kiesselbach plexus, the posterior floor of the nasal cavity, the junction of the anterior third and posterior two-thirds of the nasal septum, and the high anterior septum (11). With a well-illuminated and thorough examination, a bleeding point can almost always be identified.

Control of Anterior Epistaxis

If the bleeding point is identified and bleeding is not too brisk, application of oxymetazoline (Afrin) alone, or in combination with chemical cautery (silver nitrate), has been shown to be effective in the management of anterior epistaxis. Studies have indicated Afrin alone controlled 65% of nosebleeds in consecutive patients presenting to the ED (14). Other topical vasoconstrictors include phenylephrine (Neo-Synephrine) or epinephrine (1:1,000) applied to the area via cotton pledgets.

Electrical cautery has little advantage over chemical cautery with silver nitrate sticks (15). The nasal mucosa should be preanesthetized with 4% lidocaine solution on a cotton pledget to reduce discomfort. The principle of cautery is to injure the nasal

mucosa and underlying vasculature, resulting in immediate coagulation and vasoconstriction and immediate cessation of bleeding (3). The proper technique is to gently roll the applicator tip over the mucosa for no more than 5 seconds (16) until a grey eschar forms. Brisk bleeding may be slowed by cauterizing the four quadrants around the bleeding site or any identifiable vessel just proximal to the area of bleeding. Brisk bleeding may also decrease the effectiveness of the cautery by rapidly washing away the silver nitrate. Diffuse or extensive cautery should be avoided, and only one side of the septum should be cauterized at one time, so as to avoid septal necrosis or perforation.

For bleeding that is more brisk, pledgets soaked with an anesthetic-vasoconstrictor solution should be inserted into the nose on the side of the bleeding to provide hemostasis and anesthesia (17). An acceptable pledget can be fashioned by winding a piece of cotton tightly around the bayonet forceps. The cotton is pulled off the forceps and soaked in 4% cocaine or a 1:1 solution of 4% topical lidocaine and epinephrine (1:1,000), phenylephrine, or oxymetazoline. Oxymetazoline is suggested for increased safety in the elderly and hypertensive patients (18). Multiple pledgets may be placed, one above the other, onto the floor of the nasal cavity and allowed to remain in place for 10 to 15 minutes. If this fails to stop the bleeding, then cautery should still be attempted over the now well-anesthetized area.

If direct attempts to cauterize a bleeding point fail, anterior nasal packing should be placed. At this point, it may be a good idea to reconsider whether bleeding is posterior, because placing a posterior pack will necessitate first removing any anterior packing. Furthermore, if the site of bleeding is from the meatus, or from the medial surface of a turbinate, packing may prove to be of little value, and attempts to arrest the bleeding with other methods will be needed.

Traditional anterior nasal packing with Vaseline gauze has been supplanted by preformed nasal tampons or epistaxis balloons. Several nasal tampons are currently available, including Merocel, Rhino Rocket, and Rapid Rhino Nasal Pac with Gel Knit. The 85%

success rate of Merocel anterior packing is similar to that of traditional Vaseline gauze (8). After sufficient anesthesia is obtained, the Merocel tampon is lubricated with antibiotic ointment and inserted at a 45-degree angle into the nasal cavity for a distance of 1 to 2 cm. Antibiotic ointment is used to minimize infection as well as to lubricate the packing during insertion. The length of the Merocel is grasped with bayonet forceps and the long axis of the Merocel is rotated into the horizontal plane and then pushed straight backward into the nasal cavity. Merocel is supplied in different lengths that may be trimmed with scissors for both anterior and anterior–posterior hemorrhage. If an anterior–posterior sponge is employed, it should be inserted until it touches the back wall of the posterior nasal space. If the pack does not fully rehydrate with blood, then saline should be applied. The drawstring is secured to the patient's cheek.

The Rhino Rocket is a nasal tampon that is inserted using a supplied applicator. The nose should first be anesthetized with 4% lidocaine. The tampon is lubricated with antibiotic ointment and inserted along the floor of the nose. The Rapid Rhino Nasal Pac with Gel Knit is the newest nasal tampon. This is an inflatable balloon coated with a carboxymethylcellulose hydrocolloid compound. The compound acts as a platelet aggregator and lubricant when soaked in water (7). To insert the Rapid Rhino, the tampon is soaked in sterile water for 30 seconds and then completely inserted into the patient's nostril. The attached balloon is then inflated with 10 to 15 cc of air. Compared to the Rhino Rocket, the Rapid Rhino appears to be less painful to insert and easier to remove and to have similar effectiveness in stopping epistaxis (17).

Traditional anterior nasal packing is more difficult but may be considered if the foregoing measures are unavailable or unsuccessful. The nose should be packed with sterile petrolatum ribbon gauze (0.5 to 1 in wide), to which is added an antibacterial ointment to prevent toxic shock syndrome. Packing begins by grasping the ribbon with the bayonet forceps about 6 in from its end. The ribbon is then placed in the nasal cavity as far back as possible, while making sure that the free end still protrudes from the

nose. This first pass is pressed onto the floor of the nasopharynx with the closed forceps. The ribbon is then grasped about 4 to 5 in from the nasal alae, the nasal speculum is repositioned so that the lower blade holds the ribbon against the lower border of the nasal alae, and a second strip is brought into the nose and pressed downward. This process is continued superiorly in a stair-step fashion until there is no room left in the nose. Both ends of the ribbon must protrude from the anterior end of the nose, and the nostril is covered with a piece of gauze and secured with tape (19).

Other alternatives to the traditional anterior nasal pack include calcium sodium alginate (Kaltostat), Oxycel, Avitene, and balloon tamponade. Topical thrombogenic agents such as fibrin glue, gelatin sponge (Gelfoam), and microfibrillar collagen powder (Avitene) are useful in cases of epistaxis associated with coagulopathy when applied directly to the bleeding area. Floseal, a hemostatic sealant composed of collagen-derived particles and topical-derived thrombin, is applied as a gel to control epistaxis. When compared to traditional nasal tampons Floseal was found to be better tolerated and to provide superior epistaxis control. It is more costly, however (2). Thrombin-JMI epistaxis kit is a bovine derived topical thrombin that is reconstituted with saline and applied via a nasal mist device.

Control of Posterior Epistaxis

Bleeding that begins with the sensation of blood in the posterior pharynx, bleeding that cannot be localized anteriorly, or bleeding that fails to arrest with anterior packing is considered posterior and needs to be managed in consultation with an otolaryngologist. However, bleeding should be initially controlled by the emergency physician using one of a number of available techniques.

The traditional method of posterior packing with gauze rolls attached to strings is cumbersome and should be replaced with the use of an epistaxis balloon or inflatable Foley catheter. Balloon catheters are easier to install and just as effective as traditional posterior nasal packs (20). Posterior nasal packing should always be accompanied by anterior nasal packing. When the posterior balloon

is inflated and pulled forward, it acts to seal the posterior choana. The anterior naris is then packed with a nasal tampon or by inflation of an anterior balloon, effectively tamponading the entire cavity. Hence, it must be kept in mind that if the posterior pack dislodges, a large amount of blood can be aspirated (20). Posterior packs are uncomfortable when placed and usually require opioids for analgesia. Continuous pulse oximetry and cardiac monitoring are mandatory as posterior packing can cause hypoxemia, apnea, and cardiac dysrhythmia because of stimulation of the nasopulmonary reflex (3).

The commonly used balloons for control of posterior epistaxis include the Epistat nasal catheter, the Brighton balloon, and the Simpson balloon. The Epistat catheter is placed by inserting the catheter's entire length along the floor of the nose. The posterior balloon (white valve) is inflated with 10 cc of saline and pulled forward to occlude the posterior choana. The anterior balloon (clear valve) is then inflated with up to 30 cc of saline, unless the bleeding stops or the septum starts to bow. Rapid Rhino has a similar 9 cm dual port posterior pack.

If a Foley catheter is to be used, a 12 to 16Fr catheter with 30-cc balloon is placed into the nose along the floor of the nasopharynx until the tip is visible through the mouth in the posterior pharynx. It is then slowly inflated with 15 mL of saline, pulled anteriorly until it is firmly set against the posterior choana, and secured into place with an umbilical clamp wrapped around a dental roll or matted 4- $\times$ 4-in gauze, so as to avoid direct pressure necrosis of the ala or columella.

A traditional posterior pack is fashioned from a 4- $\times$ 4-in gauze rolled into a 1-in roll and secured with 3-silk sutures or umbilical tapes. This pack is brought into position in the posterior choana by passing a small red rubber catheter through each nostril and back out of the mouth, securing each of the two outer sutures to the catheters and pulling the catheters out of the nose again, drawing the pack through the mouth and into position. Each of the sutures is tied together over a gauze buttress to prevent pressure necrosis of the columella. The third suture is brought out through the mouth

and taped to the cheek to facilitate removal. Posterior packing is successful in stopping posterior bleed 70% of the time (21).

If unable to control posterior bleeding with traditional packing, emergent otolaryngology evaluation is necessary for possible endoscopic evaluation and cautery/ligation. Many otolaryngologists opt for early management of posterior bleeds with endoscopic cautery under direct visualization in the operating suite, early surgical control using arterial ligation, or referral to interventional radiology for selective arterial embolization (22). If time permits and bleeding is not severe, early consultation may spare patients with posterior nasal hemorrhage the discomfort of posterior packing altogether.

CRITICAL INTERVENTIONS

- Aggressively resuscitate patients with significant hemorrhage and signs of hypovolemia.
- Instruct patients who present to triage with epistaxis to apply squeezing pressure to the nose, as most nosebleeds are anterior and will terminate with this maneuver.
- For posterior epistaxis, control the hemorrhage with a balloon catheter, consult an otolaryngologist, and admit to the hospital.

DISPOSITION

Patients with a history of severe epistaxis or recurrent episodes of bleeding should be referred to an otolaryngologist for an outpatient examination to rule out a neoplastic process. Children with recurrent events should be evaluated for bleeding disorders (23). Patients with anterior packing should have follow-up for packing removal in 48 to 72 hours.

All patients with posterior packing should to be admitted to a high-acuity setting. These patients are at risk for cardiac and pulmonary complications and necessitate close monitoring. Clinicians should also strongly consider admitting elderly patients or those with cardiac or pulmonary disease who require anterior

packing. Patients who are coagulopathic or anemic often require admission for transfusion.

Patients who are discharged from the ED should be instructed to avoid blowing or picking the nose, straining, bending over, or participating in sports and strenuous activities and to sneeze with their mouth open. First aid instructions should be given on how to control epistaxis at home and when to seek medical help. Home humidifiers and saline nasal sprays may be helpful in drier, colder months, and patients should avoid any manipulation of the nose. Topical Naseptin cream or petroleum jelly may limit recurrent bleeds (8). Patients discharged with nasal packing should be prescribed an antibiotic, such as ampicillin/sulbactam or a second-generation cephalosporin, to prevent toxic shock syndrome or sinusitis (24). Aspirin may be discontinued if the benefit is felt to offset any risk of thromboembolic events. Anticoagulated patients with an INR in the therapeutic range can continue warfarin without interruption (25).

Common Pitfalls

- Failure to prepare the necessary equipment for control of epistaxis leads to unnecessary inconvenience and delays.
- Epistaxis in young children should prompt a search for a foreign body.
- Failure to identify the source of bleeding or to place an anterior pack properly leads to rebleeding and necessitates a return to the ED for repacking.
- Failure to prescribe antibiotics for patients discharged with an anterior pack can lead to sinusitis or toxic shock syndrome.
- Failure to identify posterior epistaxis until after an anterior pack has been placed necessitates completely unpacking the nose so a posterior pack can be placed.

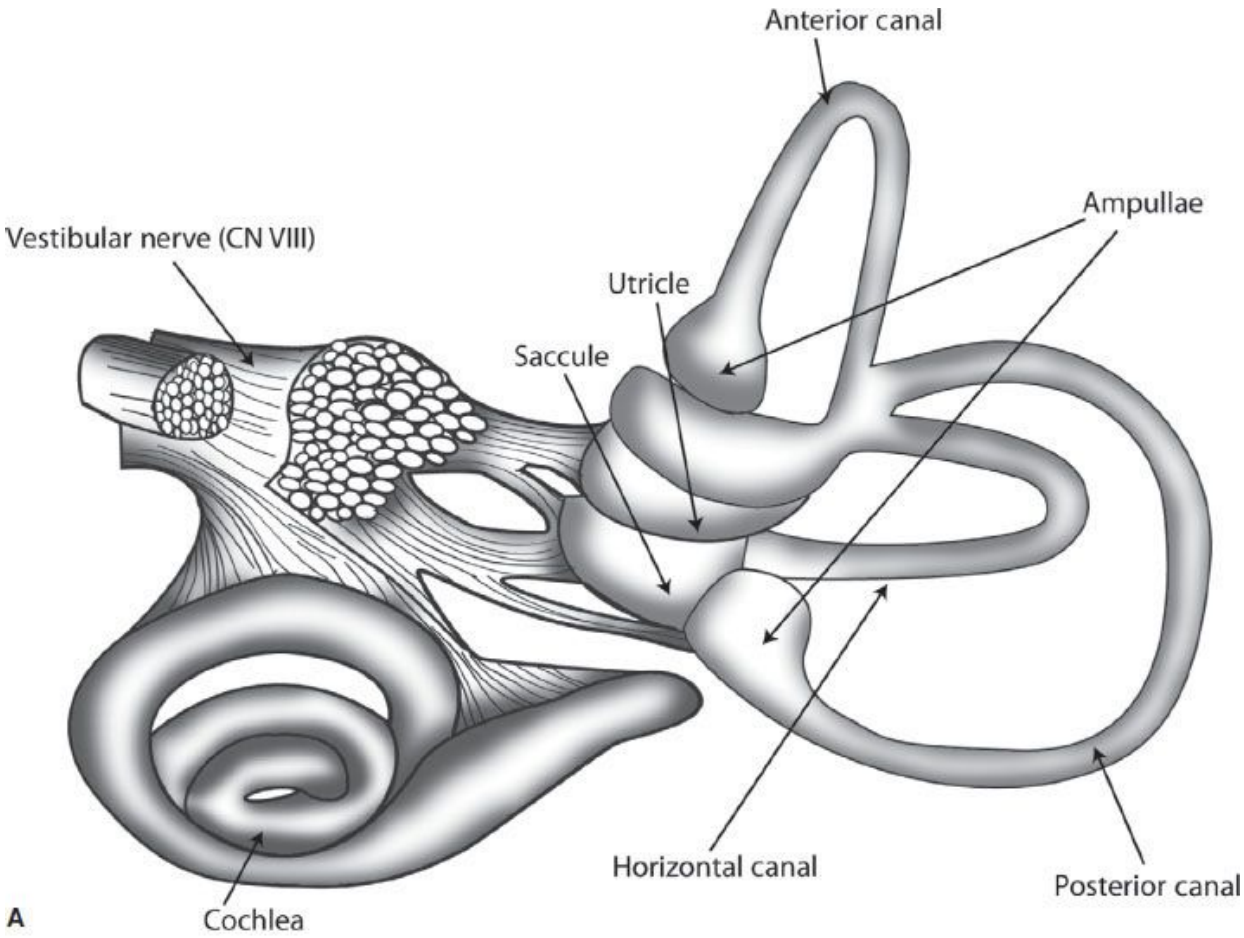
CHAPTER 70 Vertigo

Brian Chinnock

Vertigo, along with dizziness and other balance disorders, affects up to 70% of people during their lifetime. Vertigo is often categorized into peripheral and central causes. Peripheral disorders may cause considerable symptomatology but are rarely life-threatening, whereas those of central etiology may have significant morbidity and mortality.

PERIPHERAL AND CENTRAL VESTIBULAR ANATOMY

Maintenance of balance and coordination of eye movements is managed by a complex interaction of the vestibular system, the cerebellum, the brainstem, the ocular muscles, the visual cortex, and their interconnecting pathways. The peripheral vestibular system consists of three semicircular canals and two otolithic organs, the utricle, and saccule (Fig. 70.1A). Together they respond to head movement in all directions. Each canal is filled with endolymph, and has a dilated end called the ampulla which has the sail-like cupula. With head movement, the vestibular hair cells embedded in the cupula are stimulated and send input to the vestibular nerve (vestibular branch of CN VIII). Each semicircular canal is paired, and on head movement, one will give an excitatory input to the vestibular nerve, whereas the other will give an equal inhibitory input. With a unilateral peripheral vestibular deficit, the affected semicircular canal will not send in an inhibitory input to the vestibular nuclei, thus giving sensation of movement even if the head is still.



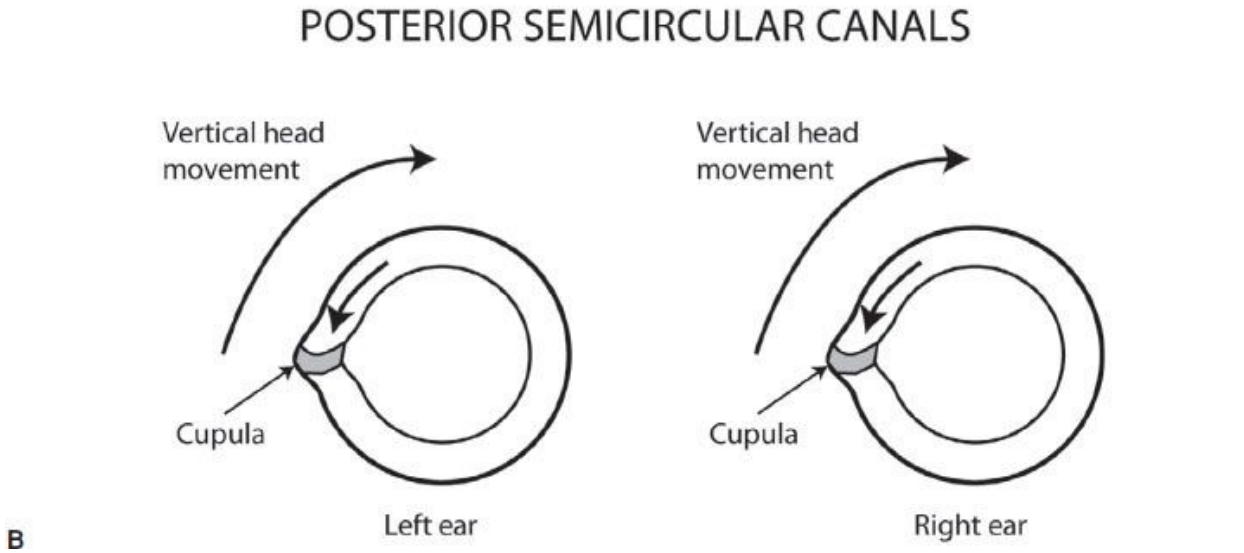


FIGURE 70.1 **A**: demonstrates the organs of the peripheral vestibular system. B: demonstrates the paired posterior semicircular canals, with vertical head movement causing the more static endolymph

inside the canal to cause pressure against the cupula, which stimulates the vestibular nerve.

The central vestibular system receives input through the vestibular nerve to the vestibular nuclei located in the brainstem. From the vestibular nuclei, there are neuronal connections through the medial longitudinal fasciculus to the ocular muscles. This pathway is responsible for the vestibuloocular reflex (VOR), which does not involve the cerebellum, and is tested with the head impulse test (HIT) (see Figure 70.3). The cerebellum is the main organ of the central vestibular system, coordinating vestibular, visual, and somatosensory input to help fine-tune motor activity. The cerebellum is composed of the lateral hemispheres and the midline vermis. The lateral hemispheres are responsible for limb movement, whereas the vermis is responsible for truncal motion. The cerebellum receives its blood supply from the posterior-inferior cerebellar artery (PICA), the anterior-inferior cerebellar artery (AICA), and the superior cerebellar artery (SCA). All originate from the vertebrobasilar system. Importantly, the cerebellum is supplied by the distal branches of each of these arteries, with the proximal parts supplying the lateral brainstem. For this reason, it is common for cerebellar CVA to also present with brainstem findings.

PERIPHERAL VERSUS CENTRAL VERTIGO

While there are many causes of vertigo, there are four primary diagnoses of significance to the emergency physician evaluating a patient with acute vertigo: (1) benign paroxysmal positional vertigo (BPPV), (2) vestibular neuronitis (VN), (3) migrainous vertigo, and (4) cerebellar/brainstem ischemia (CBI). The discussion will focus on these four diagnoses as they are the most common and important. CBI, which includes cerebellar/brainstem transient ischemic attack/cerebrovascular accident (TIA/CVA) or vertebrobasilar insufficiency, only represents 1% to 3% of vertigo patients, but has a mortality rate of up to 40% (1). It is thus the most important differential diagnosis for any vertigo patient. Other causes of peripheral and central vertigo are listed in Table 70.1.

TABLE 70.1
Less Common Causes of Peripheral and Central Vertigo

Peripheral Vertigo—Other Causes	Diagnostic Clue
Ménière disease: A chronic, progressive disease with endolymph hydrops affecting the vestibular and cochlear apparatus. Characterized by intermittent attacks of vertigo lasting 20 min–24 hrs, hearing loss that is at first episodic, but then constant, and a low pitch tinnitus. Vertigo attacks occur most commonly in clusters, and can decrease as hearing loss progresses over yrs	Intermittent vertigo, hearing loss, tinnitus
External canal and middle ear disorders: otitis media, serous otitis with effusion, tympanic membrane rupture, cholesteatoma, herpes zoster oticus, cerumen impaction and malignant otitis externa can all cause peripheral vertigo	Adequate otoscopic examination
Labyrinthine concussion: traumatic peripheral vestibular injury due to head trauma. Most patients have improved symptoms in days, but can last for weeks to months.	Vertigo after concussive head trauma
Perilymphatic fistula: Fistula develops at the otic capsule which separates the inner ear from the middle ear. May occur due to trauma or barotrauma. The defect allows middle ear pressure changes to be transmitted to the inner ear, causing episodic vertigo and/or hearing loss	Episodic vertigo and/or hearing loss caused by sneezing, heavy lifting, straining, or coughing
Labyrinthine hemorrhage: This is a rare cause of spontaneous vertigo and deafness. It has been described in patients with clotting problems related to leukemia, sickle cell disease, antiplatelet and anticoagulant therapy, cocaine ingestion and systemic lupus erythematosus. It can be detected on T2-weighted images on MRI.	Vertigo and hearing loss in a patient with clotting disorder
Cogan's disease: autoimmune disease affecting the eye and inner ear. Peak age of incidence is 22 yrs old. Causes Ménière-like attacks of vertigo, hearing loss, and tinnitus.	Vertigo/hearing loss in association with keratitis
Medications: aminoglycosides (usually IV/oral; rarely topical), loop diuretics, aspirin or nonsteroidal anti-inflammatory drugs (especially in overdose)	Medication history
Central Vertigo—Other Causes	
Vestibular schwannoma (acoustic neuroma): tumor growing from the vestibular nerve. As it slowly grows, there is gradual compressive involvement of the cochlear nerve (95%) with hearing loss, vestibular nerve (63%) with mild gait imbalance and vertiginous symptoms. Continued growth can affect the trigeminal nerve, facial nerve, and even compress the brainstem and cerebellum	Long-standing indolent hearing loss and vertigo/imbalance
Temporal lobe seizure: One type of this can involve a prodrome of vertigo and auditory hallucinations, which can occur in isolation as a simple partial seizure, or can progress to a complex partial seizure with automatisms such as lip smacking, chewing, picking, fidgeting.	Vertigo preceding complex partial or generalized seizure
Medication/ toxicology: Medications such as sedatives, antidepressants, neuroleptics, and anticonvulsants can cause central vestibular dysfunction. Alcohol is a common cause of central vertigo. PCP use, while not causing vertigo, can give a multidirectional nystagmus that mimics that seen with CBI	Medication history and examination for intoxication

BPPV: This is the most common cause of vertigo, representing up to 50% of cases. It has a cumulative incidence of nearly 10% by the age of 80. It is caused by otoconia, calcium carbonate crystals present in the utricle, that become dislodged and migrate into the semicircular canal. The presence of otoconia in the endolymph of one ear will cause increased excitatory input to the vestibular nuclei compared to the unaffected ear on head movement, causing vertigo. BPPV is characterized by intermittent episodes of sudden severe vertigo precipitated by head movement, commonly with nausea and vomiting, which usually last for less than 1 to 2 minutes. When the head stops moving, the vertigo will abate as the movement of the otoconia is the only source of abnormal input; the rest of the vestibular structures are fully functional. As the posterior canal is the most dependent of the semicircular canals and the most likely location for otoconia to settle by gravity (see Fig. 70.1A), 85% of BPPV is caused by posterior canal otoconia. While BPPV is commonly idiopathic, it may also be due to otoconia dislodged due

to minor trauma or whiplash injuries, or as a residual effect of Ménière disease.

VN: VN is caused by a selective inflammation of the vestibular nerve, likely due to a post viral cause. Concomitant involvement of the cochlear nerve is termed “labyrinthitis,” and has the same physical examination findings as VN, in addition to hearing loss. Unilateral vestibular nerve involvement will give unequal input to the vestibular nuclei, and cause vertigo. Unlike BPPV, though, keeping the head completely still will not significantly affect the vertigo, as the defect is in the nerve itself, not the canals which give output based on movement. Resolution of symptoms typically takes weeks as recovery is dependent on the vestibular nerve regenerating, and central vestibular compensation mechanisms to develop, as the nerve regeneration is typically incomplete.

Migrainous vertigo: In neurootology clinics, this is the most common cause for referral. Criteria have been developed for the diagnosis of migrainous vertigo and are listed in Table 70.2. Despite these criteria, migrainous vertigo is a diagnosis of exclusion and can be the most difficult diagnosis to make as the vertigo can have either peripheral or central features (2). In addition, the quality and duration of vertigo can range from the mild, indolent quality of CBI which lasts for days, to the severe quality of BPPV or VN, lasting for minutes or over a day, respectively.

TABLE 70.2
Neuhauser Criteria for Migrainous Vertigo

Definite

1. Episodic vestibular symptoms of at least moderate severity
   - vertigo; positional dizziness and head motion intolerance
2. Migraine according to International Headache Criteria
3. One or more of the following features during at least two vertigo attacks
   - migrainous headache
   - headache
   - photophobia
   - photophobia
   - migraine aura
4. Other diagnoses excluded by appropriate tests

Probable

- Criteria 1 and 4 as above plus at least ONE of the following:
  - Criteria 2 or 3 as listed above
  - migraine-specific triggers of vertigo
  - response to antimigraine drugs

CLINICAL PRESENTATION

A good history is extremely important in ruling out CBI in the vertigo patient. In one study, patients with isolated dizziness and no findings suggestive of CVA had a $<1\%$ incidence of CVA (3). Risk factors for CBI are the same as for other types of CVA: previous CVA, diabetes, hypertension, advanced age, atrial fibrillation, hypercholesterolemia. In a case series of patients with vertigo who had a final diagnosis of cerebellar CVA, and who had negative initial diffusion-weighted MRI (DW-MRI), the mean age was 72 years old and all had significant risk factors for CVA (4).

BPPV is usually easy to differentiate from VN and CBI by its sudden onset, short duration, and complete resolution of symptoms in between episodes (Table 70.3). Vertigo that is associated with particular head positioning is almost always due to BPPV (Table 70.3). However, rarely, a patient may have central positional vertigo due to a very localized infarction of CN VIII at the brainstem or of the vestibular nucleus. Either of these may cause a positional vertigo without other neurologic findings. The Dix–Hallpike maneuver (described below) may be particularly helpful in differentiating in this circumstance. Patients with migrainous vertigo usually have a

previous history of migraines, with new vestibular symptoms which may or may not occur at the same time as the migraine.

TABLE 70.3
Features of BPPV in Comparison with VN and CBI

	BPPV	VN	CBI
Onset	Sudden, with head movement	Minutes–hours	Sudden
Duration	Seconds–minutes	Days–weeks	Days–weeks
Improvement with keeping head still, eyes closed	Complete	Minor	Minor
Emesis	Common	Common	Less common
Dix–Hallpike maneuver	Positive	Negative	Negative

DIFFERENTIAL DIAGNOSIS

Traditional teaching emphasizes the differentiation of vertigo from presyncope, disequilibrium, or nonspecific dizziness. However, this approach may be problematic. A large ED-based study found that the incidence of CBI was similar in patients with vertigo versus nonvertiginous dizziness (3). Another ED study found that patients' descriptions of dizziness were unclear, imprecise, and unreliable (9). Therefore the many causes of vertigo should be at least considered in patients without a clear description of vertigo.

ED EVALUATION

Physical Examination

Standard neurologic examination: All the standard elements of a neurologic examination should be completed, as the presence of any abnormalities can suggest CBI as the cause. Finger–nose testing for dysmetria by itself is not an adequate test of cerebellar function, since it tests only lateral hemispheric function. Large cerebellar vermal CVAs can have a completely normal finger–nose test. Testing of gait is extremely important as patients with peripheral vestibular disorders, while often having significant symptomatology trying to

walk, will still be able to walk. Inability to walk (or sit or stand), strongly suggests CBI.

Nystagmus testing should be done by having the patient follow the examiner's finger in all horizontal and vertical directions. It is also important to hold the finger for 10 to 15 seconds at eccentric vertical and horizontal gaze positions (testing for gaze-evoked nystagmus [GEN]), and then allowing the eyes to return to normal position (testing for rebound nystagmus). When doing this, it is important to not test at the very extremes of gaze as this can evoke a sustained nystagmus even in normal patients. In VN, the nystagmus will be unidirectional, horizontal, with perhaps a slight rotatory component, suppressible by fixating on a target. CBI is more likely if the nystagmus is vertical, purely rotatory, or is not suppressible. Physiologic end-point nystagmus (EPN) occurs upon extreme lateral gaze, when a few beats of low-amplitude nystagmus occur before normal brainstem mechanisms allow the eyes to maintain the eccentric gaze without further nystagmus.

GEN occurs on far eccentric gaze, with sustained, large-amplitude nystagmus. This is caused by an abnormality in the cerebellum or cerebellar pathways. A small lesion of CBI will only manifest at very extremes of gaze. A larger lesion can appear as soon as the eyes deviate from straight-ahead. A vertical GEN, in particular, is diagnostic of cerebellar or brainstem dysfunction. With VN, as the eyes move eccentrically in the direction of the fast phase of nystagmus, the nystagmus will increase until it eventually suppresses with fixation, whereas fixation is unlikely to suppress with CBI.

Rebound nystagmus occurs after holding the eccentric gaze position for 10 to 15 seconds, then returning to the primary gaze position. Nystagmus with the fast phase in the opposite direction of the preceding eccentric gaze indicates CBI. Reversible nystagmus occurs when the direction of the fast phase changes when looking side to side, and is indicative of CBI.

Smooth pursuit is assessed by watching eye movements while performing the nystagmus assessment. It is normal for patients to have slight saccades (fast, jerky eye movements) interrupting smooth pursuit during downward gaze, but should otherwise be smooth

without saccades. Significant asymmetry of saccadic motion between each eye is suggestive of a structural brainstem/cerebellar lesion. Saccades due to slow eye movements (eyes have to make saccades to catch up with pursuit) can also be seen with medication/drug usage (alcohol, benzodiazepines).

Skew deviation is tested by asking the patient to fixate on the examiner's nose, covering one eye, then uncovering that eye while simultaneously covering the other, alternating simultaneous cover and uncover every 1 to 2 seconds. Normally, there is little or no eye movement to regain fixation on the examiner's nose. With CBI, fixation is not maintained and the eyes make a movement, usually vertical, to regain fixation. For example, as the left eye is uncovered it makes a vertical downward movement to regain fixation, and then, as the right eye is uncovered while the left eye is covered, the right eye makes a vertical upward movement to regain fixation. While not sensitive for CBI, the presence of skew deviation is very specific for CBI.

Dix–Hallpike: The Dix–Hallpike test should be performed if BPPV is a diagnostic consideration. The Dix–Hallpike test positions the head so that otoconia in the posterior semicircular canal move to cause maximal stimulation, with nystagmus and vertigo (Fig. 70.2, panels S and 1). The maneuver has an approximately 50% to 88% sensitivity in detecting BPPV (5).

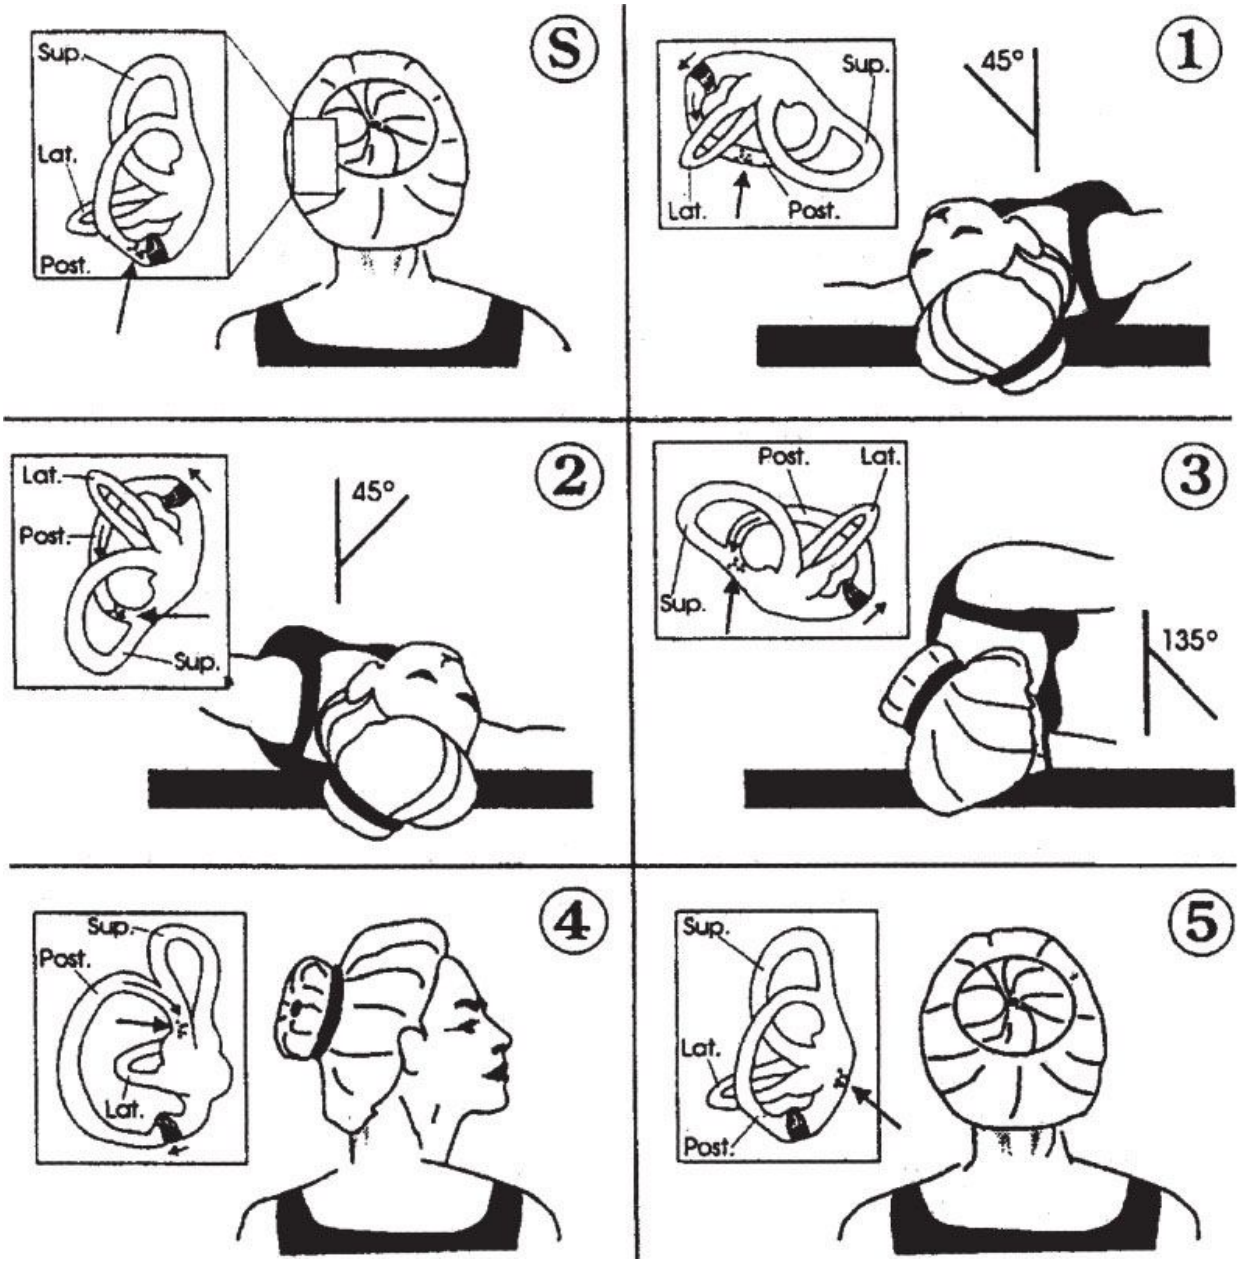

FIGURE 70.2 Dix–Hallpike test and Epley maneuver. Positioning sequence for left posterior semicircular canal as viewed by operator (behind patient). Small boxes show the labyrinth and migration of particles (large arrow). (S) and (1) represent a Dix–Hallpike test of the left posterior semicircular canal, while the entire sequence demonstrates the Epley maneuver. (S) Start-–patient seated. 1: Place head over end of table, 45 degrees to the left. For Dix–Hallpike test, with a positive test, there will be a short latency period, followed by an upward and torsional nystagmus and vertigo, which fatigue in

about 15 to 30 seconds. When the nystagmus fatigues, the patient is returned to the sitting position, at which point the vertigo and nystagmus return briefly, the nystagmus now in the opposite direction. 2: Keeping head tilted downward, rotate to 45 degrees right. 3: Rotate head and body until facing downward 135 degrees from supine. 4: Keeping head turned right, bring patient to sitting position. 5: Turn head forward, chin down to 20 degrees. Pause at each position until induced nystagmus approaches termination, or for approximately 30 seconds if no nystagmus. If able, keep repeating entire series (1 to 5) until no nystagmus in any position.

"Bow and lean" test: Patients who have symptoms consistent with BPPV, but a negative Dix–Hallpike maneuver, should have this maneuver performed to test for horizontal canal otoconia, which can represent up to 10% to 20% of BPPV cases. In this maneuver, the seated patient first bends the head forward ("bow"), aligning the horizontal canal with gravity, and then leans their head backward quickly, flipping the canal 180 degrees. The examiner looks for nystagmus in each position. With right ear horizontal canal otoconia, there will be a right-beating nystagmus on the bow, and a left-beating nystagmus on the lean. Knowing which canal is involved is important in determining the treatment maneuver.

Head impulse testing: The HIT evaluates the VOR, and is vital at differentiating VN from CBI. It is described in Figure 70.3. The sensitivity of HIT for detection of VN is 72% when done by "nonexperts" (6). A study in which the HIT was used in patients at high risk for CVA showed that 31/34 patients with a final diagnosis of CVA had a negative HIT (7). In patients suspected to have VN, the triad of a positive HIT, unilateral nystagmus, and absent skew deviation excluded 91% acute CVAs and identified 78% of peripheral vestibular lesions (8). These studies demonstrate that a positive HIT by itself must be viewed with caution in ruling out CBI, however, in association with the lack of other findings suggesting CBI (see Table 70.4). The ability to rule out CBI is similar to that of MRI, especially within the first 24 hours.

FIGURE 70.3 Head impulse test. This is a test of the VOR. The examiner grasps the sides of the patient's head and asks the patient to fixate on the examiner's nose (A). The examiner asks the patient to relax the head, and then performs a low-amplitude, high-velocity, random movement of the head to one side or the other, while having the patient maintain fixation on the nose. With an intact VOR (intact vestibular system), the patient's eyes will maintain fixation (B). C demonstrates an abnormal VOR: On movement of patients head to the right, the patient briefly loses fixation on the examiner's nose, and then has a rapid saccade of the eyes to the left to regain fixation (D).

TABLE 70.4
Features Differentiating VN from CBI

	VN	CBI
History		
Onset	Over minutes–hours	Sudden
Duration	Days–weeks	Days–weeks
Imbalance, more than vertigo	No	Yes
Headache	Yes	Yes
Vomiting	Common	Less common
Nystagmus		
On primary gaze (looking straight-ahead)	Common (first 24 hrs)	Common
Pure torsional (no horizontal component) on primary gaze	No	Yes
Suppression with visual fixation on a target in lighted conditions	Yes	Little or none
Fatigable on lateral gaze	Yes	No
High amplitude on lateral gaze	No	Yes
Up- or downbeating with vertical gaze	No	Yes
Increases during eccentric gaze toward fast phase of nystagmus	Yes	
Rebound	No	Yes
Reversible	No	Yes
Other Eye Testing		
Smooth pursuit	Normal (can be interrupted by unilateral nystagmus)	Saccadic; possibly asymmetric
Skew deviation	No	Yes
Other Neurologic Findings		
Gait—inability to walk	Rare	Common
Neurologic (especially brainstem) deficits	No	Common
Complete hearing loss	No	Yes (but rare)
Romberg examination	Abnormal—but should be able to stand with eyes open	Abnormal —but may not be able to stand with eyes open
Head impulse test	Abnormal	Normal

Laboratory Testing

Laboratory testing has a very limited role in the evaluation of vertigo. Consider evaluating for hypoglycemia, anemia, thyroid dysfunction, uremia, or electrolyte abnormalities in the patient who has a broader differential diagnosis than vertigo.

Imaging

Imaging has little role in the evaluation of BPPV or VN, except to evaluate for the serious alternative, CBI. CT scan may reveal hemorrhagic CVA. Beyond that, it has no role in the evaluation of CBI since the sensitivity for ischemic CVA is only 40%, and possibly lower for posterior fossa pathology. DW-MRI has become the standard of care in the diagnosis of ischemic CVA. DW-MRI can demonstrate an acute ischemic CVA even in the first few hours. However, the false-negative rate is 19% within 12 hours and 24% within 3 hours (10). The same artifacts that make CT difficult to evaluate the posterior fossa, also make MRI difficult to evaluate in the acute setting. For this reason, a normal DW-MRI is not reliable in ruling out CBI in the first 24 hours of symptom presentation.

KEY TESTING

- Physical examination maneuvers to detect findings consistent with central causes.
- Obtain MRI when central vertigo is suspected, but be cautious of a normal result in the first 24 hours.

ED MANAGEMENT

Vestibular neuritis: In the acute phase, medications that work either as vestibular "sedatives" (decreasing abnormal input from the vestibular system) or antiemetics can be used to decrease symptomatology. These medications include antihistamines, benzodiazepines, antiemetics, and scopolamine. Little evidence supports the use of one treatment over another. One trial examining the IV use of dimenhydrinate 50 mg versus lorazepam 2 mg found less sedation and better symptomatic relief in the dimenhydrinate

group (11). Another study showed equivalent effect of IM dimenhydrinate 50 mg and droperidol 2.5 mg (12). All of these classes of drugs can have significant side effects in elderly patients, and the risk–benefit ratio should be carefully weighed in this patient population. For more long-term relief, the use of steroids has been examined. Two studies, one using methylprednisolone in a 22-day taper and another using prednisone 1 mg/kg for 5 days with a 15-day taper, showed no better symptom improvement than placebo at 12-month follow-up (13,14). However, the smaller study using prednisone demonstrated better symptom improvement than placebo at 3- and 6-month follow-up. Therefore, if there is not a contraindication, it is reasonable to give a short course of steroids.

Posterior canal BPPV: Epley and Semont are maneuvers designed to move the head in a way that moves the otoconia out of the semicircular canal and into the utricle, where it can then be washed away. Studies show that Epley and Semont maneuvers perform equally well. As Epley is the most commonly used and most well studied, the discussion will center on this maneuver. The Epley maneuver (Fig. 70.2) has been shown to improve the symptoms in both the short and longer term in randomized controlled trials (RCTs). An ED-based RCT with 11 patients each in Epley and sham maneuver groups, had six Epley-treated patients with complete resolution of symptoms on completion of the maneuvers, compared to only one in the sham arm (15). The average time to complete the maneuvers was 2 to 3 minutes. Another RCT with 67 patients demonstrated 80% improvement in vertigo and nystagmus at 24 hours compared to 10% improvement in patients who did sham maneuver (16). Improvement in Epley-treated patients has also been demonstrated at 1 month post procedure.

Horizontal canal BPPV: Numerous maneuvers have been described, but with little supporting evidence. In the Asprella–Gufoni maneuver, the patient starts in a sitting position, lies down onto the side of the unaffected ear with the head resting on the bed with the eyes looking straight-ahead. Position is held for about 2 minutes, then head is rotated 45 degrees looking toward the bed (toward the unaffected ear). After another 2 minutes, the patient sits up with the

head still turned 45 degrees looking toward the unaffected ear. This maneuver is approximately 80% effective in resolving symptoms.

Studies of beneficial medications are scarce. Benzodiazepines have not been shown to be better than placebo. Meclizine is commonly prescribed for this condition but has only demonstrated benefit in one small study (17). Both medication classes have significant side effects, particularly in elderly patients.

Migrainous vertigo: Treatment of migrainous vertigo is similar to that of migraine headache (see Chapter 153), and includes antiemetics (prochlorperazine, metoclopramide, droperidol), and serotonin agonists (triptans, dihydroergotamine).

CRITICAL INTERVENTIONS

- Differentiate BPPV, VN, and CBI with a focused history and physical, with particular concentration on gait and nystagmus testing, Dix–Hallpike test, and HIT
- Obtain MRI in the patient with suspected CBI
- Perform an Epley maneuver and demonstrate home exercises in the patient with BPPV

DISPOSITION

Patients with peripheral vertigo should be instructed to decrease or stop activities such as driving, operating heavy machinery, or work duties until such time as the symptomatology abates. Particular caution needs to be exercised with the elderly, as they can have significant morbidity and mortality from falls due to vertigo/imbalance. Depending on the patient's functional status, home social situation, and outpatient and ED service capability, consideration should be given for prescribing walking aids, physical therapy referral in the ED to assess gait, home health referral, or admission to hospital or rehabilitation facility. Referral to ENT, a neurootology clinic, or a clinic that specializes in vestibular rehabilitation is indicated as proper rehabilitation can significantly decrease the severity of symptoms and increase functionality. Patients with vestibular neuritis should be counseled that severe

symptoms last for 1 to 2 days, with a gradual resolution over weeks to months. Recurrence is rare. BPPV patients should receive instruction on how to do the Epley home maneuvers for the appropriate affected ear. Studies have demonstrated significantly improved resolution rates in patients who were additionally given instruction in how to perform the Epley maneuver at home compared to those who only had the maneuver performed by the physician (18). BPPV does have a significant risk of recurrence: 15% to 18% at 1 year, and 37% to 50% at 5 years. Admission is indicated for workup when CBI is suspected. Neurology consultation is helpful in this setting.

Common Pitfalls

- Using a patient's description of "dizziness" symptoms to rule out vertigo.
- Using a normal finger–nose test to rule out CBI.
- Failure to use the HIT and nystagmus testing in the differentiation of VN from CBI.
- Failure to perform a Dix–Hallpike test in the patient suspected of BPPV.
- Failure to perform horizontal canal diagnostic maneuvers in patients with BPPV symptoms when the Dix–Hallpike test is negative for posterior semicircular canal involvement.
- Using CT to rule out CBI.
- Failure to recognize that a negative DW-MRI does not rule out CBI in the first 24 hours.
- Treating BPPV with medications of unproven benefit, rather than a potentially curative Epley maneuver.

CHAPTER 71 Acute Hearing Loss and Tinnitus

Carolyn Chooljian

CLINICAL PRESENTATION

Acute hearing loss (AHL) is defined as hearing loss occurring over 3 days or less and involves the loss of 30 decibels (dB) of hearing over three or more contiguous audiologic frequencies. AHL may present in isolation or with tinnitus and/or vertigo. The presence or absence of associated symptoms is useful in its evaluation. The etiology of AHL may be obvious or obscure. When it is due to trauma of the temporal bone or associated with the effusion of acute otitis media the etiology is readily apparent. However, AHL may also occur spontaneously without an obvious etiology. The patient may complain of hearing loss in one ear or both.

Auditory Pathway

Knowledge of the auditory pathway (1) is helpful in understanding the presentation, type, and cause of AHL. The auditory system can be divided into peripheral and central parts. The peripheral auditory system consists of the external ear, middle ear, and the inner ear located within the temporal bone. The external ear includes the auricle, external auditory canal, and tympanic membrane (TM). The middle ear is an air-filled space that contains the auditory ossicles—the malleus, incus, and stapes. Sound waves reach the TM and are transmitted via the ossicles of the middle ear to the fluid-filled cochlea of the inner ear. The cochlea contains the specialized

hearing organ of Corti where sound is converted from mechanical pressure to electrical signals through its neuroepithelial hair cells. Projections from the organ of Corti proceed to the bipolar spiral ganglion. The centrally projecting processes of the spiral ganglion constitute the auditory portion of the eighth cranial nerve, the cochlear nerve. These project to the ventral and dorsal cochlear nuclei, which are located in the brainstem at the level of the lower pons.

The central segment of the auditory system extends from the cochlear nuclei up to the auditory cortex of the temporal lobe. The cochlear nuclei send projections to the superior olivary nucleus of the pons. Here most of the auditory input crosses to the contralateral side via the trapezoid body to form the lateral lemniscus. The lateral lemniscus is the auditory tract that traverses the pons to the inferior colliculus of the midbrain. At this level the inferior colliculi intermingle information from both ears. Inferior colliculi axons project on to the medial geniculate bodies of the thalamus. From there the auditory radiations project to the primary auditory cortex of the temporal lobe. Each auditory cortex receives input from both ears. As a result, lesions of the central auditory pathway cause bilateral hearing loss, though the loss is greater on the contralateral side. Peripheral lesions cause unilateral ipsilateral loss. Cortical deafness only occurs when both temporal lobes are injured. Unilateral temporal insults do not clinically affect hearing.

Types of Hearing Loss

Hearing loss is divided into two broad categories—conductive hearing loss (CHL) and sensorineural hearing loss (SNHL). Mixed hearing loss is a combination of the two.

CHL involves problems of the external and middle ear. SNHL involves the cochlea, cochlear division of the eighth cranial nerve, and the central nervous system portion of the auditory pathway.

Tinnitus

Tinnitus is the perception of sound without an auditory stimulus. Ninety-four percentage of healthy young people report perceiving tinnitus at times (2). Ringing, buzzing, whistling, and humming are some descriptors of tinnitus. It may be a symptom of disease though not necessarily. Fifty percentage of persons with sudden hearing loss will describe associated tinnitus. Tinnitus may be associated with CHL or SNHL.

DIFFERENTIAL DIAGNOSIS

Acute Conductive Hearing Loss

Acute causes of CHL include cerumen impaction of the external auditory canal, TM perforation secondary to trauma or infection, acute effusion of the middle ear from otitis media, ossicular chain dysfunction, and eustachian tube obstruction. TM perforation leads to 15 to 20 dB of CHL. Acute barotrauma from the inability to equalize pressure between the external and middle ear during scuba diving or altitude changes during air flight or driving can lead to painful, temporary CHL.

Acute Sensorineural Hearing Loss

SNHL has many causes including ototoxic drugs, acute infections, chronic meningitis, loud noise, vascular disease, barotrauma, Ménière's disease, multiple sclerosis, migraine (3), and autoimmune inner ear disease (AIED). Acute SNHL may also be idiopathic. Drugs known to cause ototoxicity include aminoglycosides, intravenous erythromycin, loop diuretics, salicylates, antineoplastic agents such as cisplatin and vincristine, and has been newly reported in patients using the phosphodiesterase five inhibitors sildenafil, tadalafil, and vardenafil for erectile dysfunction (4). Aminoglycoside ototoxicity is related to the total serum concentration of the drug, though it is heightened by increasing age and appears to have a genetic component. Tinnitus is a common early symptom. Loop diuretic–associated ototoxicity is usually temporary, but can be permanent. Salicylate concentrations of 20 to 50 mg/dL can cause up to 30 dB of hearing loss. Tinnitus increases as the plasma levels exceed 40

mg/dL. Bacterial meningitis causes hearing loss in up to 35% of infections by injuring the inner hair cells of the cochlea. Viruses that have caused hearing loss include measles, mumps, rubella, CMV, herpes zoster, herpes simplex, and HIV. Spirochete infections of early and late syphilis and Lyme disease may cause unilateral or bilateral SNHL. Syphilitic hearing loss may be fluctuating and associated with vertigo resembling Ménière's disease. Chronic meningitis involving the auditory nerve—both infectious and noninfectious—may cause or present with acute SNHL. Sarcoid, mycotic, lymphomatous, carcinomatous, and tuberculous infiltrations have been described. Other cranial nerves may or may not be involved. Extreme noise levels may lead to cochlear spiral ganglion degeneration and SNHL by damaging sensory hair cells. This is often temporary, though prolonged exposure to sounds above 85 dB may cause permanent hearing loss. Hearing loss has also been described with automobile airbag detonation (5). Cerebrovascular accidents and transient ischemic attacks involving the vertebrobasilar circulation may lead to acute SNHL. The anterior-inferior cerebellar artery serves the lateral pons, middle cerebellar peduncle, and the inner ear. Strokes in this distribution cause vertigo, severe SNHL loss, and ataxia (6). Infarction in the distribution of the superior cerebellar artery leads to contralateral partial hearing loss by involving the lateral lemniscus. Cochlear anoxia due to poor microcirculation or vasculitis may cause acute SNHL. Hyperviscosity states in Waldenstrom macroglobulinemia and polycythemia can impair cochlear circulation. Spontaneous hemorrhage of the inner ear has occurred with leukemia, sickle cell disease, thalassemia, subarachnoid hemorrhage, trauma, and hypercoagulable states. Sudden SNHL and vertigo occurring within hours or days may be due to a perilymphatic fistula (PLF). PLF from rupture of the round or oval window between the air-filled middle ear and fluid-filled inner ear may be caused by barometric pressure changes from scuba diving, airplane flight, mountain travel, and even vigorous sneezing. Ménière's disease is a syndrome that causes recurrent fluctuating hearing loss, vertigo, and tinnitus. The hearing loss usually resolves within 24 hours, though it eventually becomes

permanent. Multiple sclerosis may present with acute SNHL or vertigo. Migraine headache can be associated with acute SNHL, likely due to vasospasm, and may cause migrainous infarction (3). AIED is an immune-mediated cause of SNHL which may present with rapidly progressive hearing loss. It has been associated with relapsing polychondritis, Wegener granulomatosis, systemic lupus erythematosus, rheumatoid arthritis, polyarteritis nodosa, Behcet syndrome, giant cell arteritis, sarcoidosis, and Cogan Syndrome—an interstitial keratitis and vestibuloauditory syndrome which presents with abrupt vertigo, tinnitus, hearing loss, and ataxia. AIED with immune-mediated hearing loss but without systemic symptoms can present as rapidly progressive bilateral deafness as well. Sudden idiopathic SNHL may present acutely with immediate onset or progressive hearing loss over 3 days. It may be bilateral but is unilateral in 90%. Four thousand new cases/year occur in the United States. Any age group may be affected, though it occurs more often between ages of 30 and 60 years. Associated symptoms may include vertigo, tinnitus, or both. The natural history of acute idiopathic SNHL is complete recovery without medical intervention in as many as two-thirds, often within first 3 days to 2 weeks. Hearing worsens over time in 15% (7).

Mixed Hearing Loss (CHL Plus SNHL)

Processes that extensively involve the temporal bone such as tuberculosis and trauma can cause mixed hearing loss. Temporal bone fractures can be longitudinal or transverse, though 70% to 90% are longitudinal. AHL associated with longitudinal fractures involving the external auditory canal, middle ear, and long axis of the petrous pyramid is predominantly CHL, though SNHL occurs in 35% and facial nerve paralysis in 15%. Transverse fractures involving the cochlea and/or auditory nerve can cause total sudden SNHL and may be associated with facial nerve paralysis as well. Penetrating trauma can cause both CHL and SNHL depending on the trajectory and force of the missile.

Blast injuries can cause TM disruption, ossicular discontinuity, cochlear injury, and temporal bone fracture, leading to CHL and SNHL. If a PLF develops, there may be progressive hearing loss and disequilibrium. Lightning and electrocution may produce TM perforation and CHL as well as temporal bone fracture–related SNHL. Bilateral oval window PLF from lightning strike can cause SNHL. Cerebellopontine angle tumors may present with AHL in as many as 20%. Unilateral tinnitus is often present. Meningiomas and cholesteatomas also have presented with AHL. Primary or metastatic tumors to the temporal bone may cause CHL or SNHL. Breast, prostate, and renal cell carcinoma are the most common metastatic tumor types.

ACUTE HEARING LOSS AND ASSOCIATED SYMPTOMS

AHL and Tinnitus

Acute CHL due to otitis media as well as cerumen impaction may have associated tinnitus. Acute SNHL is associated with tinnitus in Ménière's disease and other causes of sudden SNHL such as ototoxic drugs including salicylates and loop diuretics. Sixty-five percentage of patients with vestibular schwannomas will have constant tinnitus. Pulsatile tinnitus may be a sign of neoplasm; arterial, venous, and intracranial hypertension; and great vessel bruits. Paragangliomas (glomus jugulare tumors) present initially with pulsatile tinnitus and CHL.

AHL and Vertigo

Vertigo can be associated with both CHL and SNHL. Labyrinthine disorders, PLF, Ménière's disease, multiple sclerosis, and cerebellopontine angle tumors can cause both. Brainstem, cerebellar, and higher causes of vertigo do not usually affect hearing (8).

ED EVALUATION

The ED evaluation of AHL should include a directed history and physical examination regarding the hearing loss complaint; an

assessment of hearing, differentiating between CHL and SNHL; recognition of the presence of tinnitus, vertigo, and other focal neurologic findings as well as underlying diseases such as cancer and autoimmune disease; and assessment of the medication list for ototoxic medications.

The ED physician's tools to differentiate CHL from SNHL include the tuning fork tests. Using a 256- or 512-Hz tuning fork, the Weber test is performed by placing the tuning fork on the patient's forehead or front teeth. Normally sound is heard the same in both ears. With CHL sound is louder in the poorer-hearing ear (lateralizes to the bad ear). In SNHL sound is louder in the better-hearing ear (lateralizes to the good ear). The Rinne test is performed by first placing the tuning fork on the mastoid bone. When the patient no longer hears sound, the fork is then placed at the auditory meatus. Normally sound should still be heard because air conduction is greater than bone conduction. Inability to hear in front of the ear indicates CHL. In SNHL hearing at both positions will be decreased.

CT scan of the temporal bone is indicated in the setting of head trauma and AHL. CT is best at evaluating fractures and the integrity of the middle ear ossicular chain. MRI is best for fluid, blood, and soft tissue masses. Nontraumatic acute idiopathic SNHL is best evaluated by MRI with gadolinium contrast. Routine laboratory tests and CT scan of the head are not recommended in the evaluation of acute idiopathic SNHL (9). Tinnitus with concerning characteristics —persistent unilateral, pulsating, or fluctuating, and associated with vertigo warrants investigation.

KEY TESTING

- Differentiate CHL from SNHL by physical examination
- Carefully assess for associated symptoms or neurologic deficits
- Consider MRI for acute idiopathic SNHL

ED MANAGEMENT

If the cause of hearing loss is obvious, the management should be directed toward it, for example, remove cerumen from the ear canal,

treat infections, including otitis media or meningitis, or reduce or discontinue ototoxic medications. An Ear, Nose, and Throat (ENT) specialist should be consulted for patients with hearing loss associated with temporal bone trauma. Acute idiopathic SNHL is considered a medical emergency (10). Patients with acute idiopathic SNHL may be candidates for special interventions including high-dose corticosteroids orally, intravenously, or intratympanically. It is recommended that if oral corticosteroid therapy is used it should be initiated immediately, ideally within the first 14 days of hearing loss. The initial dose of prednisone is 1 mg/kg/d (maximum 60 mg/d) at full dose for 7 to 14 days and then tapered over a similar time period. Immediate consultation with the ENT specialist is ideal (9–11). Intratympanic steroids may be used as salvage therapy, although there is now evidence that the intratympanic approach is equivalent to oral therapy in outcome. Intratympanic steroids may be preferred for patients who are not good candidates for high-dose oral corticosteroids due to other comorbidities, for example, diabetes (12). Other therapies may include hyperbaric oxygen, antiviral medications, carbogen inhalation, and bed rest although empiric antiviral therapy is not currently recommended (9). The ENT specialist may choose to hospitalize the patient. PLF may require surgery. As many as two-thirds of patients with acute SNHL improve without intervention (7). Most of the patients who will improve usually do so within 2 weeks. Evaluating the efficacy of interventions is beyond the scope of this discussion. A clinical guideline published by the American Academy of Otolaryngology-Head and Neck Surgery in 2012 outlines the current recommendations of the ENT community for the evaluation and management of sudden hearing loss (9).

CRITICAL INTERVENTIONS

- Emergent discussion with ENT specialist for acute SNHL

DISPOSITION

Most cases of AHL may be discharged home with appropriate follow-up, depending on the suspected cause and underlying comorbidities. If the patient has acute SNHL, emergent discussion with an ENT specialist is recommended.

Common Pitfalls

- Not distinguishing between CHL and SNHL.
- Not contacting ENT emergently for patients with acute SNHL.
- Not considering ototoxic medications, autoimmune disease, neurologic disease infections, cancer or hematologic disease as a cause of acute SNHL.
- Not considering simple causes such as cerumen impaction for hearing loss.
- Not considering tumor as a cause of acute unilateral tinnitus and/or hearing loss.

CHAPTER 72

Complications of Tracheostomies

Valerie Dobiesz, Samreen Vora, and Carissa Tyo

Tracheostomy placement is a mainstay in airway management of critically ill patients. A tracheostomy tube is placed because of mechanical obstruction, inability to clear secretions, or need for prolonged ventilation. A tracheostomy provides access for mechanical ventilation, clearance of secretions, and protection of the airway. Placement may be done in the operating room using an open technique, or at the bedside in the intensive care unit (ICU) using a percutaneous dilational tracheostomy (PDT) technique. This surgical procedure has been known for centuries, with references to this practice in Eber's Papyrus (1550 BC) and the ancient Rig Veda texts (two of the three oldest known medical works) (1,2).

Complications of these devices range from minor inconveniences for the patient to life-threatening emergencies and may occur immediately postoperatively or may be delayed in nature. Complications include local bleeding, obstruction, infection, stenosis, tracheoesophageal fistula, pneumothorax, pneumomediastinum, air leaks, dislodgement, false passage, tracheostomy tube fractures with aspiration, and decannulation. Rarely, an extra-long tube can lead to right mainstem bronchus intubation recognized in the immediate postoperative period. The overall mortality rate is $<1\%$ with a total complication rate of up to 65%. A greater mortality rate and complication rate are seen in emergency situations, ICU patients, and pediatric patients (3,4). Because the tracheostomy tube is frequently encountered in the

emergency department (ED), emergency physicians must be aware of the purpose, structure, and proper maintenance of these devices, so they will be prepared for complications.

HEMORRHAGE

Major hemorrhage during and soon after tracheostomy is rare but can be life threatening. Bleeding complications account for 20% of ED tracheostomy visits (5). There are numerous vessels in the vicinity that can bleed and cause problems, including the superficial blood vessels, thyroid vessels, carotid arteries, anterior jugular veins, and the innominate (brachiocephalic) artery. The lacerated thyroid gland can bleed, as can granulation tissue. Incisional or stomal bleeding may be controlled with cauterization or packing the wound with petroleum jelly gauze.

Of particular concern is the potential for a tracheoarterial fistula. This fistula is typically caused by erosion of the tip of the tracheostomy tube into the innominate artery, producing massive bleeding that is universally fatal if not recognized and treated immediately. Tracheo-innominate artery fistula (TIF) is reported in approximately 0.1% to 1% of surgical tracheostomy patients and 0.35% of PDT patients; moreover, delayed hemorrhage is underreported (6). Although rare, TIF has a mortality rate of 50% to 75% despite emergent management (5). The clinical presentation may include a sentinel bleed in the form of hemoptysis or mild bleeding at the tracheostomy site hours or days before massive bleeding occurs.

The ED evaluation should include a rapid assessment for airway patency and for signs of shock or coagulopathy. Basic laboratory studies and a type and screen are helpful in this regard.

The ED management should initially focus on resuscitation, if necessary. Vigorous resuscitation with isotonic fluids and possibly blood should be started for any brisk bleeding while emergent surgical consultation is obtained for definitive management. Bronchoscopy is the diagnostic method of choice. Temporizing measures should be attempted to control the bleeding, such as

hyperinflation of the tracheostomy cuff to compress bleeding vessels against the sternal wall. If cuff inflation is unsuccessful, digital pressure should be applied to the anterior tracheal wall through the tracheostomy, compressing the anterior tracheal wall against the sternum until definitive care can be provided (7,8).

OBSTRUCTION

A patient with a tracheostomy who presents with respiratory distress must first be assessed for either a partial or complete obstruction of the tracheostomy tube. Patients with tracheostomies lack the humidification of air inspired by nasal passages, and this often results in thick, dry secretions. Improper care and maintenance of tracheostomy tubes in the outpatient setting are common. Mucus, inspissated secretions, blood, or dislodgement of the tracheostomy tube may cause life-threatening obstruction. Secretions may act as a ball valve, allowing air in but restricting outward ventilation (9).

The clinical presentation may range from slow, progressive shortness of breath to sudden obstruction and respiratory arrest.

The initial ED management should include verification of proper placement of the tracheostomy tube, with repositioning as needed. Treatment with high-flow oxygen should be initiated. Saline, hypertonic saline, or N-acetylcysteine may be used to help loosen secretions, followed by suction with an endotracheal suction catheter. Nebulized sodium bicarbonate raises the pH of secretions and weakens the saccharide structure of the mucus, and may offer an additive benefit when combined with nebulized N-acetylcysteine (10).

The inner cannula should be removed and cleaned, as this is a common source of obstruction. However, if the problem persists, the outer cannula should be removed and replaced with a new tracheostomy tube. Mechanical problems with the tube such as cuff leak or tube fracture may also necessitate tube replacement or consultation for bronchoscopy (9,11). Replacement of the tracheostomy tube in nonemergent circumstances is described in

Table 72.1. However, the process may need to be abbreviated in the prehospital or emergency setting. A patient in respiratory distress not relieved by conservative methods such as suction, oxygen, and bronchodilators should be treated by immediate removal of the tracheostomy tube and tube replacement. Most obstructions occur in patients with long-standing tracheostomies, and those patients generally have uncuffed tracheostomy tubes that can be easily removed (12). If a new tracheostomy tube needs to be emergently replaced, the procedure may be simplified by passing a catheter or gum elastic bougie through the old tracheostomy tube and using it to guide the removal and replacement of the tube (12).

TABLE 72.1
Replacement of the Tracheostomy Cannula

1. Preoxygenate the patient and extend the head slightly to facilitate placement. Removal and replacement of tracheostomy tubes should follow the curved path of the tube itself.
2. Lubricate the new tube with a water-soluble lubricant, and place the obturator inside the tube to facilitate insertion. This obturator will be removed after tube placement.
3. A well-positioned tube can be advanced gently with little resistance. Tracheal hooks or a dilator may be used to hold the stoma open.
4. If force is necessary to place the tube, efforts should be discontinued because of the possibility of creating false passages, bleeding, and edema.
5. A safe method to ensure proper placement of a tracheostomy tube is to use a thin red rubber catheter as a guide. The catheter can be placed through the existing tracheostomy before removal. If the tracheostomy tube has accidentally fallen out, the catheter may be placed directly through the stoma. Once the old tracheostomy tube is removed, the new tube without the obturator can be passed over the catheter into place. The red rubber catheter can then be removed.[a]
6. Secure the tube with tracheal tube ties tightened enough so that only one finger can fit between the patient's neck and the tube tie.
7. Correct tube placement may be confirmed clinically, radiographically, or using end-tidal CO_2 detection.

[a]Adapted from Rowe BH, Rampton J, Bota GW, et al. Life-threatening luminal obstruction due to mucous plugging in chronic tracheostomies: Three case reports and a review of the literature. *J Emerg Med.* 1996;14(5):565–567.

INFECTION

Serious infection of the stomal site is rare, despite most fresh wounds being colonized by nosocomial organisms (13). The patient's underlying medical condition, the presence of an indwelling device, and exposure to flora-colonizing ventilator tubing predisposes to infection, including lower respiratory infections. Prophylactic antibiotics, however, are not indicated.

The clinical presentation ranges from cellulitis or drainage around the tracheostomy tube to tracheitis, bronchitis, pneumonia, or sepsis.

The ED management of peristomal cellulitis consists of outpatient antibiotics for mild cases. Rarely, the wound infection may spread inferiorly, causing mediastinitis, mediastinal abscess, and paratracheal abscess. Patients with signs or symptoms of systemic infection or pain with breathing and swallowing should be evaluated for these complications, usually by imaging with computed tomography (CT) scan, and given intravenous antibiotics. Antibiotics should cover common respiratory flora, though methicillin-resistant Staphylococcus aureus must also be considered.

STENOSIS

Constant pressure from the cuff may cause pressure necrosis, ulceration, and formation of granulation tissue that subsequently causes tracheal stenosis (14). This is a late complication presenting weeks to months after decannulation.

The clinical presentation is insidious. Typically, patients do not become symptomatic until the endotracheal lumen has been reduced by 50% to 75%, at which point they may complain of cough, dyspnea, and inability to clear secretions.

The ED evaluation includes consultation or referral, because the diagnosis of stenosis is typically made with bronchoscopy. Once identified, significant stenosis is treated with operative dilation or resection of granulation tissue.

TRACHEOESOPHAGEAL FISTULA

Tracheoesophageal fistula is a rare but potentially life-threatening complication. It is caused either by perforation of the posterior wall of the trachea during the tracheotomy or erosion into the esophagus by the tracheostomy tube.

The clinical presentation may include signs and symptoms of cuff leak, aspiration of food contents, abdominal distention, or copious secretions (4).

The ED evaluation includes making arrangements for bronchoscopy or swallowing studies to confirm the diagnosis. This complication has also been associated with PDT (1,15).

PERCUTANEOUS DILATIONAL TRACHEOSTOMY

An alternative technique to surgical tracheostomy is a PDT, which was first described in 1985 and has become a popular alternative and has recently been proposed as the new gold standard (16–19). This technique has several advantages compared to surgical tracheostomies, including lower rates of pneumothorax, major hemorrhage, and laryngeal granulation (18). PDT can be done at the bedside, thereby reducing the operative risk and the cost. A major advantage is the ability to gain and maintain competence with the procedure in the elective setting (20). Long-term complications are the same as for standard surgical tracheostomy, although there is a slight reduction in tracheal stenosis with PDT. This procedure also has some unique risks not encountered with surgical tracheostomy, such as paratracheal insertion of a tracheostomy tube and posterolateral tracheal wall laceration (21). However, these complications are not common and are rarely lethal with a reported mortality rate of 0.17% (3,14).

REPLACEMENT OF TRACHEOSTOMY CANNULA

Tracheostomy tubes may be cuffed or uncuffed and may come with an inner cannula that can be removed for cleaning (Table 72.1). Indications for replacement of the tracheostomy tube in the ED include cuff rupture or leak and complete or partial obstruction. Changing the tracheostomy should be avoided for at least 1 week

after the creation of the stoma, if possible. A replacement tube should be the same type and size as the original. In an emergency, replacement with a smaller size is preferred if maintaining a patent airway depends on it. If the appropriate-sized tracheostomy tube is unavailable in an emergency situation, a standard endotracheal tube may serve as a temporary replacement, typically a size 6 mm to 7.5 mm cuffed tube in an adult.

If the tracheostomy tube cannot be replaced and the airway is in jeopardy, the physician should consider oral endotracheal intubation. The original indication for the tracheostomy may hamper attempts at endotracheal intubation (e.g., laryngeal malignancy). If respiratory distress persists after adequate tube replacement, the physician must not overlook other causes such as pneumothorax, pulmonary embolus, pneumonia, or congestive heart failure.

CRITICAL INTERVENTIONS

- Obstruction of a tracheostomy tube can be life threatening. Remove the inner cannula and clear the obstruction to restore airway patency.
- Gain rapid control of hemorrhage, and consult a surgeon for definitive care.

DISPOSITION

Patients with minor bleeding or infection around a tracheostomy tube site may be treated and discharged with appropriate follow-up. Those patients with partial obstruction caused by deposits or secretion buildup on the tracheostomy tube may also be discharged after the tube is cleaned or changed and the symptoms are resolved.

Patients with persistent bleeding, more serious infection, or difficulty breathing mandate consultation and admission. Those patients with suspected tracheoesophageal fistula or early stenosis may be further evaluated on an inpatient or outpatient basis, depending upon the severity of symptoms.

Common Pitfalls

- Failure to rapidly clear or remove an obstructed tracheostomy tube.
- Inadequate control of hemorrhage around a tracheostomy tube. A tracheoarterial fistula should be suspected if a patient presents with brisk bleeding from the tracheostomy tube site.
- Overly aggressive application of force when replacing a tracheostomy tube must be avoided to prevent the creation of a false tract.

SECTION VII
Pulmonary Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 73 Respiratory Failure

Micelle J. Haydel

Respiration is the exchange of gases at the level of the alveoli occurring by simple diffusion. Gas in the alveoli has a high concentration of oxygen and a low concentration of carbon dioxide relative to the deoxygenated blood passing through the alveolar capillary bed. Oxygen and carbon dioxide both diffuse freely through alveolar membranes. Oxygen molecules bind to hemoglobin to be off-loaded in the tissues to be used to generate cellular energy, and the by-product CO_2 which is then carried back to the alveoli for exhalation. The O_2–CO_2 gradient at the capillary-alveolar border is constantly maintained, permitting the passive diffusion of gases, while the contraction and relaxation of intercostal muscles actively draws oxygenated gases into the alveoli and then pushes the carbon dioxide–rich gas out of the alveoli. Any part of this process can be altered leading to respiratory distress and failure.

CLINICAL PRESENTATION

Respiratory distress implies that the work of breathing has increased to the point that a patient displays clinical evidence of difficulty in breathing, such as tachypnea, dyspnea, and accessory muscle use. *Dyspnea* is the sensation of difficulty breathing and is most commonly caused by congestive heart failure, asthma, chronic obstructive pulmonary disease, and pneumonia. *Respiratory failure* implies that a patient is not able to maintain adequate oxygenation and/or ventilation. Respiratory failure is a clinical diagnosis, although measurements of the partial pressure of oxygen and carbon

dioxide are used to assess the patient's respiratory status. In general, patients with clinical respiratory failure exhibit hypoxemia (PO_2 <60) and/or hypercapnea (PCO_2 >45) with a concomitant respiratory acidosis (pH <7.34) (1). Symptoms of respiratory distress and failure depend on the chronicity of the respiratory impairment, the presence of comorbidities, and the patient's physical ability to perform the increased work of breathing.

Hypoxia leads to a physiologic increase in respiratory rate and cardiac output to compensate for the oxygen deficit. As the patient attempts to compensate for the hypoxemia, clinical findings will include tachypnea, accessory muscle recruitment, abdominal paradoxical movements, and intercostal retractions. This increased work of breathing increases a patient's oxygen consumption to 10 times the resting state (2). Patients with mild–moderate hypoxemia display tachypnea, tachycardia, and hypertension, and may complain of headache. Patients with severe hypoxemia display somnolence, confusion, and seizures. As hypoxemia worsens, patients develop bradycardia and hypotension, leading to permanent hypoxic encephalopathy or death.

Hypercarbia leads to physiologic increase in rate and depth of respirations, and signs and symptoms of hypercarbia depend on the level and rate of increase in PCO_2. A high PCO_2 can be well tolerated if it develops slowly, minimizing acidemia via renal compensatory mechanisms. Acute noncompensated hypercarbia (PCO_2 >80) leads to intracellular acidosis, myocardial depression, dysrhythmias, cerebral vasodilation, and elevated intracranial pressure. Patients with hypercarbia may have agitation, confusion, headaches, seizures, and/or coma, although these neurologic effects of hypercarbia are reversible in patients without concomitant intracerebral injury or stroke (3).

DIFFERENTIAL DIAGNOSIS

Respiratory complaints account for up to 10% of emergency department (ED) visits and dyspnea as a chief complaint has the highest association with inhospital mortality (4). A differential

diagnosis can be based on the primary blood gas abnormality, such as hypoxic, hypercapnic, or mixed respiratory failure. In hypoxic respiratory failure, gas exchange is blocked in an area of the lungs due to disease processes such as pneumonia, pulmonary edema, pulmonary embolism, or pneumothorax. Carbon dioxide has a high diffusion capacity and may be unaffected by this "increased shunt," but will be greatly affected by hypoventilation. Hypercarbic respiratory failure is the inability of gas flow to maintain the necessary off-loading of carbon dioxide at the alveolar level, and is commonly seen in COPD, neuromuscular disease, and opiate toxidromes.

While the most common causes of dyspnea are pneumonia, asthma/COPD, congestive heart failure, and pulmonary embolism (5), several potentially lethal disease states can cause dyspnea and respiratory failure without hypoxemia or hypercarbia on blood gas analysis. When the etiology of dyspnea cannot be explained by the hypoxic/hypercarbic approach, a cognitive map based on four general categories: pulmonary, cardiovascular, neuromuscular, and systemic (Table 73.1), leads the clinician to consider less common causes of respiratory distress, to identify contradictory findings in the H&P, and to determine if more than one disease process is involved. The differential diagnosis of dyspnea in the trauma setting is listed in Table 73.2.

ED EVALUATION

Emergency patients with undifferentiated respiratory distress or impending respiratory failure should be approached in a logical, step-wise manner (Table 73.3) with a goal of:

1. Immediately detect and mitigate life-threatening hypoxemia and hypercarbia.
2. Formulate and initiate critical actions without a complete dataset.
3. Establish a differential diagnosis based first on the most lethal, and then the most likely diagnosis.

Assess Upper Airway

Clinicians must rapidly evaluate the upper airway of patients with dyspnea to rule out the possibility of obstruction, as well as to prepare for the possibility of difficult airway management. Patients with stridor, muffled voice, drooling, neck hematoma, or swelling should be examined for mechanical obstruction due to infection, foreign body, malignancy, or trauma. The presence of obesity, facial hair, poor or absent dentition, and older age are associated with a difficult bag-mask seal. Mallampati classification and measurement of the thyromental and inter-incisor distance can be used to assess for challenges in intubation (6) (see Chapter 1).

TABLE 73.1
Differential Diagnosis of Respiratory Distress and Failure

Upper Airway
Acute obstruction: Foreign body, trauma, tumor
Epiglottitis, laryngotracheitis
Angioedema, anaphylaxis

Lower Airway
Asthma, COPD, emphysema
Pneumonia, bronchiolitis
Acute lung injury, ARDS, pneumonitis, vasculitis, pulmonary contusion
Cystic fibrosis, interstitial lung diseases
Autoimmune lung diseases, lung cancer

Pleural Processes: Effusions, empyema, hemothorax, pneumothorax

Pulmonary Emboli

Cardiovascular Diseases
Congestive heart failure
Myocardial infarct
Valvular disease, congenital structural disorders
Dysrhythmias, cardiomyopathies
Pericardial tamponade, aortic dissection
High output heart failure (see systemic processes)

Neuromuscular Diseases
Guillain–Barré, Myasthenia gravis
Botulism, tetanus

Systemic Diseases
High output heart failure: Severe anemia, beriberi, thyrotoxicosis
Sepsis
Massive obesity, sleep apnea
Toxins: Cyanide, carbon monoxide, organophosphates, salicylates
Metabolic, acid–base or electrolyte disturbances

COPD, chronic obstructive pulmonary disease; ARDS, adult respiratory distress syndrome.

Assessment of Adequacy of Oxygenation

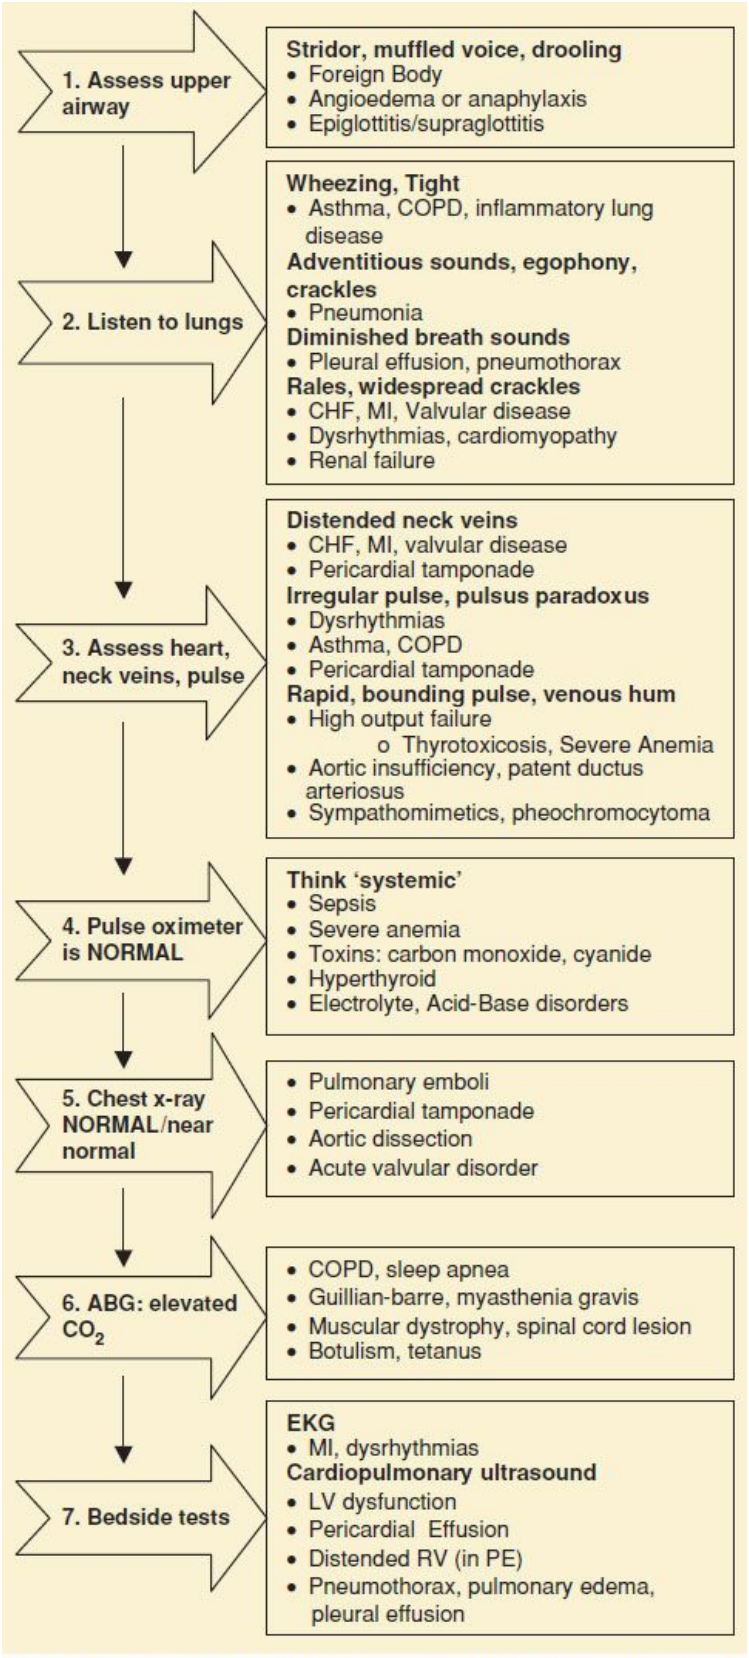
Oxygen delivery to vital organs is the cornerstone of the management of respiratory failure. Bedside pulse oximetry estimates hemoglobin oxygen saturation (SaO_2) by analyzing the transmission of light through a cutaneous vascular bed. Pulse oximetry will overestimate arterial oxygenation in the presence of poor perfusion or carboxyhemoglobin; it will underestimate it in the presence of

methemoglobin (7). An arterial blood gas (ABG) analysis, most commonly measures SaO_2 indirectly by plotting the PaO_2 on a standardized temperature- and pH-adjusted O_2–hemoglobin dissociation curve, while ABG analysis using a co-oximeter has the ability to directly measure the concentrations of oxygenated and deoxygenated hemoglobin.

TABLE 73.2
Differential Diagnosis of Dyspnea in the Trauma Setting

Hemothorax
Pneumothorax
Pulmonary contusion
Cardiac contusion
Severe hypovolemia
Flail chest
Pericardial tamponade

TABLE 73.3
Severe Undifferentiated Respiratory Distress



The vast majority of patients with respiratory distress can be diagnosed based on the physical examination (1, 2, 3). When the diagnosis remains elusive, bedside tests (4, 5, 6, and 7) will narrow the diagnosis.

TABLE 73.4
Formula to Predict Acid–Base Compensation

Acute Respiratory Acidosis
pH will change 0.08 for each 10 mm Hg change in PCO_2
HCO_3^- will rise 1 mEq/L for each 10 mm Hg rise in PCO_2

Acute Respiratory Alkalosis
pH will change 0.08 for each 10 mm Hg change in PCO_2
HCO_3^- will decrease 2 mEq/L for each 10 mm Hg decrement in PCO_2

Chronic Respiratory Acidosis
pH will decrease 0.03 for each 10 mm Hg increase in PCO_2
HCO_3^- will rise 3.5 mEq/L per 10 mm Hg increment in PCO_2

Chronic Respiratory Alkalosis
pH will increase 0.02 for each 10 mm Hg decrease in PCO_2
HCO_3^- will fall 5 mEq/L per 10 mm Hg decrement in PCO_2

Winter's formula for mixed disorders: Calculate the expected $PCO_2 = (1.5 \times HCO_3) + 8$ (if measured PCO_2 on an ABG is higher than the expected PCO_2, then a respiratory acidosis is also present)

Assessment of the Adequacy of Ventilation

While pulse oximetry is used routinely in most emergency settings, it does not provide information about ventilation, and can be falsely reassuring if the clinician assumes that a normal pulse oximetry reading reflects adequate alveolar ventilation. Noninvasive measures of ventilation (exhaled CO_2) have gained widespread use in the ED as an adjunct to pulse oximetry. Bedside capnography provides a numeric and waveform representation of exhaled CO_2 ($ETCO_2$), corresponding to arterial PCO_2. Patients with a normal baseline (35 to 45 mm Hg) $ETCO_2$ can be expected to have an increase in their $ETCO_2$ during hypoventilation and a decrease during hyperventilation. $ETCO_2$ measures only the exhaled CO_2, not the actual $PaCO_2$ and therefore a low $ETCO_2$ can also be seen in the setting of reduced cardiac output and pulmonary embolism.

ABG analysis remains the time-honored gold standard for assessing the adequacy of gas exchange and the acid–base balance. Many diseases are neither acute nor found in isolation, and the ABG is very useful in helping to determine the chronicity of the process, as well as the presence of a mixed respiratory–metabolic disorder. Commonly used acid–base formulas are listed in Table 73.4.

Physical Examination

In the early stages of respiratory distress, vital signs may reflect tachycardia, tachypnea, and hypertension, with the patient demonstrating increased work of breathing and accessory muscle use. As respiratory distress progresses, the patient is unable to speak in complete sentences and must rely on the tripod position to maintain respirations. Increasing hypoxemia or hypercarbia may lead to confusion and combativeness, progressing to a patient who is obtunded or comatose. Depending on the etiology of the respiratory distress and the patient's physical abilities, the progression from dyspnea to respiratory failure can be gradual or precipitous. In order to prepare for the possibility of a difficult airway, the initial assessment of any patient with respiratory complaints should include assessment of visibility of the soft palate, sternomental distance, and thyromental distance (6) (see Chapter 1).

Diagnostic Studies

An electrocardiogram (ECG) should be obtained in any adult with risk factors for coronary disease or cardiac symptoms. Dyspnea can be a symptom of cardiac as well as pulmonary disease; therefore, the ECG is useful in the evaluation of both adult and pediatric patients with undifferentiated dyspnea.

The measurement of peak expiratory flow rate as a surrogate index for forced expiratory volumes and should be standard practice in the management of patients with respiratory distress due to asthma or COPD. Flow rates $<50\%$ of personal best or baseline indicate a severe exacerbation and typically require consideration of

inpatient therapy if there is no satisfactory improvement after treatment.

Chest radiography can detect disease processes not identified by physical examination alone, while computed tomography (CT) is useful in patients when lung parenchymal or pleural disease cannot be delineated by plain radiography alone. CT angiogram has largely replaced ventilation–perfusion scanning in detecting pulmonary embolism. Bedside ultrasound can be used to identify pneumothorax, pleural effusion, and pulmonary edema. Ultrasound has more recently been proven to be very useful in the approach to the undifferentiated patient with respiratory distress (8).

Routine complete blood count, electrolytes, glucose, and renal indices should be obtained in patients with respiratory distress of unknown etiology. Other studies that may be indicated when specific diseases are suspected include cardiac enzymes (acute coronary syndromes), brain natriuretic peptide (congestive heart failure), D-dimer assay (thromboembolic disease), coagulation profile, liver enzymes (multisystem involvement), erythrocyte sedimentation rate (autoimmune diseases, pericarditis, myocarditis), and lactate dehydrogenase (LDH) (*Pneumocystis carinii* pneumonia).

ED Management Approach to the Undifferentiated Patient with Impending Respiratory Failure

1. Exclude upper airway obstruction: Foreign body, hematoma, infection, cancer, angioedema
2. Assess and ameliorate hypoxia
3. Assess ventilation and ameliorate hypercarbia
4. Initiate mechanical ventilation for hemodynamic instability, unstable dysrhythmias, fatigue, progressive respiratory acidosis and/or hypoxemia, loss of airway protective reflexes, alteration in level of consciousness, expected clinical course or lack of response to NIPPV
5. Bedside testing: Portable chest radiograph, electrocardiogram, ultrasound
6. Targeted treatment based on differential diagnosis (Table 73.1)

Oxygen Supplementation

The first step in the management of patients with respiratory distress is the addition of supplementary oxygen, titrating to optimize the individual clinical situation (9). Supplementary oxygen may be provided using a nasal cannula, simple face mask, and nonrebreathing face mask. Nasal cannula provides 24% to 40% oxygen via 1 to 6 L of flow, but high flow rates are poorly tolerated. A face mask provides supplemental O_2 concentrations of 40% to 60% when set to 10 to 12 LPM, whereas a nonrebreathing mask with a collapsible bag reservoir of high flow O_2 (10 to 15 LPM), optimally delivers O_2 concentrations of more than 70%. If these modalities do not provide adequate oxygenation, then mechanical modalities should be initiated to add positive pressure.

Noninvasive Ventilation

Noninvasive positive pressure ventilation (NIPPV) delivers mechanically assisted breaths without the need for intubation. The positive pressure improves oxygenation and gas exchange by increasing both tidal volume and functional residual capacity, and recruiting collapsed alveoli. NIPPV does reduce the work of breathing, but does not "protect the airway" and is therefore contraindicated in patients at high risk for aspiration, those with impaired level of consciousness or need for prolonged ventilator support (Table 73.5). NIPPV has been established in a variety of disease states in the emergency setting, including COPD, cardiogenic pulmonary edema, hypoxemic respiratory failure, and in patients with an acute respiratory exacerbation who do not wish to be intubated (10–12). NIPPV can be used cautiously as a bridge in patients with asthma or pneumonia, but these patients continue to require close monitoring (typically ICU) for deterioration (10). NIPPV failure is not uncommon, and can be predicted during the first hour of use by monitoring closely for continued respiratory distress, or failure to normalize respiratory rate and ABGs (13).

TABLE 73.5
NIPPV—Exclusion Criteria

Severe cardiopulmonary instability
Respiratory arrest
Hypotension or shock
Serious dysrhythmia
Acute myocardial infarction
Anatomic problems
Recent facial, esophageal, or gastric surgery
Craniofacial trauma or burns
Chronic anatomic abnormalities of the upper airway, nasopharynx, oropharynx
Inability to clear or maintain a patent airway and prevent aspiration
Impaired protective reflexes

NIPPV ventilators used in the ED are usually set to either continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). CPAP provides the patient with airway pressure above the ambient atmospheric pressure and is held constant throughout the respiratory cycle, conceptually similar to extrinsic positive end-expiratory pressure (PEEP). BiPAP provides two distinct airway pressures cycled during inspiration (IPAP) and exhalation (EPAP). The work of breathing is a function of initiating and maintaining airflow throughout the inspiratory phase. The tidal volume is set by the clinician, and peak inspiratory pressures can be monitored to minimize the risk of barotrauma.

Suggested Protocol for Initiation of Noninvasive Positive-Pressure Ventilation

With the ventilator set in CPAP mode, the selected mask should be held to the face, allowing a brief period of acclimatization. Once patient cooperation is established, the mask is secured with straps. After the patient is accustomed to CPAP, the ventilator may be changed to BiPAP.

- CPAP settings: Start with 5 cm H_2O and titrate to a maximum of 20 cm H_2O.

- BiPAP settings: Start with IPAP of 10 cm H_2O and EPAP of 5 cm H_2O.
- IPAP is then incrementally adjusted to obtain exhaled tidal volume of 7 to 9 mL/kg ideal body weight, and RR <30. Maximum IPAP is typically 25 cm H_2O.
- EPAP is adjusted to maintain adequate oxygenation, with a typical maximum of 15 cm H_2O.
- FiO_2 is typically started at 40% and titrated to maintain oxygen saturations of $>90\%$.
- Tidal volumes: 10 to 15 mL/kg, which is typically higher than invasive ventilators due to the expected air leak around mask.

Endotracheal Intubation

No specific set of laboratory or clinical criteria can be used to identify all patients who require endotracheal intubation. The decision to intubate should begin with consideration of the patient's underlying disease process, cardiopulmonary reserve, and initial response to other medical therapies. Patients with respiratory distress and hemodynamic instability, dysrhythmias, fatigue, progressive respiratory acidosis and/or hypoxemia, loss of airway protective reflexes, alteration in level of consciousness, expected clinical course or lack of response to NIPPV should prompt plans to intubate (Table 73.6) (see Chapters 1 and 2).

TABLE 73.6
Indications for Initiation of Invasive Mechanical Ventilation in Adults with Respiratory Failure

Apnea or impending respiratory arrest
Cardiovascular hemodynamic instability
Altered mental status with need to protect the airway for:
Patency
To reduce risk of aspiration
To manage or control secretions
Acute ventilatory insufficiency in neuromuscular disease with one of the following:
Acute respiratory acidosis
Progressive decline in vital capacity to <10–15 cc/kg
Progressive decline in maximum inspiratory pressure to <20–30 cm H_2O
Failure of intensive therapy, possibly including NIPPV, in these states:
Acute exacerbation of COPD or asthma
Acute hypoxemic respiratory failure
Acute traumatic brain injury
Traumatic thoracic injury
Acute respiratory distress, any cause

NIPPV, noninvasive positive-pressure ventilation; COPD, chronic obstructive pulmonary disease.

Selection of a Ventilator Mode

The goal of mechanical ventilation in the acute care setting is to take over the work of breathing and maintain adequate gas exchange. The ventilator mode that accomplishes this most effectively is assist control (AC), and is the initial mode of choice in many ED scenarios. Oxygenation is optimized by titrating the FiO_2 quickly down from 100% to a goal of $<60\%$, whereas the PEEP is titrated up from 3 to 5 cm H_2O to prevent alveolar collapse. Ventilation (carbon dioxide off-loading) is optimized with a tidal volume of 8 mL/kg (ideal body weight) and a respiratory rate of 10 to 12 per minute. Patients with asthma or COPD benefit from a prolonged expiratory phase, achieved by lowering the rate to 8 per minute and tidal volume of 6 mL/kg. These settings must be tailored to the individual patient to avoid iatrogenic lung injury.

AC mode provides the highest level of ventilator assistance, because every breath the patient receives is at a predetermined tidal volume. The clinician sets both the tidal volume and the minimum rate. In AC mode, the ventilator delivers the set tidal volume each

time the patient initiates a breath, and also provides ventilator-initiated breaths at the same set tidal volume if the patient's respiratory rate is lower than that set by the clinician.

Synchronized intermittent mandatory ventilation (SIMV) differs from AC mode because the patient is allowed to control the tidal volume and flow rate of any spontaneous breaths exceeding the ventilator's set rate. When the patient breathes below the set rate, the mandatory breaths are synchronized with patient-initiated breaths and the work of breathing is similar to the AC mode. In contrast, spontaneous breaths above the set rate require the patient to generate enough negative force to pull air through the ventilator and to expand the chest cavity against the elastic recoil of the lungs. This increased work of breathing can be great enough to result in respiratory or metabolic acidosis. Clinicians can reduce the work of breathing by adding positive pressure (typically 20 cm H_2O) during the spontaneous breaths that exceed the set rate. In SIMV with pressure support, the patient initiates and terminates inspiration, thereby determining tidal volume.

In selected cases, when the reason for intubation is protection of the airway and the patient's ventilatory drive is intact, CPAP (+/– pressure support) may be appropriate. Positive pressure is provided during inhalation and exhalation, but the patient initiates and terminates each breath, controlling the tidal volume. The work of breathing occurs as the patient initiates each breath and maintains inspiratory effort throughout inhalation.

Monitoring Ventilator Pressures

Mechanical ventilation can cause damage to the lungs at both the macroscopic and microscopic levels. Ventilator-induced lung injury (VILI) encompasses all forms of injury, including pneumothorax, pneumomediastinum, bronchial rupture, and alveolar overdistension.

Peak inspiratory airway pressure is the highest pressure that is generated during inflation of the lung. Peak pressures are highly variable, dependent on lung compliance and airway resistance.

Plateau pressure is the end inspiratory airway pressure, measured just after airflow has ceased, and represents the pressure at the alveolar level. Plateau pressures in an adult with normal lung compliance is usually in the range of 5 to 15 cm H_2O, but is higher in patients with lung disease or overdistension. Plateau pressures should be maintained below 30 cm H_2O.

Auto-PEEP is ventilator-induced lung overdistension caused by inhalation initiated before exhalation is complete. Auto-PEEP and plateau pressures can be reduced by an incremental decrease in the tidal volume and respiratory rate.

CRITICAL INTERVENTIONS

- Anticipate difficult intubations to avoid unexpected failed airways.
- Use the AC ventilator mode as the initial mode after intubation.
- Monitor and control plateau pressure delivered to the alveolar level to help prevent VILI.

Disposition

The overwhelming majority of patients who present with acute respiratory failure require admission to the hospital. Indications for admission to the ICU include hemodynamic instability, respiratory failure requiring mechanical ventilation, need for frequent respiratory therapy and monitoring, rapid progression of respiratory failure, and failure to respond to intervention. Patients who improve with therapy and become stable may be managed on observation units or inpatient wards. Occasionally, a patient with asthma or mild congestive heart failure responds rapidly to treatment and remains stable during further observation in the ED. These patients may be cautiously discharged with close outpatient follow-up, if the patient's primary care physician is agreeable and can assure prompt follow-up.

Common Pitfalls

- Failure to recognize impending respiratory failure.
- Failure to consider alternative etiologies of respiratory failure.
- Failure to consider initiating noninvasive ventilation, leading to endotracheal intubation that might have been avoided.
- Overreliance on pulse oximetry to predict adequacy of oxygenation and ventilation.
- Failure to monitor airway pressures after initiation of mechanical ventilation.
- Failure to individualize ventilator settings, with consequent VILI.
- Use of CPAP or SIMV modes without sufficient pressure support, causing increased work of breathing.

CHAPTER 74 Pneumonia

Gregory J. Moran and David A. Talan

In the United States, more than 3 million persons contract community-acquired pneumonia (CAP) annually, resulting in about 500,000 hospital admissions. Pneumonia is the most common infectious cause of death in the United States. Most deaths occur in the elderly or immunosuppressed, but pneumonia also occurs in otherwise healthy persons. To manage patients with pneumonia successfully, emergency physicians must maintain an awareness of the expanding spectrum of pathogens, changing antibiotic-resistance patterns, and availability of new antimicrobial agents.

Streptococcus pneumoniae, Haemophilus influenzae, Mycoplasma pneumoniae, and viruses continue to be the most common causes of CAP, with *Legionella* sp and *Chlamydophila pneumoniae* less frequently diagnosed (1). Less common etiologies include gram-negative bacilli and oral anaerobes. *Staphylococcus aureus* was considered an uncommon cause of CAP, but recent studies indicate it is among the more common pathogens, particularly in seriously ill patients (2). *Pneumocystis jirovecii* (previously known as *P. carinii*) and *Mycobacterium tuberculosis* are important as pathogens related to pulmonary infections in patients with acquired immunodeficiency syndrome (AIDS). Knowledge of local prevalence patterns for pathogens of CAP is important to make appropriate choices regarding evaluation and treatment.

CLINICAL PRESENTATION

Typical and Atypical Pneumonias

Pneumonia is often divided into typical (pyogenic bacterial) and atypical categories, but this division is somewhat artificial. Prediction of these etiologies based on clinical and radiographic findings is inaccurate. The classic presentation of typical pyogenic bacterial pneumonia is the abrupt onset of fever and chills, followed by development of productive cough with purulent sputum and pleuritic chest pain. Elderly or debilitated patients can present with nonspecific complaints, such as altered mental status. Tachypnea and tachycardia are usually present. Physical examination signs of pneumonia include findings of consolidation such as dullness to percussion, coarse rales, bronchial breath sounds, or increased tactile fremitus.

The atypical pneumonia syndrome is caused by organisms such as *M. pneumoniae, C. pneumoniae,* viruses, *Legionella* sp, or rickettsial organisms such as *Coxiella burnetii.* Patients with this type of pneumonia generally present with a subacute onset of systemic complaints, such as fever, headache, malaise, and myalgias, associated with a nonproductive cough. Although mucopurulent sputum generally indicates the presence of pyogenic bacterial pneumonia or bronchitis, it can also be present with mycoplasmal or viral pneumonia. Chest examination often reveals scattered rhonchi or rales. Signs of consolidation are less common.

The high degree of overlap between the clinical and radiographic features of typical pyogenic and atypical pneumonia makes it impossible to accurately predict the specific type of pneumonia. Typical and atypical pathogens sometimes coexist in the same patient, and bacterial infections often coexist or follow viral respiratory infections. It is usually not possible to determine the specific etiology of pneumonia within the timeframe of an emergency department (ED) evaluation, however, certain clinical factors can suggest a likely etiology and guide empiric therapy. The clinical characteristics of several types of pneumonia are noted next.

Common Etiologies

S. pneumoniae is the single most common identified etiologic agent among adults with CAP. The classic presentation of pneumococcal

pneumonia is the abrupt onset of a single shaking chill, followed by fever, cough productive of rust-colored sputum, and pleuritic chest pain. However, many patients have a more insidious onset. Patients with a history of asplenia, sickle-cell disease, AIDS, multiple myeloma, or agammaglobulinemia are at increased risk of pneumococcal bacteremia and sepsis. Extrapulmonary complications such as meningitis, endocarditis, or arthritis occasionally develop.

In a recent study of hospitalized ED patients, staphylococcal pneumonia was the second most common identified etiology of CAP. Although CAP due to methicillin-resistant *S. aureus* (CA-MRSA) occurred in less than 3% overall, patients were distinctly more seriously ill and had chest radiographs with cavitation characteristic of necrotizing pneumonia (2). Intravenous (IV) drug users can present with pneumonia due to septic emboli from hematogenous spread of *S. aureus* (often associated with tricuspid-valve endocarditis), and with multiple small bilateral infiltrates.

H. influenzae is a common pathogen in adults with chronic obstructive pulmonary disease (COPD), alcoholism, malnutrition, malignancy, or diabetes. *Moraxella catarrhalis* is a gram-negative rod that can be found in patients with COPD and appears to be associated with exacerbations of chronic bronchitis much more frequently than it is associated with pneumonia.

Klebsiella pneumoniae is a rare cause of CAP, but it can cause severe pneumonia in debilitated patients with alcoholism, diabetes, or other chronic illness. *Pseudomonas aeruginosa* is also uncommon, but it can be present in patients with underlying lung disease, such as bronchiectasis or cystic fibrosis, or in patients who have recently been in a hospital or nursing home.

C. pneumoniae is a relatively common etiology of CAP, accounting for at least 8% of cases in adults; however, this is probably an underestimate because of the difficulty in diagnosing infection with this organism. Most infections in young adults cause a minor, self-limited upper-respiratory illness; radiographically evident pneumonia is more common in the elderly, in contrast to the common perception that atypical pneumonias occur in the young.

M. pneumoniae is one of the most common causes of CAP in previously healthy patients <40 years of age. It tends to be a more mild illness, with extrapulmonary manifestations such as maculopapular, vesicular, urticarial, or erythema-multiforme–type rashes and rarely pericarditis, glomerulonephritis, aseptic meningitis, and Guillain–Barré syndrome. Many patients complain of sore throat or ear pain, but the classic finding of bullous myringitis is less common and is nonspecific. *Legionella* sp is an intracellular organism that lives in aquatic environments, including tap water. There is no person-to-person transmission but outbreaks can occur due to a common water-related point-source exposure. Some patients present with a mild, self-limited atypical pneumonia, but older patients with chronic disease are at risk for more severe systemic illness. Gastrointestinal symptoms such as diarrhea are often prominent.

Winter influenza outbreaks, usually caused by influenza type A, result in an average of 20,000 deaths yearly in the United States, mostly among persons age 65 years or older (3). Cytomegalovirus (CMV) can cause pneumonia in persons with severe immunosuppression (e.g., transplant recipients). Varicella zoster virus (chickenpox) may rarely cause pneumonia; it is seen more often in adults and especially with pregnancy. Periodically, new viral pneumonia threats emerge in various parts of the world, including avian influenza strains, some with high case fatality, and novel coronaviruses. Emergency physicians should be aware of newly emerging pathogens, and screen for geographic exposures when appropriate. Up-to-date information on outbreaks can be found on the US Centers for Disease Control and Prevention (CDC) website, cdc.gov.

Although *P. jirovecii* pneumonia (PCP) does not occur in normal hosts, the possibility of opportunistic infection and unrecognized AIDS must always be considered. Many patients are unaware of their human immunodeficiency virus (HIV) status. All patients who present with pulmonary complaints should be questioned about HIV risk factors, and clinicians should search for signs of immunosuppression, such as weight loss, lymphadenopathy, and oral

thrush. PCP typically presents subacutely with fatigue, exertional dyspnea, nonproductive cough, pleuritic chest pain, and fever.

Lower-respiratory infection caused by anaerobic organisms generally results from the aspiration of oropharyngeal contents. These infections are typically polymicrobial, including many anaerobes such as *Peptostreptococcus* sp, *Bacteroides* sp, *Fusobacterium* sp, and *Prevotella* sp. Clinical factors that suggest an anaerobic infection include risk for aspiration (e.g., central nervous system depression or swallowing dysfunction), severe periodontal disease, fetid sputum, and radiographic appearance (e.g., location in posterior segment of right upper lobe or superior segment of lower lobe, lung abscess).

Fungal infections caused by organisms such as *Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides immitis* commonly present as pulmonary disease. These organisms are present in the soil in various geographic areas of the United States: *H. capsulatum* in the Mississippi and Ohio River valleys, *B. dermatitidis* in a poorly defined area extending beyond that of *H. capsulatum,* and *C. immitis* in desert areas of the Southwest. These infections should be considered in persons in appropriate geographic areas, especially those near activities that disturb the soil (e.g., construction, dirt bike riding), or those who fail to respond to antibacterial treatment. The clinical presentation ranges from an acute or chronic pneumonia to an incidental finding of asymptomatic granulomas on chest radiography.

Unusual Causes of Pneumonia

Hantaviruses have been associated with a syndrome of severe respiratory distress (hantavirus pulmonary syndrome) and shock that has occurred in persons in several areas of the United States. Infection appears to occur from inhalation of aerosols of material contaminated with rodent urine and feces. Characteristic laboratory findings include thrombocytopenia, hemoconcentration, leukocytosis, and mild elevation of hepatic transaminases. The chest radiograph demonstrates bilateral interstitial lung infiltrates that are more pronounced in dependent areas. While there is no known

effective antiviral therapy, if the patient can be adequately supported, including the use of extracorporeal membrane oxygenation (ECMO) if necessary, then recovery is usually complete.

Plague, caused by *Yersinia pestis,* is endemic in many parts of the world and has been implicated as an organism that could be used in biologic terrorism. Plague occurs in the southwestern states of the United States in persons bitten by fleas from infected rodents or carnivores. Hematogenous spread may lead to severe pneumonia that is highly contagious.

Anthrax (caused by *Bacillus anthracis*) has been used as an agent of biologic terrorism. Inhalation of anthrax spores can cause a syndrome that presents as severe sepsis with or without pneumonia and meningitis. Chest radiography may reveal a wide mediastinum caused by swelling of mediastinal nodes.

Tularemia is a febrile illness, caused by *Francisella tularensis,* that is spread by contact with body fluids of infected mammals (especially rabbits) or the bite of an infected arthropod. The illness usually begins with an ulcerated skin lesion and painful regional lymphadenopathy. Some patients have a typhoidal form, with only fever, malaise, and weight loss. Pneumonia can occur with either form.

Psittacosis is a chlamydial infection that can be spread to humans from infected birds. Illness often begins rapidly with chills, high fever, myalgias, and nonproductive cough; severe headache is often the major complaint.

Q fever is an acute febrile illness caused by the rickettsial organism *C. burnetii* that may present as pneumonia, often with severe headache. Q fever is most common in persons with occupational exposure to animals.

DIFFERENTIAL DIAGNOSIS

Cough is a very common presenting complaint; however, only a small fraction of patients presenting with cough have pneumonia. Most patients with acute cough have a viral upper-respiratory infection or bronchitis. Several noninfectious etiologies can also result in inflammatory lung processes. These include exposure to

mineral dusts (e.g., silicosis), chemical fumes (e.g., chlorine, ammonia), toxic drugs (e.g., bleomycin), radiation, thermal injury, or oxygen toxicity. Immunologic diseases such as sarcoidosis, Goodpasture syndrome, and granulomatosis with polyangiitis (GPA, previously known as Wegener's) may cause pneumonia. Tumors can mimic pneumonia radiographically or present initially as a postobstructive infection. Pulmonary emboli and infarcts must be considered in patients who present with tachypnea, hypoxia, tachycardia, or chest pain in the appropriate clinical setting. Cardiac illness often presents with respiratory complaints such as dyspnea. Aspiration of a foreign body may cause a focal pulmonary infiltrate, and should be considered in at-risk patients (e.g., toddler).

No microbial etiology can be determined in one-third to one-half of CAP cases, even after thorough investigation. To a great extent, the likely etiologies must be predicted based on epidemiologic considerations and prevalence of pathogens in research studies (Table 74.1). In general, the likelihood of *S. pneumoniae* is higher with greater severity of illness, accounting for as many as 50% of intensive care unit (ICU)-admitted and fatal cases, with CA-MRSA also now associated with severe disease. Atypical organisms such as viruses and *Mycoplasma* sp account for a relatively higher proportion of pneumonias in those who have milder illness amenable to outpatient therapy.

TABLE 74.1
Most Common Etiologies of Community-Acquired Pneumonia

Patient Type	Etiology
Outpatient	*Streptococcus pneumoniae*
	Mycoplasma pneumoniae
	Haemophilus influenzae
	Chlamydophila pneumoniae
	Respiratory viruses[a]
Inpatient (non-ICU)	*S. pneumoniae*
	M. pneumoniae
	C. pneumoniae
	Staphylococcus aureus
	H. influenzae
	Legionella sp
	Aspiration
	Respiratory viruses[a]
Inpatient (ICU)	*S. pneumoniae*
	S. aureus
	Legionella sp
	Gram-negative bacilli
	H. influenzae

ICU, intensive care unit.
[a]Influenza a and b, adenovirus, respiratory syncytial virus, and parainfluenza.
Table is adapted from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis* 2007;44(suppl 2):S27–S72.

ED EVALUATION

ED evaluation should focus on establishing the diagnosis of pneumonia, identifying host factors that will influence decisions regarding the need for hospitalization, and determining the presence of clinical features associated with specific infectious etiologies that will guide choice of antibiotics. In most healthy older children and adults, the diagnosis of pneumonia can be reasonably excluded on the basis of history and physical examination, with suspected cases further evaluated by chest radiograph. Absence of any abnormalities in vital signs or chest auscultation substantially reduces the likelihood of pneumonia. No single clinical finding is highly reliable in establishing or excluding a diagnosis of pneumonia (4).

Chest Radiography

The chest radiograph is generally the most important test to determine the presence of pneumonia. Predictive models have been developed to optimize chest x-ray use in patients with cough in whom pneumonia is suspected. Clinical findings found to be associated with radiographically confirmed pneumonia are fever, tachycardia, and tachypnea; rales or decreased breath sounds, sputum production. Absence of rhinorrhea or sore throat have also been predictive in some models. Predictive models can reduce unnecessary chest x-rays but appear to be less sensitive than physician judgment (5). Chest x-ray, because of its relatively low cost and risk, is appropriate when management will be affected by the result (e.g., hospital admission, antimicrobial use, exclusion of other diagnoses). Chest x-ray can be particularly useful in groups who often have subtle clinical signs of pneumonia, such as the elderly and those at risk for tuberculosis (TB), to quickly establish the need for isolation. Healthy adults who will receive outpatient treatment with empirical antimicrobials can have the chest radiograph deferred unless there is suspicion of immunosuppression or other unusual features of disease. Routine chest radiography for patients with exacerbation of chronic bronchitis or COPD is of low yield and can be limited to those with other signs of infection or heart failure. Computed tomography (CT) of the chest is more sensitive than plain radiography for detecting the presence of pulmonary consolidation, although the natural history of CT-positive, plain-radiograph–negative pneumonia is unclear.

Certain radiographic patterns tend to be associated with specific pathogens. In pyogenic bacterial pneumonias, radiographs usually show an area of segmental or subsegmental infiltration and air bronchograms. Lobar consolidation is present in a minority of cases of bacterial pneumonia and is often caused by pneumococcus or *Klebsiella* sp. Bronchopneumonia resulting from spread of infection along the intralobular airway causes fluffy or patchy infiltrates in the involved areas of the lung. Viruses and a wide variety of bacteria can cause this pattern, including *C. pneumoniae, M. pneumoniae, Legionella*

sp. An interstitial pattern on the chest radiograph is typically caused by *M. pneumoniae,* viruses, or *P. jirovecii.* Tiny nodules disseminated throughout both lungs represent a miliary pattern typical of granulomatous pneumonias such as due to *M. tuberculosis* or fungal infection. The location of infiltrates can also give a clue to the etiology. Aspiration pneumonia occurs in dependent areas of the lung, most commonly the superior segments of the lower lobes or the posterior segments of the upper lobes. Pneumonia produced by hematogenous spread (such as due to staphylococci) tends to be multifocal and peripheral. Apical infiltrates suggest TB. An infiltrate associated with hilar or mediastinal adenopathy suggests the presence of TB or fungal disease or pneumonia associated with a neoplasm. Cavitation is most commonly present with infections caused by anaerobes, gram-negative organisms, fungi, or *S. aureus:* Cavitation can also be present in fungal disease or TB. Pneumatoceles or spontaneous pneumothorax can be seen in AIDS patients with PCP. Pleural effusions can be seen with a wide variety of organisms, including many types of pyogenic bacterial pneumonia, *C. pneumoniae, Legionella* sp, and TB. Anaerobic infections are especially prone to the development of empyema.

However, despite these characteristic associations, radiographic presentations vary greatly among patients with a specific infection etiology and are also modified by the host response. Immunocompromised patients are particularly likely to have atypical radiographic appearances. Occasionally, patients with a clinical picture strongly suggestive of pneumonia have a normal chest radiograph. The absence of findings on the chest radiograph should not preclude the use of antimicrobial therapy in patients thought to have pneumonia on clinical grounds.

Other Tests

Patients with respiratory complaints should be screened with pulse oximetry at triage because hypoxia may not be otherwise clinically suspected and its presence has therapeutic implications (6). Severe hypoxia is an indication for hospital admission.

Most laboratory studies available in the timeframe of ED care are of limited utility in establishing the diagnosis and specific etiology of pneumonia. Although an elevated peripheral white blood cell (WBC) count can increase the likelihood of a pyogenic bacterial etiology, this finding is of limited value in making decisions regarding therapy in an individual patient and must be considered in light of other clinical and epidemiologic features (i.e., the pretest probability of various etiologies). A WBC count may be helpful if it yields evidence of immunosuppression, such as neutropenia, or if it reveals lymphopenia that may indicate immunosuppression from HIV. Serum lactate dehydrogenase (LDH) can be helpful in evaluating possible PCP in patients at risk of AIDS. Rapid HIV tests are available that can be helpful in this situation. Serum chemistry studies can be helpful in identifying patients with metabolic acidosis or renal–hepatic dysfunction associated with sepsis or with underlying disease that predicts a complicated course and influence decisions regarding disposition, choice of antimicrobial agents, and dosages. In addition, elevated lactic acid levels, even in the absence of fluid-unresponsive hypotension, can indicate the need for early and aggressive hemodynamic resuscitation. These ancillary tests are not necessary in patients with mild illness. B-type natriuretic peptide (BNP) or echocardiography can be helpful in cases in which heart failure is a consideration.

Inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein have not been demonstrated to be helpful in clinical decision-making regarding pneumonia. Procalcitonin level has been suggested as a means to assess risk of a bacterial etiology, response to antimicrobial therapy, and prognosis in pneumonia. However, its utility in the ED, such as to assess need for hospitalization or ICU admission compared to other risk-stratification systems (see below) has not been established (7).

Although a Gram stain of the sputum is often recommended as a means to identify a bacterial pathogen, the use of the Gram stain as a basis for empiric therapy in the ED can be problematic due to difficulty obtaining an adequate sputum specimen and infection control hazards associated with sputum induction. Moreover,

correlation between pneumococcal identification on Gram stain and by sputum culture is poor even with an adequate specimen, and Gram stain is even less likely to demonstrate gram-negative pathogens. If sputum Gram stain and culture are considered, they should be reserved for the subset of patients with more serious illness (e.g., admitted to the ICU), in whom the bacteriologic diagnosis is highly uncertain, and for whom it is felt that the outcome may be most dependent on optimal antimicrobial therapy. For example, in the ED, those patients with pneumonia and respiratory failure requiring intubation should have endotracheal suction specimens obtained. Patients with a pleural effusion should have a diagnostic thoracentesis performed, with fluid sent for cell count, differential, pH (pH <7.2 is predictive of a need for chest tube), Gram stain, and culture. Although it is preferred to obtain pleural fluid specimen as early as possible, because of time constraints it is not always possible to perform diagnostic thoracentesis in every patient with pleural effusion in the ED. For most patients, thoracentesis can be safely deferred until after hospital admission. However, patients in significant respiratory distress or with evidence of tension and mediastinal shift require emergent therapeutic thoracentesis.

The utility of routine blood cultures is questionable because studies of nonimmunocompromised adults with pneumonia have demonstrated a low prevalence of noncontaminant bacteremia, and management is rarely changed based on the results (8–10). The follow-up of false-positive blood cultures can be costly, labor intensive, and may lead to unnecessary use of antibiotics such as vancomycin or linezolid when results are initially reported as gram-positive cocci. Blood cultures should be obtained from immunocompromised patients, those with severe sepsis or shock, or those with risk factors for endovascular infection (e.g., prosthetic valves or IV drug use). When cultures are drawn, they should be obtained prior to the initiation of antibiotics (although antibiotics should not be delayed for this reason).

Serologic tests are available for the diagnosis of a number of organisms, including *C. pneumoniae, Legionella* sp, and fungi. Serologic tests to determine the etiology of pneumonia may be

helpful retrospectively, but both acute and convalescent serum titers are usually required; therefore, they are of little use to the emergency physician. Urine-antigen tests for organisms such as *S. pneumoniae* and *Legionella* sp can give results quickly. Rapid diagnostic tests for viral antigens are available for several viruses, including RSV and influenza. These tests may be useful for infection-control decisions in hospitalized patients and may provide an indication for influenza therapy. In the future, rapid testing using technology such as the polymerase chain reaction may provide emergency physicians with a reliable method for determining the specific etiology of pneumonia.

KEY TESTING

- Chest radiograph
- Pulse oximetry
- For seriously ill patients:
  - Blood culture
  - Serum lactate level
  - Complete blood count
  - Chemistry profile
  - Blood and sputum culture

ED MANAGEMENT

Initial attention should focus on ensuring adequate ventilation, oxygenation, and perfusion. Hypoxic patients with pneumonia should receive supplemental oxygen. Those patients with severe respiratory compromise may require endotracheal intubation. Patients with underlying asthma or COPD who present with wheezing may benefit from bronchodilator therapy. Seriously ill patients who present with volume depletion or septic shock will require fluid resuscitation and may require more intensive management with vasopressors, transfusion, and inotropic agents as part of sepsis resuscitation (11).

It is usually necessary to begin empiric antimicrobial therapy for pneumonia before a definite microbiologic etiology is established.

Antimicrobials should be started in the ED for patients who are being admitted to the hospital: deferring treatment until arrival on the ward can cause significant delays. Timely administration of antimicrobials has been associated with improved outcomes for hospitalized pneumonia patients (12). However, a rush to treatment without a diagnosis of pneumonia can result in inappropriate antibiotic use.

The antibiotics chosen must provide coverage of the likely etiologies based on clinical, laboratory, radiologic, and epidemiologic information. Though care must be taken not to miss possibly dangerous pathogens, the regimen should be as selective as possible to avoid problems with drug toxicity, promotion of antimicrobial resistance, and excessive cost.

The prevalence of drug-resistant *S. pneumoniae* (DRSP) has increased steadily in recent years. In most areas of the United States, high-level penicillin resistance occurs in approximately 15% to 20% of outpatient pneumococcal sputum isolates. Isolates that are resistant to penicillin are often also resistant to other β-lactams as well as macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP/SMX). Most remain susceptible to third-generation cephalosporins such as ceftriaxone. Extended-spectrum fluoroquinolones such as levofloxacin and moxifloxacin have activity against DRSP as well as other typical and atypical organisms that commonly cause pneumonia and may offer additional alternatives to vancomycin if DRSP is a concern. However, it is not clear that in vitro resistance is related to adverse clinical outcome. Most cephalosporins and macrolides will achieve adequate levels in serum and tissues to successfully treat *S. pneumoniae* respiratory tract infections, even if the laboratory reports that the organism is resistant.

CA-MRSA has rapidly emerged as the most common pathogen isolated in community-acquired skin and soft-tissue infections and is also increasingly recognized as a cause of severe, rapidly progressing pneumonia with sepsis, often in children or healthy young adults. Antimicrobials with consistent in vitro activity against CA-MRSA isolates include vancomycin, ceftaroline, TMP/SMX, and linezolid.

Although vancomycin is used most often for suspected or documented MRSA infections, vancomycin may be losing efficacy, at least as based on increasing minimum inhibitory concentrations (MICs) observed during the last few years. Daptomycin is active against CA-MRSA but is inactivated by pulmonary surfactant, so is inappropriate for pneumonia. Although it is not necessary to provide empiric coverage of MRSA for all pneumonia cases, it should be strongly considered for patients with severe pneumonia associated with sepsis, especially those with concurrent influenza, contact with someone infected with MRSA, or radiographic evidence of necrotizing pneumonia (13).

Guidelines have been issued for empirical antibiotics for patients with CAP (14). For patients whose illness is severe enough to require hospital admission and parenteral antibiotics, options include a combination of a third-generation cephalosporin and a macrolide (e.g., IV or oral azithromycin) or an extended-spectrum fluoroquinolone alone. These regimens will treat the most common bacterial pathogens, such as *S. pneumoniae,* methicillin-susceptible *S. aureus, H. influenzae,* and atypical pathogens such as *Mycoplasma* sp, *Chlamydophila* sp, and *Legionella* sp. A regimen with activity against atypical pathogens (e.g., macrolide) is recommended in guidelines, but studies have not clearly demonstrated better outcomes in hospitalized patients compared to regimens without atypical activity (15). If anaerobic organisms are suspected (e.g., with aspiration), clindamycin or metronidazole could be added to the regimen, or a β-lactam–β-lactamase-inhibitor antibiotic such as ampicillin-sulbactam or piperacillin-tazobactam could be used. Moxifloxacin is also active against anaerobes.

Severely ill and compromised patients are at relatively greater risk of infection caused by *S. pneumoniae, S. aureus* including MRSA, aerobic gram-negative bacilli, and, in some areas, *Legionella* sp. Because antimicrobial resistance is more likely to impact the outcome in these patients, it is important to include agents with activity against DRSP and CA-MRSA. Appropriate empirical therapy could include a combination of a third-generation cephalosporin or a β-lactam–β-lactamase-inhibitor antibiotic plus vancomycin, plus a

fluoroquinolone. Outcomes with severe pneumonia appear to be better with combination therapy when compared with a single agent such as a fluoroquinolone alone (16,17).

Healthcare-associated pneumonia (HCAP) characterizes patients in nursing homes or other extended-care facilities who are at increased risk for infection with resistant organisms such as *P. aeruginosa, K. pneumoniae* (including strains producing extended spectrum β-lactamases [ESBL]), *Acinetobacter* sp, and hospital-associated strains of MRSA (18). Other risk factors for infection with multidrug-resistant pathogens include (a) hospitalization for 2 or more days in an acute-care facility within 90 days of infection; (b) patients who attended a hemodialysis clinic; and (c) those who received IV antibiotic therapy, chemotherapy, or wound care within 30 days of infection. It is therefore appropriate to give broader-spectrum empiric therapy to patients with HCAP, usually with a combination of antimicrobials to increase the chance that at least one antibiotic will be active against the causative pathogen. Appropriate combinations would include an antipseudomonal β-lactam agent such as piperacillin/tazobactam, cefepime, imipenem, or meropenem combined with either an aminoglycoside or a fluoroquinolone, and vancomycin or linezolid to cover for MRSA (19).

Studies of antiviral agents for influenza have generally focused on uncomplicated cases in which benefit appears to be limited to patients treated within 48 hours of symptom onset. Arrival treatment may also benefit patients hospitalized with influenza or bacterial complications of influenza. If influenza is suspected (or confirmed by testing), empirical antiviral treatment should be considered, based on clinical judgment, for patients with severe or progressive illness. These would include those with pneumonia, as well as those with the following: age <5 (particularly <2) and ≥ 65 years, chronic comorbidities, immunosuppression, pregnancy or within 2 weeks post-partum, age ≤ 18 years on chronic aspirin treatment, long-term care facility residence, morbid obesity (BMI ≥ 40), or hospitalization (3). Neuraminidase inhibitors such as oseltamivir are a better choice than amantadine and rimantadine, because they are active against influenza A and B and because many circulating strains are resistant

to these older agents (3). Zanamavir is given by inhalation and is not recommended for patients with underlying reactive airway disease because it can induce bronchospasm.

For patients with AIDS, it is important to treat *P. jirovecii* and bacterial pathogens such as *S. pneumoniae.* TMP/SMX is the treatment of choice: the usual regimen is 20 mg/kg of TMP and 100 mg/kg of SMX in four divided doses (3 amps IV q6h for most adults) to be continued for 21 days. For patients allergic to sulfa, pentamidine can be given in a dose of 4 mg/kg throughout 1 hour. Because pentamidine has no activity against *S. pneumoniae* or other bacterial pathogens, it is important to add a cephalosporin or other antibacterial agent to the initial empiric regimen. Other options include clindamycin 600 mg IV q8h plus primaquine 30 mg po daily or TMP plus dapsone, atovaquone, or trimetrexate. The addition of steroids (prednisone 40 mg PO bid) has been shown to reduce mortality and clinical deterioration in patients with Pa_{O_2} $<$70 mm Hg or A-a gradient $>$35 mm Hg.

Outpatient Management

Appropriate agents for outpatient treatment of adults include macrolides (erythromycin, clarithromycin, azithromycin), respiratory fluoroquinolones such as levofloxacin or moxifloxacin, or doxycycline. Alternative options that would be appropriate in those patients with a higher likelihood of a "typical" bacterial etiology include amoxicillin-clavulanate or an oral cephalosporin such as cefdinir, cefpodoxime, or cefprozil. These β-lactam agents do not have activity against atypical pathogens. In patients properly identified as low risk for complications, use of a macrolide or doxycycline is reasonable, even when there is concern about DRSP. Use of more expensive and more broad-spectrum agents, such as respiratory fluoroquinolones, may be justified based on convenience, avoidance of side effects and drug interactions, or concern about DRSP in patients with a higher likelihood of bacterial etiology. Some agents, including azithromycin and levofloxacin (750 mg daily), can be given as a 5-day course. Use of ampicillin or amoxicillin is not

generally recommended because of the high incidence of β-lactamase production in pneumonia pathogens, although these have been used successfully in higher doses (e.g., amoxicillin 1 g tid) in other conditions with a high prevalence of DRSP. TMP/SMX has also been largely abandoned for treatment of pneumonia because of increasing resistance. Except for the administration of fluoroquinolones, these recommendations also apply to school-aged children and adolescents, in whom *Mycoplasma* sp is common.

Many EDs initiate outpatient therapy in moderately ill patients who previously might have been hospitalized with an initial parenteral dose of a long-acting antibiotic such as ceftriaxone and employ extended observation (i.e., 12 to 24 hours) while administering supportive care such as hydration, antipyretics, and bronchodilators before discharge on an oral regimen. Certain patients may also be brought back to the ED for follow-up in 24 hours and receive a second parenteral or observed oral dose of antibiotics. Extended-spectrum fluoroquinolones are another option that may be employed in this strategy, and they have additional activity against atypical pathogens and DRSP. Oral administration of these agents results in blood and tissue levels similar to those with IV therapy, provided that intestinal absorption is normal.

Empiric therapy for pneumonia is summarized in Table 74.2.

TABLE 74.2
Empiric Therapy for Pneumonia

Clinical Setting	Antibiotic Regimen	Comments
Parenteral Regimens		
Community-acquired, nonimmuno-compromised	Ceftriaxone 1 g q24h + azithromycin 500 mg q24h IV or PO	Could substitute cefotaxime, ceftaroline, or ertapenem for ceftriaxone
	Respiratory fluoroquinolone (levofloxacin 750 mg IV q24h or moxifloxacin 400 mg IV q24h)	Treats most common bacterial and atypical pathogens. Active vs. DRSP
Severe pneumonia ICU	Ceftriaxone 1 g IV q24h + levofloxacin 750 mg IV q24h + vancomycin 1 g IV q12h	Can substitute cefotaxime, cefepime, ertapenem or β-lactam–β-lactamase inhibitor for ceftriaxone. Can substitute moxifloxacin for levofloxacin. Can substitute linezolid for vancomycin
Severe pneumonia with neutropenia, bronchiectasis, or recent hospitalization (risk for *Pseudomonas* sp)	Cefepime 2 g IV q12h + ciprofloxacin 500 mg IV q12h + vancomycin 1 g IV q12h	Can substitute other antipseudomonal β-lactam such as piperacillin-tazobactam, imipenem, or meropenem for cefepime. Can substitute aminoglycoside plus macrolide for ciprofloxacin
Presumed pneumocystis pneumonia	TMP/SMX 160/800 mg IV q6h	Add ceftriaxone to TMP/SMX if severe, until PCP confirmed. Alternatives for sulfa allergy include pentamidine + third-generation cephalosporin; clindamycin + primaquine; atovaquone + ceftriaxone
Oral Regimens		
Previously healthy, no antimicrobials in last 3 mos	Doxycycline 100 mg PO bid	Preferred for adolescent/young adult when likelihood of mycoplasma is high; variable activity vs. *S. pneumoniae*
	Azithromycin	Treats common typical bacterial and atypical pathogens. Variety of dosing regimens: 500 mg once followed by 250 mg daily for 4 d; 500 mg PO daily for 3 d; 2 g PO extended release suspension once. Can substitute clarithromycin
Comorbidities or antimicrobials in last 3 mos	Levofloxacin 750 mg PO daily for 5 d	Can substitute moxifloxacin. Treats common typical and atypical bacterial pathogens; active vs. DRSP. Use if recently received β-lactam or macrolide
	Cefpodoxime 200 mg PO bid + azithromycin 500 mg PO daily	Use if recently received fluoroquinolones. Can substitute cefdinir, cefprozil, or amoxicillin/clavulanate for cefpodoxime. Variable activity against DRSP

Doses are for 70 kg adult with normal renal and hepatic functions.
IV, intravenous; PO, by mouth; DRSP, drug-resistant *S. pneumoniae;* TMP/SMX, trimethoprim-sulfamethoxazole; PCP, *P. jirovecii* pneumonia.

CRITICAL INTERVENTIONS

- Obtain blood cultures from immunocompromised patients, those with severe sepsis or shock, or those with risk factors for endovascular infection (e.g., prosthetic valves or IV drug use).
- Initiate antimicrobials in the ED for patients who are being admitted to the hospital.
- Isolate patients who may be infected with organisms that could put hospital staff and other patients at risk, such as TB or influenza.

DISPOSITION

Disposition of patients with pneumonia is dictated by the patient's underlying medical conditions, severity of illness, likelihood of clinical deterioration, and feasibility of home care and outpatient follow-up. Outpatient treatment is 15 to 20 times less expensive than inpatient treatment, and most patients prefer the home environment. There is tremendous variability in physician admission decisions for pneumonia (20). The more common tendency is overestimation of disease severity, leading to hospitalization of patients at low risk for death or serious complications. The decision to hospitalize for

pneumonia does not necessarily commit the patient to a prolonged inpatient stay. Twelve- to 24-hour ED or hospital-ward observation may allow the early discharge of certain moderate-risk patients.

Scoring systems have been developed to assist with decisions regarding hospitalization for pneumonia. One commonly used system is based on the Pneumonia Patient Outcomes Research Team (PORT) study, a prospectively validated predictive rule for mortality among immunocompetent adults with CAP (21), also known as the pneumonia severity index, or PSI. This is a two-step approach to assess risk. Patients in the lowest-risk class may not need testing and can be treated as outpatients. These patients include those younger than age 50 years, without significant comorbid conditions (neoplasm, congestive heart failure, cerebrovascular disease, renal disease, liver disease, or HIV), and without the following findings on physical examination: altered mental status, pulse $\geq$125 beats/min, respiratory rate $\geq$30 breaths/min, systolic blood pressure $<$90 mm Hg, and temperature $<$35°C or $\geq$40°C. Patients who do not fit the lowest-risk category are classified into categories based on a scoring system that accounts for age, comorbid illness, physical examination findings, and laboratory abnormalities (Table 74.3). Hospitalization is recommended for those with a score $>$91 (class IV–V), and brief admission or observation may be considered for those with a score of 71 to 90 (class III).

TABLE 74.3
Pneumonia Severity Index: Scoring System for Pneumonia Mortality Prediction

Patient Characteristics	Points
Demographic factor	
Age	
Male	Years of age
Female	Years of age-10
Nursing home resident	10
Comorbid illness	
Neoplastic disease	30
Liver disease	20
Congestive heart failure	10
Cerebrovascular disease	10
Renal disease	10
Physical examination findings	
Altered mental status	20
Respiratory rate >30 breaths/min	20
Systolic blood pressure <90 mm Hg	20
Temperature <35°C or >40°C	15
Pulse >125 beats/min	10
Laboratory or radiographic findings	
Arterial pH <7.35	30
Blood urea nitrogen >30 mg/dL	20
Sodium <130 mEq/L	20
Glucose >250 mg/dL	10
Hematocrit <30%	10
Arterial P_{O_2} <60 mm Hg	10
Pleural effusion	10

Table is adapted from Bartlett JG, Dowell SF, Mandell LA, et al. Practice guidelines for the management of community-acquired pneumonia in adults. Infectious Diseases Society of America. *Clin Infect Dis.* 2000;31(2):347–382.

Although this method of assessing the likelihood of successful outpatient management is helpful in establishing general guidelines, it can be cumbersome to use, has not been modeled to predict acute life-threatening events, does not take into account dynamic evaluation over time, and has many important exceptions (e.g., an otherwise low-risk patient with severe hypoxia would be discharged by its strict interpretation). Additional discharge criteria could include improving and stable vital signs during a several hour observation period, ability to take oral medications, an ambulatory

pulse oximetry >90%, home support, and ability to follow-up. A study in which physicians were taught this system and provided the patient's risk score revealed a significantly lower overall admission rate, cost savings, and similar quality-of-life scores compared to patients conventionally managed by their physicians (22).

A simpler tool is the CURB-65 rule (23). This rule uses only five simple criteria to identify patients at lower risk for adverse events: confusion, uremia (blood urea nitrogen [BUN] ≥20 mg/dL), respiratory rate ≥30, blood pressure <90 systolic or ≤60 diastolic, and age 65 years or greater. The risk of 30-day mortality increases with a greater number of these factors present: 0.7% with no factors, 9.2% with two factors, and 57% with five factors. It is recommended that patients with zero to one feature can receive outpatient care, those with two should be admitted, and ICU-level care should be considered for those with three or more. No randomized trials of hospital-admission strategies have directly compared the PSI to the CURB-65 score. In a comparison of scores in the same population of CAP patients, the PSI gave a slightly higher percentage of patients in the low-risk category, with a similar low mortality rate (24). Most emergency physicians do not routinely use these scoring systems for admission decisions (20).

In some cases it is obvious that ICU admission is indicated, including those patients who are intubated or require vasopressors for hemodynamic stabilization. It is more difficult to identify those patients who do not require these interventions initially but may be at greater risk for deterioration. Objective criteria using the PSI (class V) and CURB-65 have been proposed but have not been prospectively validated for the ICU-admission decision (14). ICU admission may be indicated for patients with signs of more serious infection such as severe hypoxia, confusion, multilobar infiltrates, or the need for aggressive fluid resuscitation. Another ICU risk-stratification score is abbreviated SMART COP; intensive respiratory or vasodepressor support was predicted by several clinical features (Table 74.4). A SMART-COP score of ≥3 points identified 92% of patients who received intensive respiratory or vasodepressor support,

including 84% of patients who did not need immediate admission to the ICU (25).

TABLE 74.4
SMARTCOP Scoring System for ICU Admission Decision

Clinical Feature	Points Assigned
Systolic blood pressure <90 mm Hg	2
Multilobar infiltrates	1
Albumin <3.5 mg/dL	1
Respiratory rate (age ≤50, 25/m; >50, 30/m)	1
Tachy ≥125/min	1
Confusion (new)	1
Oxygen saturation (age≤50 <93%; >50 <90%)	2
pH <7.3	2
Score Interpretation	
≥7 points	Very high risk of needing ICU (2 in 3)
5–6 points	High risk of needing ICU (1 in 3)
3–4 points	Moderate risk of needing ICU (1 in 8)
≤2 points	Low risk of needing ICU

Table is adapted from Charles PG, Wolfe R, Whitby M, et al. SMART-COP: A tool for predicting the need for intensive respiratory or vasopressor support in community-acquired pneumonia. *Clin Infect Dis.* 2008;47:375–384.

Most patients with CAP do not need respiratory isolation. Those patients who are suspected of having an etiology of pneumonia that could pose a threat of transmission to other patients (e.g., influenza, varicella, TB, plague) should be isolated. Persons with fever and respiratory symptoms who have been in an area with possible exposure to agents such as avian influenza or coronavirus should be immediately isolated. Frequent hand washing and use of masks to prevent droplet exposure are also helpful to prevent transmission of pathogens. Neutropenic patients are generally placed in reverse isolation. HIV-infected patients who present with any form of pneumonia should be considered for isolation until TB can be ruled out by sputum acid-fast bacillus (AFB) smears, because delayed diagnosis of TB in these patients is a well-recognized cause of

nosocomial TB outbreaks. The chest radiograph cannot be relied on to rule out TB in AIDS patients because it often does not have the typical appearance of TB or is negative. Isolation should be strongly considered for others at high risk for TB, such as inner-city homeless persons or IV drug users.

Common Pitfalls

- Delay in initiating of antibiotics for seriously ill patients.
- Failure to consider treatment of influenza.
- Failure to question patients who present with respiratory complaints about HIV risk factors.
- Failure to recognize TB and initiate respiratory isolation in a patient with HIV infection or other TB risk factors.
- Failure to ask about travel and exposure history during outbreaks of new respiratory pathogens.

CHAPTER 75 Pleural Effusion

Micelle Haydel

The visceral and parietal pleura are serous membranes that line the outer surface of the lung, mediastinum, diaphragm, and the inner surface of the thoracic wall, forming the right and left pleural spaces. Under normal homeostatic conditions, the parietal pleura secretes about 0.01 mL/kg/hr of pleural fluid which is continuously resorbed by the pleural lymphatics, maintaining a steady state of less than 10 mL in the pleural space (1). About 30% of healthy men have 3 to 5 mm of fluid visible on ultrasound, whereas 80% of women have up to 5 to 7 mm visible on MRI (2,3). A pleural effusion occurs when fluid formation increases beyond the capacity of lymphatic clearance, or when lymphatic clearance is impaired. Pleural fluid has a chemical composition similar to that of interstitial fluid, but is altered in the setting of inflammation, infection, malignancy, or trauma. Fluids that collect in the pleural space include transudative, exudative, hemorrhagic, and chylous.

CLINICAL PRESENTATION

The clinical presentation of pulmonary effusions ranges from incidental findings to life-threatening cardiopulmonary distress or sepsis. Patients with a pleural effusion often present with complaints related to the underlying disease process rather than to the pleural effusion itself. Pleural effusions are graded as small when up to 25% of the pleural cavity is involved, moderate when 25% to 50% is involved, and large when more than 50% is involved (4). Signs and symptoms in patients with pleural effusion vary based on the size

and cause of the effusion, as well as associated underlying disease processes.

- Fever: A pleural effusion caused by infection is typically associated with fever.
- Pain: Inflammation of the parietal pleura causes referred pain to the overlying chest wall, whereas irritation of the diaphragmatic pleura causes referred pain to the ipsilateral shoulder. The visceral pleura is not innervated, therefore does not cause pain.
- Cough: Lung compression with bronchial irritation can cause a nonproductive cough.
- Dyspnea: Large pleural effusions can compromise pulmonary mechanics, impair gas exchange and cause dyspnea, tachypnea, and respiratory distress. A pulmonary embolism or infarct often will cause dyspnea that is out of proportion to the associated effusion.
- Tachycardia and hypotension: A large pleural effusion can cause cardiac collapse during diastole, physiologically mimicking cardiac tamponade.
- Weight loss: The review of systems often reveals unexplained weight loss in patients with tuberculosis, malignancy, and HIV.
- Ascites: Cirrhosis, ovarian cancer, and Meigs syndrome are associated with ascites.
- Size: The size of an effusion can suggest its etiology. Large or massive effusions are associated with malignancy, but can also be found in tuberculosis and bacterial parapneumonic effusions.
- Laterality: Most bilateral effusions are caused by a transudative process, such as heart failure, renal or hepatic failure, or low protein states. Bilateral effusions are rarely seen in malignancy, pulmonary embolism, and rheumatoid arthritis. When bilateral effusions are of unequal size, more than one etiology should be suspected.

DIFFERENTIAL DIAGNOSIS

Pleural effusions are quite common, diagnosed in over 1 million patients each year in the United States (5). Over 50 etiologies are known, and in the United States the most common causes are heart

failure, pneumonia, malignancy, and pulmonary embolism (6). In children, pneumonia is the most common cause of pulmonary effusion. The medical history and symptoms (or lack thereof) can be very helpful in developing a differential diagnosis and management plan. The most common causes of pleural effusions include the following.

- Congestive heart failure: Over 80% of patients with decompensated CHF have some degree of bilateral or unilateral transudative pleural effusions due to elevated pulmonary capillary pressure (7,8).
- Pneumonia: About 40% of patients with bacterial pneumonia have an exudative pleural effusion, known as a parapneumonic effusion. Most are uncomplicated and resolve with antibiotic therapy, but about 1% progress to an empyema with the potential for rind formation and constrictive pleuritis (9). Parapneumonic effusions are further classified in Table 75.1.

TABLE 75.1
Stages of Parapneumonic Effusion

Stages	Clinical Course	Macroscopic	Cell Count and Chemistry of Fluid	Treatment
Uncomplicated	Improves with antibiotics	Small, sterile, free-flowing, clear to slightly cloudy fluid	LDH <200, pH >7.2 glucose >60 mg/dL WBC count <1,000 No bacteria	Antibiotics and monitor for resolution
Fibropurulent	Fails antibiotics, fever, sepsis	Cloudy to frank pus; fibrin sheets causing loculations	LDH >200, pH <7.0, glucose <40 mg/dL WBC >50,000 Bacteria invasion	Antibiotics and chest tube
Organization	Fever, sepsis Fibroblasts restrict lung movement	Inelastic, fibrous peel in pleura space	As above, plus fibroblastic invasion with fibrin deposition	Antibiotics and surgery

- Malignancy: Patients with malignant effusions typically present with a complaint of dyspnea or chest pain. Malignant cells in a pleural effusion imply disseminated disease and a reduced life-expectancy. Malignant effusions tend to recur within a month of being drained, with lung and breast cancer accounting for ~60% of malignant effusions (10). Paramalignant effusions are caused by lymphatic obstruction, superior vena cava syndrome, or postobstructive atelectasis; but do not involve pleural metastasis (11). Malignant effusions can be hemorrhagic or chylous (lymphoma).

- Pulmonary embolism: One-third to one-half of patients with pulmonary embolism have a small, unilateral, frequently hemorrhagic, exudative effusion (12). Dyspnea is typically out of proportion to the size of the effusion, and the presence of pleuritic pain and a pleural effusion is suggestive of pulmonary embolism (6,13).

Less common causes of pulmonary effusions are very diverse, but the past medical history and physical examination can offer important diagnostic clues and include the following.

- Tuberculosis: In the United States about 5% of patients with tuberculosis have plural effusions, but in countries with a higher prevalence of tuberculosis, TB is often the primary cause of pulmonary effusions (14).
- HIV: Pulmonary effusions are frequently found in hospitalized patients with HIV, most commonly due to infections (including tuberculosis) and malignancy (lymphoma and Kaposi) (15). Parapneumonic effusions in patients with HIV are caused by the bacteria encountered in the general population, as well as *Mycobacterium, Pneumocystis, Cryptococcus,* and *Histoplasmosis.*
- Cirrhosis, ascites, and peritoneal dialysis are all associated with transudative pleural effusions due to the imbalance of pleural oncotic and hydrostatic forces.
- Nephrotic syndrome can cause a transudative pleural effusion, but the associated hypercoagulable state also predisposes to pulmonary embolism.
- Trauma and postsurgical: While small left-sided pleural effusions are expected in the first week post-CABG, up to 10% of patients will develop moderate to large or persistent effusions (16). Large pleural effusions develop after a complete pneumonectomy. Potentially lethal causes of pleural effusions include hemothorax and ruptured esophagus.
- Disruption of the thoracic duct (due to trauma or malignancy) causes a chylous effusion due to fatty acids that give lymphatic fluid a milky appearance.
- Autoimmune diseases such as lupus, rheumatoid arthritis, and sarcoidosis are rare causes of pleural effusions.

- Drug induced: Numerous medications have been associated with a pleural effusion. Most resolve with cessation of the culprit drug, but some continue long after the medication has been stopped. The most common drugs associated with pleural effusion are methotrexate, phenytoin, nitrofurantoin, β-blockers, and amiodarone (6). Procainamide and hydralazine can cause lupus syndrome with effusions. Ovarian hyperstimulation syndrome secondary to infertility treatments can cause pulmonary effusions.
- Sympathetic effusion: Virtually any abdominal infection or inflammatory process can alter the surrounding capillary permeability leading to an effusion. Examples include pancreatitis, hepatitis, cholecystitis, hepatic amebiasis, splenic abscess, pyelonephritis, glomerulonephritis, peritonitis, pelvic inflammatory disease, and abdominal abscess.

ED EVALUATION

The physical examination of a patient with a pleural effusion can be benign or markedly abnormal, depending on the size of the effusion. As the pleural space fills with fluid, the involved cavity increases in total volume while the lung parenchymal volume decreases. The chest may be visibly asymmetrical with bulging or retraction of the intercostal spaces, and tracheal deviation. The cardiac apical pulse may be displaced due to a shift in the heart's location due to fluid accumulation. Diminished breath sounds and/or a pleural rub may be appreciated. Dullness to percussion and tactile fremitus are the most useful physical examination signs of pulmonary effusion (17). The change in the sound of percussion can identify the upper limit of a pleural effusion.

Upright posteroanterior (PA) and lateral chest radiographs should be part of the initial evaluation of the patient with suspected pleural effusion. The subpulmonic space is the most dependent area of the diaphragm below the lungs where effusions initially collect. Easily mistaken for an elevated hemidiaphragm, a 25- to 50-mL subpulmonic effusion is seen as a shifting of the peak of the right diaphragm laterally (see arrow in Fig. 75.1) or an increased distance

between gastric bubble and left lobe lung on upright PA chest film. Blunting of the costophrenic angles can be seen on the lateral film when more than 50 mL of fluid has collected, and can be seen on the PA film when more than 150 mL has collected. A meniscus can typically be seen on the PA film when 200 mL has collected, and when 500 mL has collected the diaphragm is obscured (18). Lateral decubitus films (Fig. 75.2) are useful to determine layering of the fluid, and a dependent fluid layer more than 10 mm thick is considered significant.

FIGURE 75.1 Subpulmonic effusion. Note (arrow) shifting of the peak of the diaphragm laterally. (From Crapo JD, MD, Glassroth J, MD, Karlinsky JB, MD, MBA, et al. *Baum's Textbook of Pulmonary Diseases*. 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

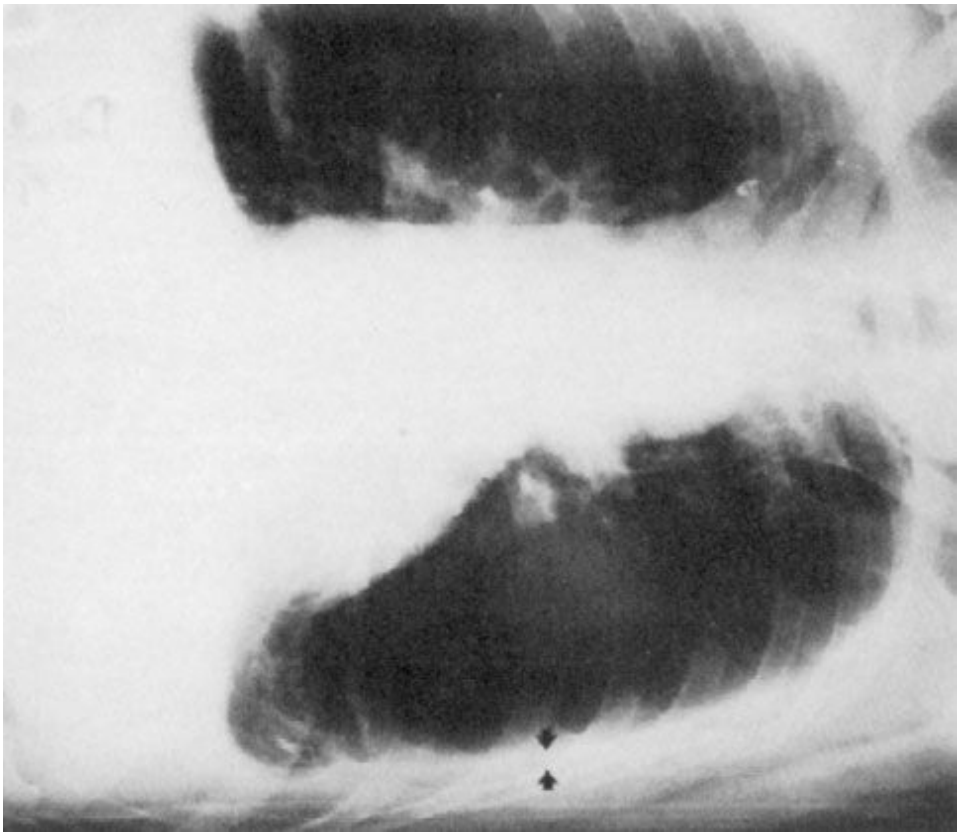

FIGURE 75.2 Lateral decubitus film showing layering out of effusion. Courtesy of LifeArt 2014.

Ultrasonography has been shown to have better sensitivity than plain radiographs in identifying effusions, especially in the setting of small effusions or loculations (1). With a 5- to 10-MHz linear transducer and the patient supine or upright, the hemidiaphragms are visualized just above the liver and spleen. As shown in Figure 75.3, fluid is demonstrated above the diaphragm and between the kidney and liver. The normal pleural space appears as a black line <0.5 mm thick between the two pleural (white) lines which appears to glide during respiration. A pleural effusion is seen as an echo-free (black) space which may change in size with respiration. The volume of the effusion (in milliliters) can be estimated using the following equation: (mL $=$ 16 $\times$ D), where D (depth) is the maximum size of effusion measured from parietal to visceral pleura in millimeters (19). If the effusion is large, the lung size is reduced and is seen as a free-floating hyperechoic/white area within the effusion. If the

effusion is organized or loculated, the septa will appear hyperechoic (white) within the effusion.

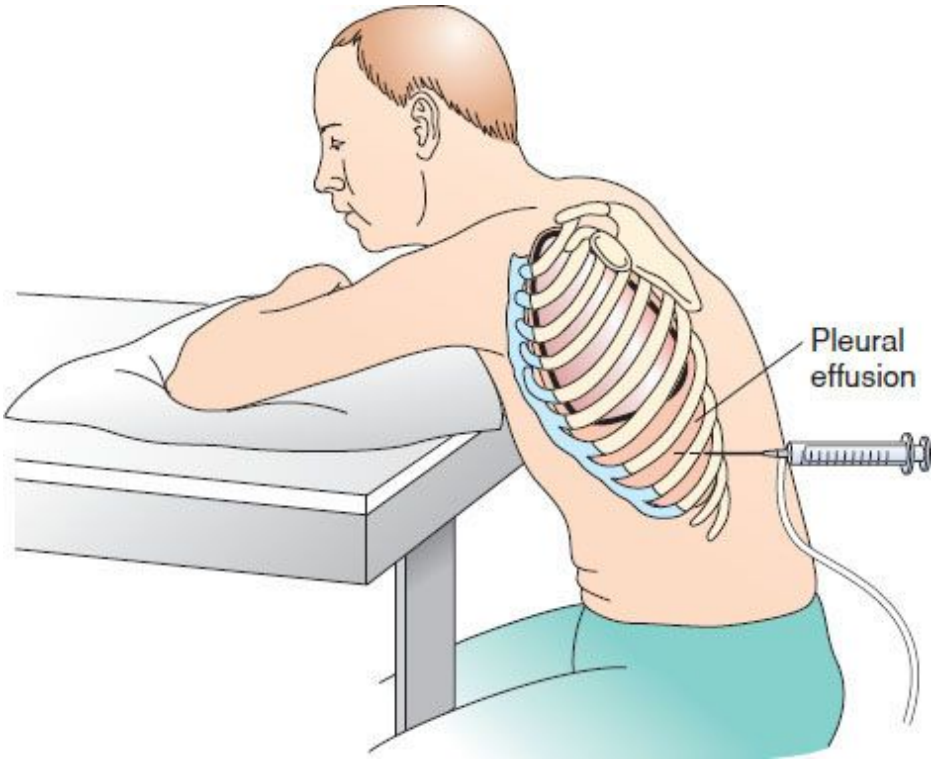

FIGURE 75.4 Position for patient undergoing thoracentesis. From Smeltzer SC, Bare BG, Hinkle JL, et al. *Brunner & Suddarth's Textbook of Medical Surgical Nursing*. 11th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.

Computed tomography (CT) is indicated for suspected pulmonary embolism, malignancy, or ambiguous parenchymal findings on plain films.

KEY TESTING

- CXR—upright PA and lateral films should be initial evaluation. Perform lateral decubitus if cannot obtain upright CXR or to check if effusion layers out.
- Ultrasound—better sensitivity than plain radiographs to identify effusions and useful in small or loculated effusions.
- CT—indicated for suspected pulmonary embolism, malignancy, or ambiguous parenchymal findings on CXR.

ED MANAGEMENT

Once a pleural effusion is identified in an ED patient, the management involves the following four key considerations.

1. Is the effusion most likely transudative? Most transudative effusions (CHF, low protein states, ascites, peritoneal dialysis) can be identified based on the history and physical examination alone, and do not require intervention unless the presentation is atypical and/or does not respond to appropriate therapy.
2. Are antibiotics indicated? Antibiotics should be initiated early in the setting of parapneumonic effusions, and selection should be based on the source (community- vs. hospital-acquired pneumonia) and severity of illness.
3. Is an ED thoracentesis indicated? Indications for emergent thoracentesis include symptomatic large effusions or sepsis with suspected empyema. Small (<10 mm), free-flowing parapneumonic effusions do not require thoracentesis, unless the patient is septic or fails to respond to appropriate antibiotics (20). Pleural effusion in the setting of pulmonary embolism, or medication-related effusions that resolve with cessation of the offending medication do not require thoracentesis.
4. Is a chest tube indicated? Chest tubes are indicated in patients with frank pus or an infected effusion with a pH <7.20. Chest tubes are also indicated in patients with large or symptomatic pneumothorax after thoracentesis.

Thoracentesis

Contraindications to thoracentesis are generally relative. An INR >2 or platelets <25,000 represent relative contraindications to thoracentesis, while the decision to give platelets, clotting factors, or fibrinogen should be made on an individual basis (21). A technically difficult thoracentesis, or one with higher risk of complications, should be expected in the setting of mechanical ventilation, a loculated effusion, congenital or acquired diaphragmatic structural abnormality, bleb disease or scarring from past disease or trauma. Thoracentesis in the settings of both very small and very large effusions have a higher risk of complications. If a difficult thoracentesis is anticipated, consultation with an invasive radiologist

or pulmonologist may be the most appropriate course of action. Bedside ultrasound increases the yield, reduces the complication rate, and should be used if available (22). The following steps outline the thoracentesis procedure.

1. After informed consent, the patient should be upright, leaning forward on a raised bedside table, as shown in Figure 75.4. The lateral decubitus position may be used if the patient cannot tolerate sitting.
2. Using a bedside ultrasound, mark the location of the effusion and the area to be punctured. The diaphragm excursion should be marked at full inspiration and expiration to avoid puncturing.
3. The puncture site should be 8 to 10 cm lateral to the midline, toward the posterior axillary line, typically in the seventh to ninth intercostal space, one to two interspaces below the fluid level, and above the diaphragm marks.
4. After sterile preparation of the aspiration site, local anesthesia is injected.
5. Using Seldinger technique, a small-gauge catheter covered needle is inserted over the superior margin of the rib avoiding the intercostal vessels.
6. The catheter is advanced into the chest, and a maximum of 1,500 mL of fluid should be removed.
7. A postprocedural chest radiograph or ultrasound should be obtained to rule out iatrogenic pneumothorax. While a small amount of air entering the pleural cavity during thoracentesis leads to a clinically insignificant pneumothorax, inadvertent puncture of the lung parenchyma can lead to a large and/or symptomatic pneumothorax which may require a chest tube (23). Less common complications of thoracentesis include hemothorax, hemoperitoneum, shearing of the catheter tip, and infection.
8. Trapped lung due to malignancy or pleural inflammation should be suspected when the lung remains unexpanded despite adequate thoracentesis. If symptomatic, a chest tube and/or surgical consult will be indicated.

TABLE 75.2
Etiology of Pleural Effusions

Transudate	Exudate
Common Causes	

• Congestive heart failure
• Cirrhosis
• Renal:
  • Nephrotic syndrome
  • Glomerulonephritis
  • Peritoneal dialysis
	• Parapneumonic effusion:
	  • Bacterial
	  • Viral
	  • Tuberculosis
	• Malignancy: Metastatic, lymphoma, leukemia, and mesothelioma
	• Pulmonary embolism

Less Common Causes	

• Other low protein states
• CSF leak after spinal surgery or ventriculopleural shunt
• Atelectasis due to increased negative pressure
• Urinothorax due to obstructive uropathy
	• Infection
	  • Fungal or parasitic
	  • Hepatic or splenic abscess
	• Trauma or surgical
	  • Post cardiac surgery
	  • Traumatic hemothorax
	  • Esophageal rupture/Boerhaave's
	• Drug-induced
	• Collagen vascular disease
	  • Rheumatoid arthritis
	  • Systemic lupus erythematosus
	  • Sarcoidosis
	• Uremia
	• Chylothorax : Traumatic injury or malignancy
	• Sympathetic effusions: Pancreatitis, pericarditis, hepatitis, radiation-induced pleuritis
	• Ovarian hyperstimulation syndrome

Can Cause Either Transudate or Exudate	
• Meigs syndrome • Hypothyroidism • Lung entrapment • Superior vena cava obstruction • Pulmonary embolism can *occasionally* be transudative • Malignancy can *occasionally* cause transudative effusion if blocking lymphatic outflow	

Evaluation of the Fluid

After gross examination of the pleural fluid, the differential diagnosis can be narrowed by determining if the fluid is a transudate or an exudate. The most common causes of transudative effusion are congestive heart failure and cirrhosis; the most common causes of exudative effusion are pneumonia (bacterial, viral, and tuberculosis), malignancy, and pulmonary embolism (Table 75.2). Light's criteria (24) is the most widely accepted method to identify exudative effusions (Table 75.3), using pleural LDH and protein levels as markers of capillary permeability. Exudates have a large differential diagnosis and require further fluid analysis to help identify the etiology. Markers of increased cellular metabolism (pH and glucose) help identify and grade infectious processes, while cell counts, cultures, specific stains, and cytology measures assist in identifying exact organisms or malignancy. Additional pleural fluid biomarkers may aid in the identification of congestive heart failure (BNP), tuberculosis (adenosine deaminase), pancreatitis (amylase), chylothorax (triglycerides), and malignancy (mesothelin, fibulin-3, immune-cytochemical stains).

CRITICAL INTERVENTIONS

- ED thoracentesis is indicated in patients with effusions (>10 mm) associated with respiratory distress or sepsis, and in patients thought to have a complicated parapneumonic effusion.
- Antibiotics should be initiated early in parapneumonic effusion.
- Ultrasound should be routinely used to guide thoracentesis.
- A chest tube is indicated in patients with frank pus, loculations, or fluid with a pH <7.20.

DISPOSITION

The patient's condition and underlying disease process dictate the need for admission. The presence of a pleural effusion, in and of itself, does not necessitate admission, but does require a discussion with the primary care physician regarding the timing and setting of thoracentesis. If thoracentesis is performed, hospital admission is

usually indicated for further treatment of the underlying disease, although the occasional patient with an uncomplicated effusion might be discharged after 4 to 6 hours of observation.

TABLE 75.3
Gross, Microscopic, and Biochemical Examination

Differential Diagnosis	Gross Appearance	Biochemical Profile (PF = Pleural Fluid)	Microscopy
Transudative effusion	Straw-colored, clear, odorless	• Light's criteria: Exudate if any are present: • PF: Serum protein ratio >0.5 • PF: Serum LDH ratio >0.6 • PF LDH >2/3 normal serum LDH Additional markers of exudate: • PF cholesterol >45 mg/dL • PF protein >2.9 g/dL • Glucose <60 mg/dL • WBC >1,000/mm (3)	
Exudative effusion	Clear to cloudy depending on protein and cell content		
Differential Diagnosis of Exudates:			
Infectious (see Table 75.1)	Cloudy to purulent	Glucose <60 mg/dL pH <7.4	WBC >50,000/mm (3)
Malignancy	Serosanguinous to bloody	Elevated protein and decrease pH if rapid cellular turnover	Variable
Pulmonary embolism	Serosanguinous to bloody	Variable	Variable
Hemothorax	Bloody	Similar to serum	Hemothorax: PF-whole blood HCT >0.5
Tuberculosis	Serosanguinous to bloody	Variable TB: Protein >5 g/dL	WBC >10,000, with Lymphocytosis
Chylothorax	Milky	Elevated lipids and triglycerides	Variable, but typically elevated WBC

Common Pitfalls

- Failure to identify an effusion, leading to inadequate or delayed evaluation and treatment.
- Failure to initiate antibiotics in patients with parapneumonic effusion.
- Failure to identify patients with complicated parapneumonic effusions that require chest tube to prevent rind formation and constrictive pleuritis.
- Failure to consider pulmonary embolism in patients with pleural effusion.
- Failure to identify hemothorax or esophageal rupture.
- Presumption that an effusion is old and unchanged can result in an inadequate evaluation or treatment. Comparison with previous radiographs is essential.

CHAPTER 76

Asthma

Lauren M. Smith

Asthma is characterized by increased airway responsiveness to various stimuli. Asthma is caused by a variety of processes including bronchoconstriction, widespread bronchial wall edema, and increased mucous secretions. However, airway inflammation is the primary pathophysiologic mechanism. Although the reversibility of airflow obstruction was once considered a cornerstone of the diagnosis, it is now recognized that reversibility may be incomplete in some patients because of airway remodeling (1).

Asthma affects between 5% and 10% of adults in the United States and the prevalence of asthma has been on the rise for the last three decades. However, mortality has declined. Asthma accounts for just over 2 million emergency department (ED) visits per year, adult and pediatric. Most deaths occur prior to hospital arrival and the highest rates of death occur in those older than 65. About half of all cases are diagnosed before the patient reaches age 10, and another one-third are detected before age 40. The male-to-female ratio of this disease is higher during childhood but reverses in adulthood. Higher asthma prevalence is seen in lower socioeconomic households and in the Afro-American population (2).

The natural course of asthma has not been investigated thoroughly, but studies suggest that 50% to 80% of patients have a good prognosis, especially those with mild disease or disease that develops in childhood. Chronic asthma is categorized by severity, ranging from intermittent to mild, moderate, or severe persistent. Treatment is focused on reduction of impairment and reduction of risk. Periods of symptom-free intervals are interspersed with

exacerbations, which trigger visits to the ED. Only about l0% or less of asthmatics are considered to have severe or refractory asthma, and it is these patients that are difficult to control and are prone to exacerbations.

Asthma is a heterogeneous disease. Clinically, it can be separated into two groups: allergic or extrinsic asthma, and nonallergic or intrinsic asthma. Many patients have components of both types. *Extrinsic asthma* accounts for $<10\%$ of patients with asthma and tends to develop early in life. It is associated with a well-defined sensitivity to inhaled allergens, a family history of allergic diseases, increased serum levels of immunoglobulin (Ig) E, positive immediate skin tests, and blood eosinophilia. It may be seasonal (trees, grasses, and spores) or perennial (animals, gardens, and house dust). A good response to bronchodilator therapy is usually observed.

Intrinsic asthma is the more common type of the disease. An inciting allergen cannot be identified, a family history of allergies is less common, IgE levels may be normal or low, and skin tests are negative. Intrinsic asthma is perennial, tends to be more severe than extrinsic asthma, and has a limited response to bronchodilator therapy.

All individuals with asthma have hyperresponsive airways that narrow when exposed to various stimuli: allergic, infectious, pharmacologic, environmental, occupational, exercise-related, or emotional stimuli.

Allergic asthma occurs when inhaled allergens bind to IgE molecules that are bound to mast cells in the lining of the tracheobronchial tree. During the early response, various mediators are released, causing increased vascular permeability, mucosal edema, and bronchial smooth-muscle contraction. A second wave of reaction, the late response, is seen hours to days later and involves the accumulation of inflammatory cells in the bronchial mucosa, thereby perpetuating the reaction.

Although several theories attempt to explain the pathophysiologic changes that occur in nonallergic asthma, none adequately explains all clinically observed phenomena. Research suggests that even

patients without atopy have the same pathophysiologic basis for the disease as atopic patients.

Respiratory infections, particularly viral infections, commonly precipitate bronchospasm. Viruses cause mucosal inflammation and lower the firing threshold of the subendothelial vagal receptors, resulting in enhanced airway reactivity. This hyperactivity may last up to 8 weeks, even in nonasthmatic persons.

Pharmacologic agents also may induce acute asthma. The agents most frequently implicated are aspirin and nonsteroidal anti-inflammatory compounds, coloring agents, and β-adrenergic antagonists.

Up to 10% of adults with asthma experience the triad of aspirin-induced bronchospasm, nasal polyps, and eosinophilia. Ingestion of aspirin, nonsteroidal anti-inflammatory compounds, and tartrazine (FDC yellow dye no. 5) and other dyes may induce severe asthma in these patients, possibly by diverting arachidonic acid metabolism toward the lipoxygenase pathway and causing the production of leukotrienes, which are potent bronchoconstrictors.

Sulfating agents are used widely as food preservatives and antioxidants in pharmaceutical products. Exacerbation of asthma has been reported after food ingestion and after the use of sulfite-containing drugs, including some inhalation bronchodilators.

A large variety of occupational dusts and fumes may provoke acute airway obstruction. Patients with occupational asthma typically give a cyclic history. They are symptom-free during weekends, vacations, and on arrival at work. As the workday progresses, wheezing develops. A history of similar symptoms in fellow employees may be noted. Three mechanisms are involved in occupational asthma: immunologic reactions (e.g., animal handlers), direct liberation of bronchoconstrictors (e.g., cotton workers), and direct irritant effects (e.g., meat wrappers).

Exercise also may stimulate an asthma attack. Exercise-induced bronchospasm is usually noted within 5 to 20 minutes after the completion of exercise and is related to thermal changes in the respiratory tree. Exercising in a cold, dry environment causes a more marked response than exercising in a warm, humid environment.

Endocrine factors have been recognized as yet another cause of airway hyperresponsiveness. Normal variations in progesterone and estradiol levels are believed to modulate airway reactivity.

Psychological factors also influence asthma exacerbations, probably through modification of vagal efferent activity. The extent to which psychological factors participate in the induction and continuation of an asthma attack is unknown but probably varies from patient to patient and from episode to episode.

Regardless of the underlying precipitant, airway narrowing, bronchial wall edema, bronchial smooth muscle contraction, and mucosal plugging ensue. These changes result in increased airway resistance, decreased forced expiratory volumes and flow rates, lung hyperinflation, increased work of breathing, and ventilation–perfusion mismatch.

CLINICAL PRESENTATION

The classic triad of symptoms during an asthma attack is cough, dyspnea, and wheezing, but chest tightness and nonproductive cough may precede dyspnea and wheezing. Asthmatic patients coming to the ED are frequently anxious, tachypneic, tachycardic, and mildly hypertensive. As airway obstruction worsens, the expiratory phase becomes prolonged and lung hyperinflation, accessory respiratory muscle use, muscle retraction, and pulsus paradoxus may be noted. Patients may attempt to sit upright or lean forward (tripod position) in an effort to ease the work of breathing. However, these signs may be absent despite severe airway obstruction. A silent chest indicates insufficient air movement or extensive mucous plugging and is an ominous sign. Cyanosis may appear only immediately before respiratory arrest and should not be relied on as an indication of the severity of the attack. The termination of an exacerbation is often marked by a cough productive of thick mucous plugs and bronchial casts (Curschmann spirals).

A subset of asthmatic patients experiences the sudden onset of severe symptoms. These individuals tend to respond rapidly to treatment but appear to be at significant risk for a fatal outcome.

Occasionally, an asthmatic patient may complain of intermittent dyspnea or cough on exertion. Patients with cough-equivalent asthma tend to have normal breath sounds on examination, even during an exacerbation, but reversible bronchospasm may be demonstrated on pulmonary function testing.

Complications of asthma include pneumothorax, pneumomediastinum, and subcutaneous emphysema. Pneumothoraces may require insertion of a chest tube for evacuation. Mild atelectasis may occur as a result of bronchial mucous plugging but rarely requires intervention other than conventional bronchodilator therapy. In addition, rib fractures and costochondral strain may occur as a result of excessive coughing. Cough syncope, a rare complication of asthma, is noted most frequently in moderately obese, middle-aged asthmatic men. Finally, dysrhythmias may occur as a result of hypoxia, especially in patients who have received oral adrenergic agents.

DIFFERENTIAL DIAGNOSIS

Wheezing, coughing, and dyspnea are present in many conditions. Common problems include pneumonia, bronchitis, croup, bronchiolitis, chronic obstructive lung disease, congestive heart failure, pulmonary embolism, allergic reactions, and upper airway obstruction from edema or a foreign body. Less common problems include cystic fibrosis, hypersensitivity pneumonitis, carcinoid syndrome, and exposure to odors, dust, and gas. A careful history and physical examination should help differentiate asthma from these conditions.

ED EVALUATION

The ability to perform a thorough history and physical examination before initiating treatment is often limited by the patient's dyspnea. Aggressive therapy directed at relieving airway obstruction begins as soon as a diagnosis of asthma is established. Meanwhile, an attempt is made to obtain a history from family members or the patient. Important points to establish include the following (3,4).

- Duration and onset of the current attack

- Identification of precipitating causes
- Type and amount of medications (inhaler/nebulizer) used before arrival in the ED
- Response to prior therapy, including current or previous use of steroids
- Frequency of ED visits and hospitalizations
- Previous need for intubation or ventilation
- History of concurrent medications and allergies
- History of concurrent medical problems
- History of illicit drug use

Patients at high risk of asthma-related death include those with previous intubations; more than two hospitalizations or more than three ED visits in the past year; use of more than two canisters of short-acting β_2-agonist (SABA) per month; difficulty perceiving airway obstruction or worsening asthma; low socioeconomic status or inner-city residence; illicit drug use; major psychosocial or psychiatric disease; age; and comorbidities such as cardiovascular or other chronic lung diseases.

Immediate attention is also directed to the patient's appearance and work of breathing (i.e., use of accessory muscles), vital signs, chest, heart, mental status, and skin examination. The presence of a pulsus paradoxus (a drop of SBP of more than 12 mm Hg during inspiration) may be noted. However, judging the state of a patient's ventilatory status and pulmonary function on clinical grounds alone can be misleading. The failure to recognize impending respiratory failure is a key contributor to patient death. The degree of tachycardia and tachypnea often do not correlate well with the degree of airway obstruction. Pulsus paradoxus may be absent in up to one-third of severe asthmatics (5). Furthermore, wheezing is absent if airflow is minimal. To complicate matters, all of the aforementioned clinical parameters can normalize with even minimal improvement in pulmonary function (6). Therefore, quantification of airway changes must be assessed by using either the forced expiratory volume in 1 second (FEV_1) or the peak expiratory flow rate (PEFR). An initial FEV_1 of <1 L ($<30\%$ predicted) or a PEFR of

$<$100 L/min ($<$20% predicted) indicates very severe obstruction (3,4).

Hypoxemia is not common during most acute exacerbations. Pulse oximetry may be useful in assessing and following oxygenation. A saturation of $<$91% generally correlates with severe hypoxemia. Arterial blood gas (ABG) measurements are rarely needed in the management of acute asthma, unless the practitioner desires to know the pCO_2 or pH. In general, hypercapnia, severe hypoxemia, or metabolic acidosis does not occur until the PEFR or FEV_1 is $<$25% of predicted values (7), but young children and elderly patients commonly present exceptions to this rule. The degree of hypoxemia determined by ABG generally reflects the extent of ventilation–perfusion mismatch. A normal or increased $PaCO_2$ indicates severe airway obstruction and impending ventilatory failure (7).

Expectorated sputum may appear purulent because of the presence of eosinophils, but this finding may not reflect infection. A wet preparation of sputum may contain Charcot-Leyden crystals (eosinophilic granules), Curschmann spirals (mucous casts), and bacteria.

Chest radiographs may demonstrate hyperinflation and atelectasis but are usually nondiagnostic. A chest radiograph is necessary only if pneumonia, pneumothorax, or pneumomediastinum is suspected or if the patient fails to respond to aggressive bronchodilator therapy.

Although electrocardiography occasionally reveals evidence of right ventricular strain, it is generally not helpful except to rule out concurrent cardiac problems. However, all older patients, especially those with cardiac disease, should be monitored during therapy.

Blood tests, including a complete blood count, are unlikely to help guide the acute management of an asthma attack. Asthma scores that incorporate subjective and objective criteria (pulse, respiratory rate, pulsus paradoxus, subjective dyspnea, accessory muscle use, wheezing, and PEFR) should not be relied on for predicting emergency treatment or determining disposition.

ED MANAGEMENT

ED interventions are guided by pulmonary function tests (FEV_1, PEFR), vital signs, chest, heart and mental status examinations, and the patient's subjective assessment of dyspnea. The goal of emergency treatment is to ensure adequate oxygenation and to relieve airflow obstruction.

Supplemental oxygen, inhaled β-adrenergic agonists, oral or intravenous corticosteroids, and, to a lesser extent, inhaled anticholinergic agents are the mainstays of asthma treatment in the ED. It is now thought that timely administration of glucocorticoids for serious exacerbations is the single most effective strategy for reducing ED visits and hospitalizations (8,9). The methylxanthines (e.g., theophylline) are not a component of emergency care (10). The benefits of ketamine remain largely anecdotal and have not been substantiated in controlled trials (11). The National Asthma Education and Prevention Program (NAEPP) Expert Panel (Fig. 76.1) (3,4) has established guidelines for the diagnosis and management of acute exacerbations of asthma. Acute pharmacologic therapy can be divided into three categories: β-adrenergic agonists, glucocorticoids, and anticholinergics. Chronic management is primarily composed of treatment with inhaled corticosteroids and long-acting inhaled β-agonists; however, these have no role in the acute setting. Despite effective therapies for chronic management, there is still frequently poor compliance, leading to poor control (1). Much work is being done to develop medications that further address the inflammatory component of asthma. This includes anti-IgE therapy and blockers of specific mediators (e.g., IL-5, 9, and 13) or receptors. These remain under investigation and their potential utility in the acute setting remains unclear (1).

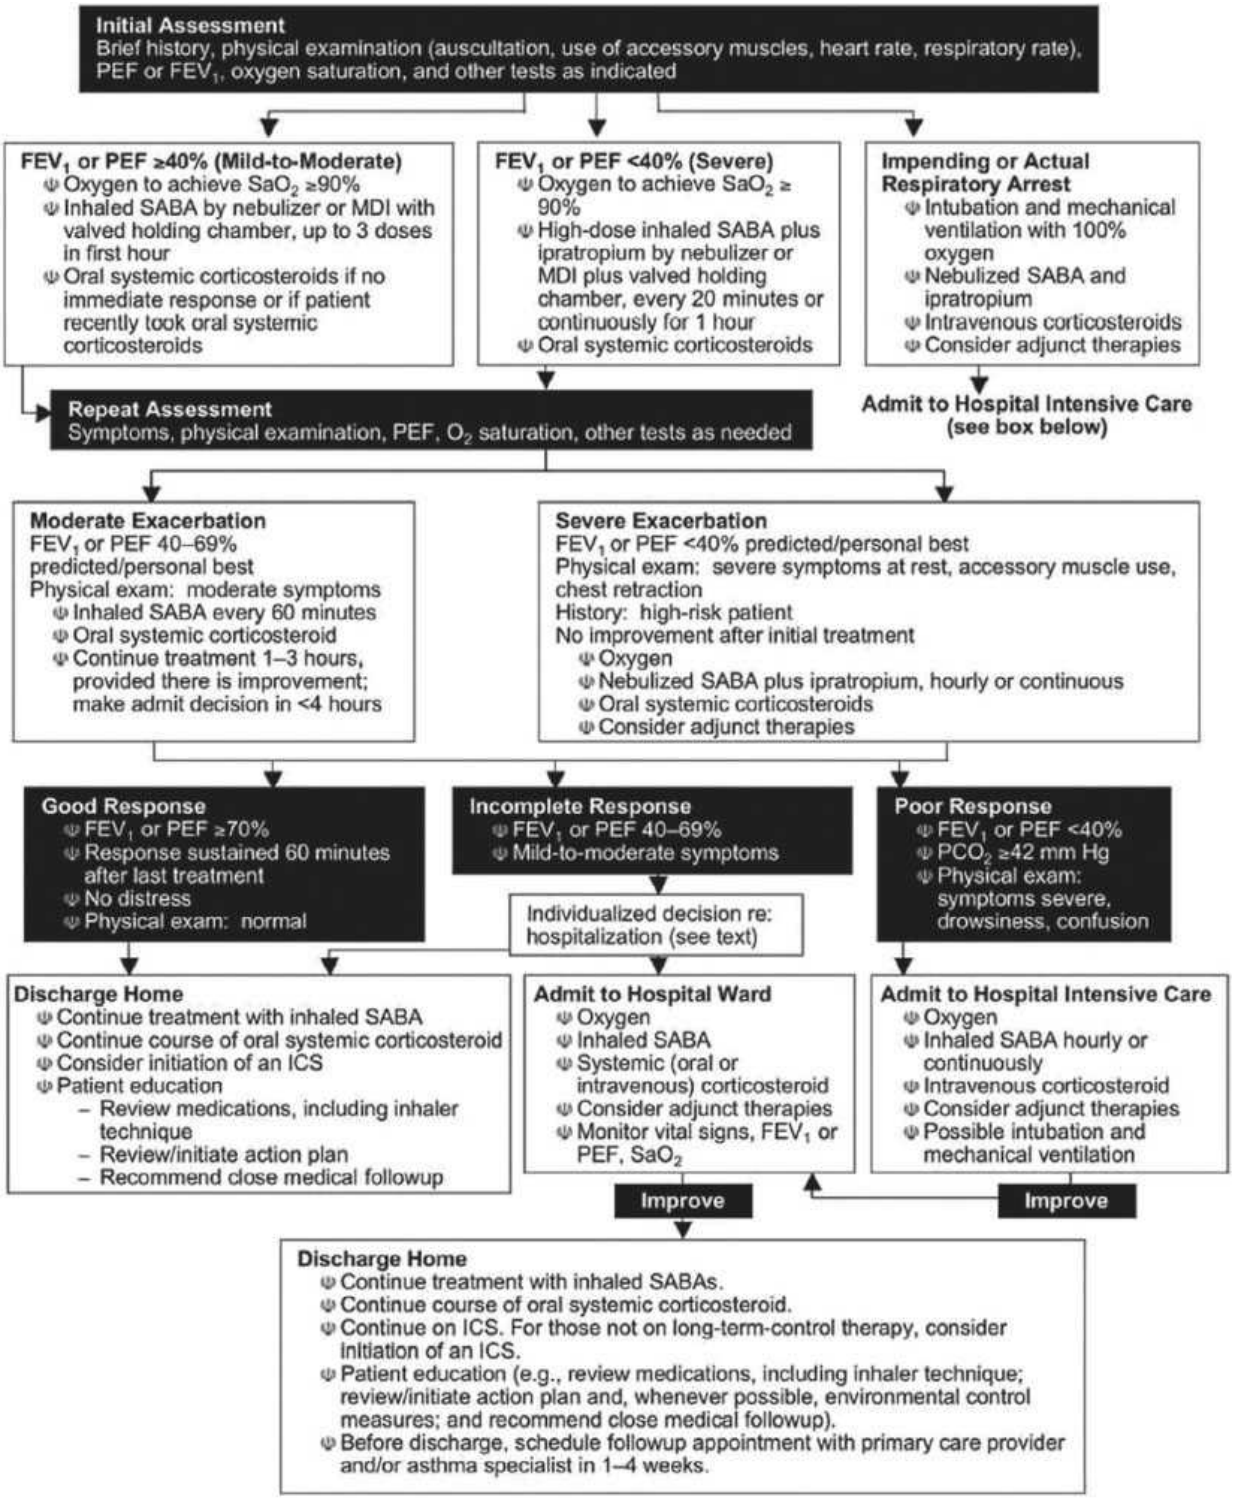

FIGURE 76.1 Management of asthma exacerbations: Emergency department and hospital-based care. Key: FEV_1, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered-dose inhaler; PCO_2, partial pressure carbon dioxide; PEF, peak expiratory

flow; SABA, short-acting β_2-agonist; SaO_2, oxygen saturation. (Adapted from National Asthma Education and Prevention Program, *Expert Panel Report 3: Guidelines of the Diagnosis and Management of Asthma* (NIH Publication Number 08–5846). Baltimore, MD: Department of Health and Human Services, National Institutes of Health, 2007.)

Table 76.1 outlines the preferred treatments recommended by the NAEPP Expert Panel (3,4).

TABLE 76.1
Dosages of Drugs for Asthma Exacerbations in Emergency Medical Care or Hospital

Medication	Dosages		
	Adult	Child[a]	Comments
Short-Acting Inhaled β_2-agonists			
Albuterol			
Nebulizer solution (5 mg/mL, 2.5 mg/3 mL, 1.25 mg/3 mL, 0.63 mg/3 mL)	2.5–5 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 hrs as needed, or 10–15 mg/hr continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 min for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 hrs as needed, or 0.5 mg/kg/hr by continuous nebulization	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to a minimum of 3 mL, as gas flow of 6–8 L/min.
MDI (90 µg/puff)	4–8 puffs every 20 min up to 4 hrs, then every 1–4 hrs as needed	4–8 puffs every 20 min for 3 doses, then 1–4 hrs inhalation maneuver; use spacer/holding chamber	As effective as nebulized therapy if patient is able to coordinate
Bitolterol			
Nebulizer solution (2 mg/mL)	See albuterol dose	See albuterol dose; thought to be half as potent as albuterol on a milligram basis	Has not been studied in severe asthma exacerbations; do not mix with other drugs
MDI (370 µg/puff)	See albuterol dose	See albuterol dose	Has not been studied in severe asthma exacerbations
Levalbuterol (R-Albuterol)			
Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL)	1.25–2.5 mg every 20 min for 3 doses, then 1.25–5 mg every 1–4 hrs as needed, or 5–7.5 mg/hr continuously	0.075 mg/kg (maximum dose 1.25 mg) every 20 min for 3 doses, then 0.075–0.15 mg/kg up to 5 mg every 1–4 hrs as needed, or 0.25 mg/kg/hr by continuous nebulization	0.63 mg of levalbuterol is equivalent to 1.25 mg of racemic albuterol for both efficacy and side effects
Pirbuterol			
MDI (200 µg/puff)	See albuterol dose	See albuterol dose; thought to be half as potent as albuterol on a milligram basis	Has not been studied in severe asthma exacerbations
Systemic (Injected) β_2-Agonists			
Epinephrine			
1:1,000 (1 mg/mL)	0.3–0.5 mg every 20 min for 3 doses subcutaneously	0.01 mg/kg up to 0.3–0.5 mg every 20 min for 3 doses subcutaneously	No proven advantage of systemic therapy over aerosol
Terbutaline (1 mg/mL)	0.25 mg every 20 min for 3 doses subcutaneously	0.01 mg/kg every 20 min for 3 doses then every 2–6 hrs as needed subcutaneously	No proven advantage of systemic therapy over aerosol
Anticholinergics			
Ipratropium Bromide			
Nebulizer solution (0.25 mg/mL)	0.5 mg every 30 min for 3 doses then every 2–4 hrs as needed	0.25 mg every 20 min for 3 doses, then every 2–4 hrs	May mix in same nebulizer with albuterol; should not be used as first-line therapy; should be added to β_2-agonist therapy
MDI (18 µg/puff)	4–8 puffs as needed	4–8 puffs as needed	Dose delivered from MDI is low and has not been studied in asthma exacerbations.
Ipratropium with Albuterol			
Nebulizer solution (each 3 mL vial contains 0.5 mg ipratropium bromide and 90 µg of albuterol)	3 mL every 30 min for 3 doses, then every 2–4 hrs as needed	1.5 mL every 20 min for 3 doses, then every 2–4 hrs	Contains EDTA to prevent discoloration. This additive does not induce bronchospasm.
MDI (each puff contains 18 µg ipratropium bromide and 90 µg of albuterol)	4–8 puffs as needed	4–8 puffs as needed	
Systematic Corticosteroids			
Prednisone			
Methylprednisolone			
Prednisolone	60 mg initially 120–180 mg/d in 3 or 4 divided doses for 48 hrs, then 60–80 mg/d until PEF reaches 70% of predicted or personal best	1 mg/kg every 6 hrs for 48 hrs then 1–2 mg/kg/d (maximum: 60 mg/d) in 2 divided doses until PEF 70% of predicted or personal best	For outpatient "burst" use 40–60 mg in single or 2 divided doses for adults (children: 1–2 mg/kg/d, maximum 60 mg/d) for 3–10 d.

Note: No advantage has been found for higher dose corticosteroids in severe asthma exacerbations, nor is there any advantage for intravenous administration over oral therapy, provided that gastrointestinal transit time or absorption is not impaired. The usual regimen is to continue the frequent multiple daily dose until the patient achieves an FEV or PEF of 50% of predicted or personal best and then lower the dose to twice daily; this usually occurs within 48 hrs. Therapy following a hospitalization or emergency department visit may last from 3 to 10 d.

[a]Children = 12 yrs of age.

EDTA, ethylenediaminetetraacetate; FEV, forced expiratory volume; MDI, metered-dose inhaler; PEF, peak expiratory flow.

β-Adrenergic Agonists

SABAs are the drugs of choice for the management of acute bronchospasm. They produce bronchodilation by stimulating β-

receptors, resulting in the formation of cyclic adenosine monophosphate (cAMP), which results in relaxation of bronchial smooth muscle, inhibition of mediator release, and increase in mucociliary clearance. Drugs in this category include resorcinols, saligenins, and catecholamines (Table 76.1).

Resorcinols and saligenins available in the United States include albuterol (salbutamol), levalbuterol, pirbuterol, formoterol, metaproterenol, and terbutaline. Aerosol forms are available for albuterol, levalbuterol, and metaproterenol. All are available in metered-dose inhalers (MDIs). Aerosol agents and MDIs are rapid-acting, are theoretically long-lasting, and may be repeated every 20 to 30 minutes in an acute situation. Levalbuterol, the R-isomer of albuterol, offers little advantage over albuterol and is more expensive. Salmeterol is a chemical derivative of albuterol with an extended duration of action and a bronchodilator effect 10 times that of albuterol. Formoterol is similar but is even longer acting than salmeterol. Neither is appropriate for use in acute exacerbations of asthma. Albuterol, metaproterenol, and terbutaline are also available in oral form. Terbutaline and epinephrine are available for subcutaneous injection.

The resorcinols and saligenins are highly β_2-selective and are virtually devoid of cardiac side effects when given in inhaled or aerosol form. A frequent noncardiac side effect is tremor. Inhaled or aerosolized β-agonists rapidly promote bronchodilation comparable with that produced by parenteral agents, appear to be longer lasting, and cause fewer side effects. Treatments given every 20 to 30 minutes or in a continuous fashion result in more effective and sustained improvement of pulmonary function than treatments given less frequently (12). The use of spacer devices enhances drug delivery and reduces oral deposition of the medication. Recent studies suggest that albuterol by MDI/spacer is as efficacious as higher doses of albuterol delivered by nebulizer (13).

Subcutaneous administration of β-agonists (epinephrine or terbutaline) may be of use in the treatment of asthmatics who cannot use inhalation devices effectively, in patients in extremis, in patients for whom initial treatment with aerosol β-adrenergic agents fails, or

when preparation of aerosol or metered-dose agents for acute use risks delaying the initiation of therapy.

The catecholamines (epinephrine, isoproterenol, and isoetharine) have largely been supplanted by their more selective and longer-acting derivatives. Epinephrine, a nonselective α- and β-adrenergic agonist, may be given by oral inhalation (in a nonprescription preparation) or subcutaneously. The usual subcutaneous dose in adults is 0.3 to 0.5 mL of a 1:1,000 solution, which may be repeated every 20 minutes to a total of three doses. Epinephrine reaches peak blood levels 20 to 40 minutes after injection, and its bronchodilating effects last up to 4 hours. Side effects include increased myocardial irritability, dysrhythmias, and nervousness. Although some studies suggest that epinephrine may be safely used in asthmatics older than 40 years of age, extreme caution should be used in patients with coronary artery disease (14).

Isoetharine is more β_2-selective than epinephrine and is an effective a bronchodilator. It is supplied as a 1% aerosol solution or in an MDI preparation. Its duration of action is 30 to 90 minutes. Doses may be repeated every 20 to 30 minutes during an acute attack.

Isoproterenol is a potent selective β-adrenergic agent. It is available in aerosol form, in a new MDI, and as an intravenous solution. The duration of action of the inhaled form is 3 hours, and inhalations may be repeated every 3 hours. Use of isoproterenol inhalants was associated with a number of asthmatic deaths in England and Wales in the 1960s, suggesting that the agent should be used cautiously, although a cause-and-effect relationship was not demonstrated. In addition, inhaled isoproterenol may cause paradoxical bronchospasm. Intravenous isoproterenol should be reserved for dire emergencies, and strict monitoring of heart rate, rhythm, and blood pressure is required.

Glucocorticoids

Glucocorticoids should be administered to any patient whose acute airway obstruction is not promptly relieved by an inhaled β-

adrenergic agent. Patients who receive glucocorticoids early require fewer hospital admissions and sustain fewer relapses after discharge from the ED (8). Corticosteroids are thought to exert their effect on acute asthma by reducing airway inflammation. The initial dose is 60 to 125 mg of intravenous methylprednisolone or 40 to 80 mg of oral prednisone (3). Additional doses of methylprednisolone (60 to 80 mg intravenous) or prednisone (40 to 80 mg PO) with a frequency range of daily to every 6 to 8 hours should follow the initial dose. *Oral administration of corticosteroids is equivalent to intravenous administration.* Inhaled corticosteroid use has led to improved asthma control; however, data on the use of inhaled corticosteroids during the acute ED treatment of asthma has yet to be clearly defined (15,16). Because the effects of steroids are not noted for 4 or more hours, vigorous concomitant bronchodilator therapy must be continued.

Anticholinergic Agents

There has been a resurgence of enthusiasm for the use of anticholinergic agents to treat acute bronchoconstriction. These medications, including ipratropium bromide and glycopyrrolate, antagonize the neuromuscular transmitter acetylcholine at the postganglionic parasympathetic receptor, reducing vagally mediated bronchoconstriction in the larger central airways. There appears to be an additive effect when β-adrenergic agents and anticholinergic agents are used together, although this effect is not dramatic (17). Nebulized ipratropium (see Table 76.1) mixed with albuterol should be used in severe asthmatics. Peak anticholinergic bronchodilation is achieved within 1 to 2 hours. Aerosolized atropine sulfate and glycopyrrolate, although effective, have fallen out of favor because of the high incidence of anticholinergic side effects (tachycardia, restlessness, irritability, dry mouth, thirst, and difficulty swallowing).

Other Agents

Magnesium sulfate, a physiologic regulator of intracellular calcium flux, is an effective bronchodilator. In addition to preventing

histamine release from mast cells and opposing the action of acetylcholine, magnesium directly inhibits bronchial smooth-muscle contraction. Both aerosolized magnesium (0.66 g in 10 mL of saline) and intravenous magnesium solutions (2 g over 20 minutes) have been used investigationally to treat patients with asthma for whom maximal standard therapy has failed, although neither form is currently approved for this indication in the United States. Bronchodilation is observed within 2 to 5 minutes after administration, but it disappears rapidly after treatment is discontinued; therefore, additional bronchodilator therapy must accompany the use of magnesium. Side effects include hypotension, malaise, and a warm sensation. Cardiac rhythm, blood pressure, pulse, neurologic status, and renal function must be monitored closely. Magnesium appears to be safe and may be helpful in some patients with severe asthma exacerbations (18).

Nedocromil and *cromolyn* inhibit the release of inflammatory cytokines from mast cells, but they have no role in acute management. Likewise, leukotriene inhibitors, although useful in long-term management, are not indicated for ED treatment.

Heliox, an 80:20 mixture of helium and oxygen, is sometimes considered for treatment in patients with respiratory acidosis who fail conventional therapy. Helium is a low-density, biologically inert gas that lowers airway resistance and decreases respiratory work. Significant improvement may be noted within 10 to 20 minutes of initiating therapy but there are currently insufficient data on whether heliox can avert tracheal intubation or change intensive care and hospital admission rates and duration or mortality; so while safe and well tolerated, no evidence exists that supports its use in the emergency setting (19,20).

Theophylline and its salts have been used to treat acute bronchospasm for more than 50 years. Studies suggest that the methylxanthines, when used alone or in combination with β-agonists during an acute episode, are associated with an increased incidence of side effects but do little to relieve bronchospasm. Methylxanthines have a narrow therapeutic-toxic window, are subject to many interactions with other drugs, and should not be used in the

treatment of acute asthma exacerbations. Toxicity may result in life-threatening cardiac dysrhythmias or seizures.

Noninvasive Assisted Ventilation

Noninvasive assisted ventilation can be in the form of continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). Noninvasive ventilation decreases the load on the respiratory muscles, improves oxygenation, and can prevent the need for intubation and invasive ventilation (21). Noninvasive ventilation does have some advantages over intubation, including the avoidance of sedation and ventilator-associated complications. Although this intervention is widely used and is reported anecdotally to be successful, literature is lacking to support its use and no guidelines currently exist. Patients most likely to benefit from noninvasive ventilation are those with a high work of breathing a $pCO_2 < 45$, and who are alert cooperative, and hemodynamically stable, with minimal coughing or vomiting (7). Bronchodilator treatments may still be administered via the ventilation circuit. Frequent monitoring must be maintained, as some patients do not improve with this internvention and may become hypercapneic and require intubation and invasive ventilation.

Invasive Assisted Ventilation

If the patient's condition deteriorates or fails to improve despite intensive therapy, use of intubation and mechanical ventilation must be considered. Although there are no absolute criteria other than respiratory arrest and coma, the following patients should be considered for intubation and mechanical ventilation, via RSI (rapid sequence intubation).

- Those with worsening pulmonary function tests despite vigorous bronchodilator therapy
- Those with decreasing PaO_2, increasing $PaCO_2$, or progressive respiratory acidosis
- Those exhibiting respiratory muscle fatigue or exhaustion
- Those with declining mental status

Ventilatory strategies yielding low tidal and low respiratory rates are recommended to minimize the risk of producing or exacerbating dynamic lung hyperinflation (11). Expiratory airflow obstruction can result in air-trapping and higher lung volumes in mechanically ventilated asthmatics. This condition may result in "auto-PEEP," a continuously increased intrathoracic pressure that may decrease venous return and cause hypotension. Auto-PEEP may be avoided in mechanically vented patients by using a rapid inspiratory flow rate, a reduced respiratory frequency, and a prolonged expiratory phase. This type of mechanical ventilation is commonly referred to as "permissive hypercapnea." Hemodynamic instability or hypoxemia may occur after intubation; possible causes to consider besides "auto-PEEP" include displaced endotracheal tube, pneumothorax, over-sedation, and equipment failure.

Opioids, sedatives, and tranquilizers should be avoided in acute asthma, because respiratory arrest may occur after their use. Mucolytics, expectorants, and hydration do not aid in the treatment of asthma. Antibiotics are advisable only for those patients with fever and purulent sputum, evidence of pneumonia, or suspected bacterial sinusitis (3).

Asthma in Pregnancy

Asthma is the most common chronic medical condition that complicates pregnancy, and affects an estimated 4% to 8% of pregnancies. One-third of pregnant patients with asthma improve during pregnancy, one-third of patients remain unchanged, and one-third become worse. Asthma therapy during pregnancy is directed at providing adequate oxygenation for both mother and fetus. The management of pregnant asthmatics is essentially the same as that for nonasthmatics. The use of subcutaneous or inhaled β-adrenergic agents and corticosteroids appears to be safe during pregnancy (22).

CRITICAL INTERVENTIONS

- Measure either the FEV_1 or the PEFR to quantify the degree of airway obstruction.

- Administer IV or oral glucocorticoids early to patients whose acute airway obstruction is not promptly relieved by an inhaled β-adrenergic agent.
- Prescribe oral corticosteroids on discharge to patients who have received glucocorticoids in the ED.
- In intubated patients, avoid auto-PEEP by using a rapid inspiratory flow rate, a reduced respiratory frequency, and a prolonged expiratory phase.

DISPOSITION

Several asthma-scoring indices have been proposed to predict the need for hospitalization, but all have proven disappointing. The following patients should be admitted to the hospital or observation unit.

- Those whose condition deteriorates in the ED
- Those with repeat exacerbations after previous recent ED visits
- Those who have dyspneic and significant hypoxemia (PaO_2 <60), hypercapnea, or acidosis
- Patients with a pretreatment FEV_1 of <10 L ($<30\%$ predicted) or a PEFR of <100 L/min ($<20\%$ predicted), and a post treatment FEV_1 <2.1 L ($<60\%$ predicted) or a PEFR <300 L/min ($<60\%$ predicted)
- Patients who remain subjectively dyspneic after aggressive therapy
- Patients with continued abnormal vital signs after therapy
- Unreliable patients

Even patients who improve enough to be discharged from the ED have residual airway obstruction for up to several weeks after the acute episode subsides. Therefore, arrangements must be made for ongoing treatment and early follow-up. A nontapering 3- to 10-day course of oral corticosteroids (40 to 60 mg/d of prednisone) and a 5- to 10-day treatment regimen of a β_2-adrenergic MDI with spacer (two puffs as needed, up to every 4 to 6 hours) should be prescribed. In addition, a chronic regimen of inhaled corticosteroids (preferred) or leukotriene modifier-inhibitor should be prescribed for all patients

who have persistent asthma in accordance with NAEPP guidelines (3,4). Instruction in the proper use of the inhaler is essential, as is a brief educational intervention, as well as cessation of smoking and illicit drug use. Patients receiving chronic theophylline therapy should be continued on a long-acting preparation pending follow-up with their physician.

Common Pitfalls

- Failure to recognize that a silent chest or a normal $PaCO_2$ is a sign of severe obstructive disease that may result in respiratory arrest.
- Withholding β-agonist therapy in the ED because of β-agonist use at home.
- Failure to use objective measurements of pulmonary function, in addition to clinical and subjective parameters of dyspnea, when judging the adequacy of bronchodilator therapy.
- Failure to give glucocorticoids to all but the mildest asthmatics, especially those who fail to respond to one or two doses of β-agonists.
- Failure to consider chronic asthma management in discharge planning.

CHAPTER 77

Chronic Obstructive Pulmonary Disease

David S. Howes and Leah W. Skjei

Chronic obstructive pulmonary disease (COPD) comprises a spectrum of chronic respiratory illnesses characterized by cough, sputum production, dyspnea, airflow limitation, impaired gas exchange, and inflammation (1–3). The mortality rate is greater than 50% within 10 years of diagnosis. COPD is the fourth leading cause of death in the United States and is expected to become the third leading cause of death worldwide by 2020 (4). The overall prevalence of symptomatic COPD in selected countries is 10.1% (5).

The term COPD includes conditions, other than asthma, that have the common feature of airflow obstruction and inflammation of the small airways and alveoli. The inflammatory response in COPD is different than that seen in asthma and involves the recruitment of neutrophils, macrophages, and cytotoxic T lymphocytes. Inflammation of the small airways leads to airway wall thickening and fibrosis, resulting in decreased airway diameter and increased resistance to flow. This is chronic obstructive bronchitis (1,6). Chronic bronchitis is characterized clinically by a productive cough caused by excessive production of bronchial mucus that must be present for 3 months in a year in at least 2 successive years. Pulmonary emphysema, in contrast, is defined from a pathologic standpoint by inflammatory infiltrates in the alveolar wall, leading to an irreversible enlargement of the alveolar air spaces with destruction of the alveolar wall and pulmonary capillary bed (1,6). The result is a reduction in the elastic pressure that generates

expiratory flow (6). Most patients with COPD will have remodeling of both their small airways and their alveoli due to abnormal inflammation, and will therefore exhibit characteristics of both chronic bronchitis and emphysema.

The predominant risk factor for COPD is tobacco use; half of smokers develop airflow obstruction (4). However, 5% to 10% of patients with COPD have never smoked, implicating other causal factors (1). Other risk factors include inhalation of organic and inorganic dusts and fumes, that is environmental pollution, passive smoke inhalation, and occupational exposure (7). α_1-Antitrypsin deficiency is a genetic risk factor and is present in 1% to 2% of patients with COPD (4). Regardless of etiology, the ultimate outcome is irreversible airflow limitation.

The natural course of COPD is one of progressively worsening dyspnea, hypoxemia, and diminished exercise tolerance, with recurrent exacerbations. Most patients with COPD have modest reversible airway obstruction. Although the forced expiratory volume in 1 second (FEV_1) is classically considered the best single prognostic indicator of disability and death, disease severity is better assessed by considering FEV_1, body mass index (BMI), and exercise performance (3). The onset of chronic hypoxemia leads to progressive clinical deterioration caused by *cor pulmonale,* which worsens already diminished lung function. Recurrent episodes of infection and respiratory failure ultimately result in death. Long-term ambulatory oxygen therapy prolongs life in patients with advanced COPD.

CLINICAL PRESENTATION

All patients with COPD exhibit airflow obstruction, but the pure forms of emphysema and chronic bronchitis have distinctive clinical features. Patients with emphysema tend to hyperventilate to compensate for the decreased ability of the lungs to oxygenate the blood due to their decreased alveolar surface area. These classic “pink puffers” work hard to establish a near-normal partial pressure of arterial oxygen (Pa_{O_2}), and they appear barrel-chested, dyspneic,

and tachypneic. They use pursed lips breathing to create positive end-expiratory pressure (PEEP) to prevent early airway closure. Breath sounds are markedly diminished, with a prolonged expiratory phase.

In contrast, patients with chronic bronchitis tolerate hypoxemia well and make no effort to hyperventilate. Chronic hypoxia induces a secondary polycythemia that, combined with the cyanosis of marked desaturation of hemoglobin, produces a plethoric appearance. These patients tolerate an elevated partial pressure of arterial carbon dioxide ($Paco_2$) and have a less labored respiratory pattern. With the decreased work of breathing, the patient with chronic bronchitis does not experience muscle wasting like the emphysematous patient. These features produce the picture of the "blue bloater." Lung examination reveals rhonchi, rales, and variable wheezing. The severity of COPD as classified by Global Initiative for Chronic Lung Disease (GOLD) is listed in Table 77.1 (8).

TABLE 77.1
Global Initiative for Chronic Lung Disease Severity of Chronic Obstructive Pulmonary Disease

Stage	Category	FEV_1	Comments
I	Mild	80%	May be asymptomatic
II	Moderate	≥50% and <80%	Dyspnea on exertion and cough
III	Severe	≥30% and <50%	Reduced exercise capacity and impact on quality of life
IV	Very severe	<30% or <50% with chronic respiratory failure	*Cor pulmonale*

FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

Most patients who present with an acute exacerbation of COPD do not fit either picture precisely. Patients with COPD exacerbation present with worsening of baseline dyspnea, cough, and/or sputum

that is beyond normal day-to-day variations, is acute in onset, and may warrant a change in regular medication (8). Physical examination may reveal a variable degree of respiratory distress, tachypnea, accessory muscle use, retractions, and cyanosis. On auscultation, one may hear diminished breath sounds, a prolonged expiratory phase, wheezing, rales, or rhonchi. Signs of *cor pulmonale* should be sought: a centrally displaced point of maximal impulse, heart gallop, tricuspid murmur, peripheral edema, jugular venous distention, hepatojugular reflux, and hepatomegaly. This complication of long-standing hypoxemia is associated with substantial mortality.

The causes of exacerbation include respiratory infection, noncompliance with (or under dosing of) medications, changes in weather, exposure to certain drugs (e.g., sedatives or β-blockers), cardiac dysrhythmias, left ventricular dysfunction, and environmental exposure to allergens or other irritants. Most exacerbations are caused by infections, either viral or bacterial, with bacterial infections accounting for 50% of COPD exacerbations. Air pollution and other environmental conditions account for approximately 15% to 20% (9). Table 77.2 lists common respiratory agents associated with COPD exacerbations (10–12). Patients typically present with a gradual, but progressive, deterioration, taking hours to days.

TABLE 77.2
Bacterial and Viral Agents Associated with Chronic Obstructive Pulmonary Disease Exacerbations

Bacteria	Viruses
Haemophilus influenzae	Rhinovirus
Streptococcus pneumoniae	Influenza
Moraxella catarrhalis	Parainfluenza
Pseudomonas aeruginosa	Respiratory syncytial virus
	Coronavirus
	Adenovirus

Acute decompensation may be the result of a number of other conditions. Spontaneous pneumothorax in COPD carries a significantly higher complication and mortality rate than in patients with a normal cardiorespiratory status. The patient with chronic bronchitis is predisposed to embolic and thrombotic phenomena because of the hyperviscosity associated with polycythemia. Other disorders, such as congestive heart failure (CHF), pneumonia, acidosis, or renal or hepatic failure, may also overwhelm the COPD patient's limited reserves, resulting in respiratory failure.

DIFFERENTIAL DIAGNOSIS

Other conditions must also be considered in the patient who presents to the emergency department (ED) with wheezing, cough, dyspnea, or respiratory failure. Pneumonia or acute bronchitis may present with varying degrees of shortness of breath, cough, and bronchospasm, and previously undiagnosed COPD may be discovered after an acute pneumonic process has resolved. The onset of respiratory symptoms in the presence or absence of chest pain, when associated with risk factors such as recent surgery, malignancy, immobility, or extended travel, or leg findings consistent with deep venous thrombosis, strongly suggest pulmonary embolism.

Acute left ventricular dysfunction may mimic many findings of COPD including cough, dyspnea, and hypoxemia, and patients may exhibit wheezing, referred to as "cardiac asthma." Orthopnea, paroxysmal nocturnal dyspnea, and cardiomegaly favor CHF, but COPD patients with *cor pulmonale* may demonstrate jugular venous distention and peripheral edema. Classically, chest radiography helped distinguish between these entities, with a lack of cardiomegaly and pulmonary venous redistribution and the presence of bullae and hyperinflation of the lungs suggesting COPD. However, patients with both CHF and COPD who present with dyspnea can present a diagnostic challenge. The rapid laboratory quantification of B-type natriuretic peptide (BNP) may allow more accurate distinction between an acute exacerbation of COPD versus

CHF. BNP is secreted from ventricles in response to pressure and volume expansion. Low levels of BNP are consistent with exacerbations of COPD, asthma, bronchitis, or pneumonia, whereas a BNP level of 100 pg/mL or greater is a strong predictor of CHF. Pulmonary embolism or COPD triggering *cor pulmonale* may also produce elevated BNP levels of 200 to 600 pg/mL (3). Therefore, it is best to use the patient's physical examination, history, and ancillary studies, together with the BNP level to make the most informed clinical diagnosis and therapeutic decisions.

ED EVALUATION

If the patient's respiratory status allows a brief history to be taken, attention should be directed to the rapidity of onset, duration of symptoms, precipitating factors, the dosage of medications, and when medications were last taken. Information should be sought regarding the character of the sputum, the course of previous exacerbations, and any history of concomitant disease processes.

The physical examination focuses on the patient's mental status and the degree of respiratory distress. Hypercapnia and hypoxia can cause confusion, somnolence, and irritability. The cardiac and pulmonary examinations are vital, and repeated examinations are mandatory after therapeutic interventions to monitor the response to treatment.

Pulse oximetry is useful in monitoring oxygen saturation and the effectiveness of oxygen supplementation. Arterial blood gas (ABG) analysis provides information on the $Paco_2$ and pH, reflecting adequacy of ventilation. The pH is the best single laboratory marker for gauging the severity of acute respiratory insufficiency, because it reflects the speed and degree of change in $Paco_2$ (8). Baseline or prior ABG results may be useful for comparison; in general, hypercapnia with acidemia suggests acute respiratory failure.

The chest radiograph (CXR) is usually done at the bedside, unless the patient is stable and can tolerate being transported to the radiology suite for posteroanterior (PA) and lateral films. The CXR is useful when findings of COPD are present, but it is even more

helpful in evaluating for other disease processes, such as pneumothorax, atelectasis, infiltrate, lung mass, or CHF.

Measurements of airflow do not always yield accurate assessments of the severity of illness but may be useful in judging the response to therapy. The peak expiratory flow rate (PEFR) is most commonly used in the ED setting, but, in contrast to the asthmatic patient's response, it does not correlate well with COPD severity during exacerbations, and does not improve as rapidly as the asthmatic patient's in response to therapy.

Laboratory studies are generally of limited value. β-Agonists may cause hypokalemia, although this is rarely clinically significant. A complete blood count may reveal anemia, which can compound the problem of hypoxemia, or a high white blood cell count, which may be a clue to pneumonia or other systemic infections. If there is suspicion for CHF or cardiac injury, BNP and troponin assays may be ordered. D-Dimer may be useful for evaluating low-risk patients when pulmonary embolism is being considered.

A 12-lead electrocardiogram (ECG) may suggest right atrial enlargement, low voltage, right ventricular hypertrophy, or strain (*cor pulmonale*). Acute ischemic patterns must be appreciated to identify an acute coronary event that may be triggering or complicating the acute COPD attack. Continuous ECG monitoring may be useful in revealing dysrhythmias that may aggravate an acute exacerbation.

Thoracic ultrasound is sensitive for ruling out pneumothorax when used by experienced operators. However, it should not be used to diagnose pneumothorax in patients with COPD because there is a high false-positive rate in this population (13).

Thoracic ultrasound is sensitive for ruling out pneumothorax when used by experienced operators. However, it should not be used to diagnose pneumothorax in patients with COPD because there is a high false-positive rate in this population (13).

KEY TESTING

- Order an ABG or VBG to obtain the pH, and thereby gauge the severity of the patient's acute respiratory insufficiency.
- Obtain a CXR to evaluate for infection, pneumothorax, mass, and edema.
- Consider a CBC and basic metabolic panel to screen for anemia, a high WBC, and hypokalemia.
- A BNP should be ordered if CHF is suspected (14).
- A troponin assay and an EKG should be ordered if symptoms or signs of cardiac ischemia or dysrhythmia are present.
- A D-dimer is useful in evaluating low-risk patients for whom PE is being considered.

ED MANAGEMENT

The effective management of the COPD patient with an acute decompensation includes rapid estimation of severity, prompt therapy, frequent reevaluation, and recognition of treatable entities that may have precipitated the ED visit or that complicate the patient's course. The patient should be placed on a cardiac monitor and intravenous (IV) access should be established. Dysrhythmias such as rapid atrial fibrillation usually reflect coexisting heart disease that is worsened by acute hypoxemia; current evidence suggests that most patients with a COPD exacerbation who exhibit ventricular dysrhythmias have underlying left ventricular diastolic dysfunction. Table 77.3 provides a summary to the approach to patients with moderate-to-severe COPD exacerbations.

TABLE 77.3
Overview of Emergency Department Management of Patients with Moderate-to-Severe Chronic Obstructive Pulmonary Disease[a]

Oxygenation and Ventilation

- Supplemental oxygen—Titrate oxygen to maintain saturation 90–92%
- Noninvasive positive-pressure ventilation—Provide to reduce work of breathing
- Endotracheal intubation—Use when NIPPV fails or is contraindicated in patients with respiratory failure

Bronchodilators

- Albuterol 2.5 mg nebulized every 20–60 min

or

- Levalbuterol 1.25 mg nebulized every 30 min to 8 hrs

and

- Ipratropium 500 µg nebulized

Steroids

- Prednisone 40–60 mg PO

or

- Methylprednisolone 125 mg IV

or

- Decadron 10 mg IV

Antibiotics

- Moxifloxacin 400 mg IV/PO every 24 hrs for 5 d

or

- Levofloxacin 500 mg IV/PO every 24 hrs for 7–14 d or 750 mg IV/PO every 24 hrs for 5 d

or

- Amoxicillin/clavulanate 500 mg PO every 8 hrs or 875 mg PO every 12 hrs

Additional Considerations

- Magnesium sulfate 2 g IV given over 30 min

PO, by mouth; IV, intravenous.
[a]This table presents a focused list of therapies. Other agents may be used. See text for greater detail.

Treatment with oxygen is critical because hypoxemia is the major immediate threat to life. The goal is to maintain a $Pa_{O_2} > 60$ mm Hg or a pulse oximetry reading of 90% to 92% to minimize further risk of hypercapnea and respiratory acidosis (15). A controlled oxygen-delivery system is preferable; a Venturi-mask system can deliver a precise oxygen concentration ranging from 24% to 50%. Adjustments in oxygen delivery should be guided by continuous pulse oximetry and ABG determinations as needed. In the acutely

hypoxemic patient, the administration of oxygen is paramount and far outweighs the risk of hypercarbia caused by blunting of the hypoxemic drive in a chronic CO_2 retainer.

Sympathomimetics, specifically β_2-agonists, are the initial pharmacologic agents of choice for acute COPD exacerbations. Effectiveness is dependent in part on the reversible component of the patient's obstructive lung disease; however, a significant benefit of bronchodilator therapy is to decrease dynamic hyperinflation by improving lung emptying during expiration (3). Side effects include tremor, agitation, insomnia, headache, cardiac tachyarrhythmias, and mild hypokalemia. Nebulizer aerosolization is the preferred delivery method in the ED. Although there are many β_2-agonists available, albuterol, is the most widely used agent. Albuterol, 2.5 mg, is used either in repeated treatments every 20 to 60 minutes, or by continuous nebulization in severe cases. Levalbuterol, the active (R) isomer of racemic albuterol, is available for treatment of COPD by nebulizer; the "on-label" dosage is 1.25 mg every 6 to 8 hours, although dosages of up to 1.25 mg every 30 minutes have been reported in clinical studies. The inactive (S) isomer found in racemic albuterol is thought to promote hypersensitivity and bronchospasm in susceptible individuals, but though patients treated with levalbuterol may require less medication and experience a longer therapeutic duration of action as compared with those given racemic albuterol (16), the considerable added expense outweighs the questionable clinical significance of these minor differences (16).

The slower onset of action renders anticholinergic agents to second-line treatment in the acute setting. Ipratropium bromide, a congener of atropine, has little systemic absorption when inhaled, thus minimizing undesirable anticholinergic effects, and has been shown to have an additive effect when combined with a β_2-agonist. This agent may be administered at a dose of 500 μg per nebulizer treatment.

Corticosteroids are considered useful in acute exacerbations of COPD. Even patients who do not respond to steroids when stable

may still benefit from them during acute attacks. Because steroid use may suppress the adrenal–pituitary axis, patients with current or recent use may require steroids for the stress of any acute illness. IV methylprednisolone at a dose of 125 mg or oral prednisone 60 mg are commonly used in the treatment of exacerbations of COPD. Patients may be given oral prednisone 30 to 40 mg daily for 7 to 14 days if they are discharged from the ED (10).

Before the widespread availability of oral or inhaled β_2-agonists, methylxanthines, most commonly theophylline, were used as monotherapy for COPD. However, methylxanthines have since been proven to be of no benefit in acute COPD exacerbations, and have potentially serious side effects (17).

Other medications may be utilized in the management of acute COPD. Magnesium sulfate has modest bronchodilatory effects and may be given a trial as adjunctive therapy to patients with severe exacerbations who have normal renal function. Some authors have shown benefit of magnesium sulfate only when administered before β-agonists (18).

Cessation of tobacco use may well be the most important intervention for COPD. Brief counseling can be effective, and an effort should be made to advise the patient to stop smoking and seek further counseling from a primary care physician (1,3). COPD patients in the ED are also candidates to receive polyvalent pneumococcal and influenza vaccines to potentially decrease the risk of future exacerbations (19).

COPD exacerbations are commonly ($>50\%$) associated with acute respiratory tract infection. The most common agents are outlined in Table 77.2 (10–12). Antibiotic therapy is indicated if dyspnea is associated with a change in the volume or purulence of sputum or with a new infiltrate on CXR. Antibiotics should also be considered for any patient with a severe COPD exacerbation, or an exacerbation requiring admission. Antibiotic treatment has been associated with better inpatient outcomes (20). Former first-line agents such as trimethoprim/sulfamethoxazole, amoxicillin, and doxycycline have proven to be inferior to advanced-generation quinolones, second-

and third-generation cephalosporins, and amoxicillin/clavulanate. Antibiotic therapy increases treatment success and decreases mortality when used to treat acute exacerbations of COPD associated with increased sputum purulence and volume production (12,21,22). Increasing resistance of *Streptococcus pneumoniae* to macrolides also limits use of this antimicrobial (12). The choice of antibiotic should be based on local resistance patterns, particularly among the bacterial species commonly isolated from sputum during exacerbations: *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis* (19). Broad-spectrum coverage should be instituted to reduce the incidence of antibiotic resistance.

For patients who do not respond to acute interventions and who begin to show signs of respiratory failure (such as deterioration of mental status, worsening hypoxemia [Pa_{O_2} of <50 mm Hg], or worsening respiratory acidosis [pH 7.25]), assisted ventilation is indicated. Noninvasive positive-pressure ventilation (NIPPV) should be considered for patients who present with moderate exacerbations of COPD and should be instituted for patients with severe exacerbations of COPD who have a relatively normal mental status and who do not require immediate endotracheal intubation. Contraindications to NIPPV include impending respiratory arrest, cardiovascular instability, and vomiting. NIPPV decreases the work of breathing and has been shown to decrease the rate of endotracheal intubation, to decrease hospital mortality, and to shorten hospital stay in patients with severe exacerbations of COPD (23). Recent studies have shown that NIPPV may safely and effectively be used in patients with altered mental status who are arousable and able to follow simple commands (24). However, for patients who are not candidates for these modalities or for whom noninvasive ventilation has failed, endotracheal intubation with mechanical ventilation is the treatment of choice.

After performing endotracheal intubation and implementing mechanical ventilation, the clinician must be aware of the potential complications associated with positive-pressure ventilation in the COPD patient. Complications include hypotension and

cardiovascular collapse caused by decreased venous return secondary to increased intrathoracic pressure. The increased intrathoracic pressure occurs in patients who "stack" breaths because of the inability to completely exhale the mechanically provided inspired volume that results in greater intrathoracic volume and pressure. If hypotension does not resolve with administration of IV fluids, the patient's endotracheal tube should be temporarily disconnected from the ventilator to relieve excessive positive intrathoracic pressure. Mechanical ventilation should be adjusted to allow for a short inspiratory and long expiratory time with a low tidal volume of 5 to 7 mL/kg. The frequency of ventilation may be gradually increased to allow for resolution of the acute respiratory acidosis and gradual normalization of pH. Extrinsic PEEP may be added to nearly equal intrinsic or auto-PEEP in an effort to keep distal small airways from collapsing with attendant gas trapping. Short-term administration of paralytics eliminates patient-ventilator dyssynchrony and reduces the risk of hyperinflation.

It is paramount that proper sedation is provided to the patient if paralytics are administered. However, hypotension can result from the administration of sedative agents that reduce sympathetic tone. Hypotension should be treated with IV fluids and pressors in more extreme cases.

CRITICAL INTERVENTIONS

- Obtain an arterial or venous pH to determine the severity of acute respiratory insufficiency, because it reflects the speed and degree of change in $Paco_2$. Hypercapnia with acidemia suggests acute respiratory failure.
- Administer oxygen in the acutely hypoxemic patient: the administration of oxygen far outweighs the risk of hypercarbia owing to blunting of the hypoxemic drive in a chronic CO_2 retainer.
- Use a controlled oxygen delivery system (Venturi mask) to maintain a Pao_2 >60 mm Hg or a pulse oximetry reading of

90% to 92% to minimize further risk of hypercapnia and respiratory acidosis in stable hypoxemic patients.
- Adjust oxygen delivery based on continuous pulse oximetry and serial ABGs.
- Start antibiotic therapy in patients with increased sputum volume and purulence, and patients being admitted with severe COPD exacerbations.
- Use NIPPV in patients with moderate-to-severe exacerbations to decrease the work of breathing when endotracheal intubation is not immediately indicated.

DISPOSITION

Many patients who present with an acute exacerbation of COPD require admission to the hospital. However, if the patient responds to therapy and the vital signs and pulmonary function tests approach baseline, discharge may be considered if good follow-up is assured. The bronchodilator regimen should be maximized: mono, dual, or triple therapy may be selected from long-acting β_2-agonists, long-acting anticholinergics, and inhaled corticosteroids (25). A short-acting β-agonist should be prescribed as a rescue inhaler. Systemic steroids should be continued for a short course, as they reduce the relative risk of treatment failure by about 30% as compared to placebo (19). Antibiotics should be prescribed for exacerbations associated with increased sputum volume or purulence. It should be recognized that approximately 15% of patients with COPD who are discharged from the ED require readmission.

Accepted criteria for hospitalization of patients with COPD include poor response to outpatient therapy, severe limitation of function, inability to eat or sleep because of dyspnea, presence of significant comorbid conditions, worsening respiratory failure, new or progressive *cor pulmonale,* and the need for invasive procedures, especially those requiring analgesics or sedatives. Guidelines for admission to the intensive care unit are not as well defined. Treatment in an intensive care unit is indicated when the close

observation, monitoring, and therapeutic interventions (including assisted ventilation) required by these patients cannot be provided elsewhere.

If transfer to another institution is required, it must be done carefully, because transfer is often associated with an interruption in treatment and increased patient fatigue. The transport team must be capable of managing the airway if decompensation occurs.

Common Pitfalls

- The COPD patient should not be expected to have disease that reverses as rapidly as the asthmatic patient. Look for a slower course of improvement, and have a lower threshold for admission.
- If patients have not slept well in the last 2 days, they are tired and the risk of respiratory failure is high. Such patients must be admitted to the hospital.
- Precipitating or complicating conditions (e.g., CHF, PE) may be overlooked when treating only the exacerbation of COPD.
- Oxygen should never be withheld because of concern about respiratory depression. If inadequate ventilation occurs, ventilatory support should be provided.
- It is easy to underestimate the severity of illness in patients with chronic dysfunction. Utilize radiography, pulse oximetry, and ABG analyses. Respect the patient's estimation of the severity of illness.
- If hypotension occurs during mechanical ventilation, the most common cause is "stacked" breaths caused by incomplete exhalation, with attendant rise in intrathoracic pressures and impaired venous return; the patient must be disconnected from the ventilator and allowed to "exhale."

CHAPTER 78

Spontaneous Pneumothorax and Pneumomediastinum

Susan M. Dunmire

Spontaneous pneumothorax and pneumomediastinum are sometimes challenging, yet critical to diagnose and treat for patients presenting in the emergency department (ED). These entities should be considered in any individual who presents with the acute onset of shortness of breath, chest pain, or subcutaneous emphysema.

A *pneumothorax* is defined by the presence of gas within the pleural space. When it occurs in the absence of penetrating or blunt injury to the chest wall, it is termed a *spontaneous pneumothorax.* A *primary spontaneous pneumothorax* occurs in individuals with no clinical or radiographic evidence of lung disease, whereas a *secondary spontaneous pneumothorax* occurs in individuals with underlying lung pathology. With large accumulations of air in the pleural space, a *tension pneumothorax,* characterized by hypotension due to impaired venous return, may develop (Fig. 78.1).

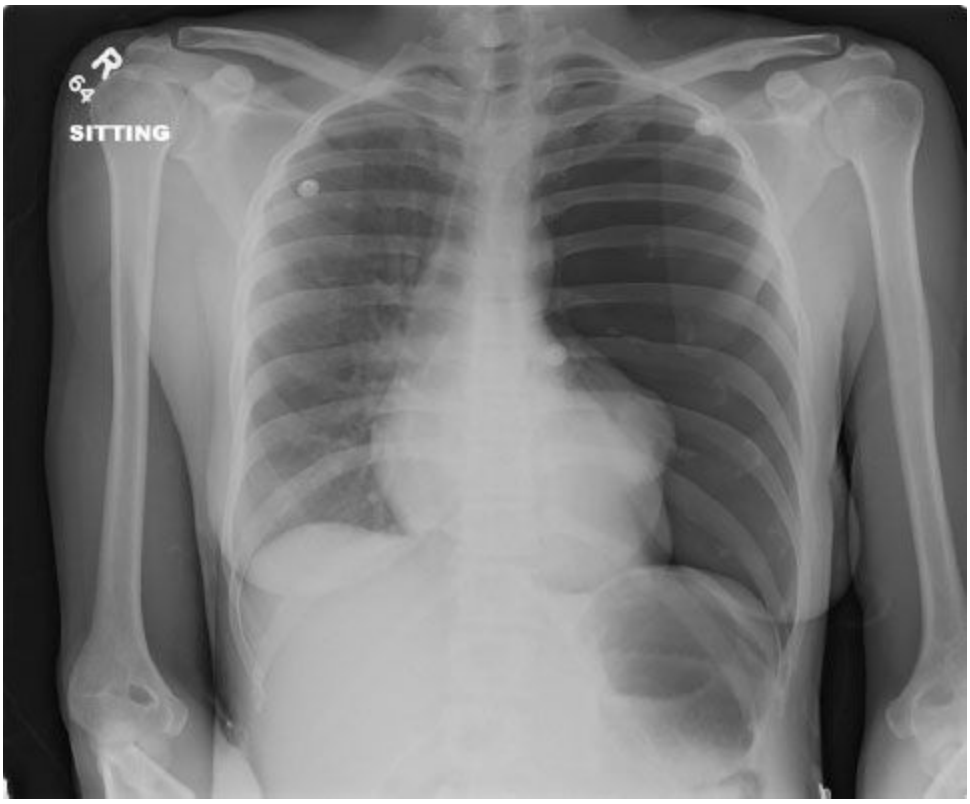

FIGURE 78.1 Left tension pneumothorax with shift of mediastinum to the right.

A primary spontaneous pneumothorax is often the result of rupture of small subpleural cysts or blebs. More than 10% of patients will report a positive family history of spontaneous pneumothorax. A mutation in the gene encoding for folliculin (FLCN) has been identified in individuals with familial spontaneous pneumothorax (1). Spontaneous pneumothorax recurs in up to 50% of patients within 2 years.

One of the most common causes of secondary pneumothorax is chronic obstructive pulmonary disease with rupture of bullae through the visceral pleura. The presentation can be misleading in that patients may report only a worsening of chronic dyspnea. The unsuspected pneumothorax is often found on chest radiography during the evaluation of a suspected exacerbation.

Pneumocystis carinii pneumonia has become an increasingly common cause of secondary pneumothorax. A subgroup of patients with *Pneumocystis* pneumonia has an accelerated inflammatory

response, with spontaneous rupture of necrotic lung tissue, resulting in pneumothorax (2). Other less common causes of secondary pneumothorax include malignancy, asthma (sometimes presenting as sudden severe respiratory compromise), cystic fibrosis, pulmonary infarction, histiocytosis X, and Hamman–Rich syndrome (acute interstitial pulmonary fibrosis). Patients with cystic fibrosis who experience a spontaneous pneumothorax have a significantly higher morbidity and mortality (3). Patients with significant underlying lung pathology may have respiratory decompensation with a relatively small pneumothorax, and therefore require aggressive therapy and close monitoring.

Another less common entity is *catamenial pneumothorax*. This is a spontaneous pneumothorax occurring in young females at the time of menstruation. Although its etiology is multifactorial, in some patients it is due to small implants of endometrial tissue in the pleural lining (4,5).

Spontaneous *pneumomediastinum* occurs when there is a sudden increase in intra-alveolar pressure resulting in alveolar rupture and dissection of air into the mediastinum. In a recent retrospective study, the use of illegal drugs (inhaling cocaine, smoking crack cocaine, and smoking marijuana) was the most common precipitating factor for a spontaneous pneumomediastinum (6). Other causes include vomiting, retching, Valsalva maneuver, and a history of recent endoscopy. Although a spontaneous pneumomediastinum is usually a benign entity, more serious causes such as esophageal rupture must be considered.

CLINICAL PRESENTATION

Primary spontaneous pneumothorax commonly occurs in young adults (male-to-female ratio 5:1) between the ages of 20 and 40 (7). Affected individuals tend to be tall and thin and frequently have a history of cigarette smoking (8). There is also a strong association with Marfan syndrome (9).

Patients with spontaneous pneumothorax typically present with the sudden onset of constant ipsilateral chest or shoulder pain that

may or may not increase with inspiration. The majority of patients complain of dyspnea, although the severity depends on the size of the pneumothorax. Most patients have the onset of symptoms at rest or during sleep. Rarely, spontaneous pneumothorax can present as a tension pneumothorax with severe cardiopulmonary compromise.

Symptoms in adults with spontaneous pneumomediastinum include retrosternal chest pain and, less frequently, subcutaneous emphysema due to tracking of air into the chest wall, neck, face, abdominal wall, and scrotum. If enough air accumulates in the mediastinum, the pleura can rupture, resulting in an associated pneumothorax in 6% to 10% of patients (10,11). Spontaneous pneumomediastinum in infants is a much more serious entity and can cause cardiopulmonary compromise by compression of the hilum (12).

DIFFERENTIAL DIAGNOSIS

Pulmonary embolism, exacerbation of chronic obstructive pulmonary disease or asthma, pneumonia, thoracic aortic dissection, and myocardial ischemia should all be in the differential diagnosis of a patient with shortness of breath and chest pain. Often the diagnosis of spontaneous pneumothorax is not considered until the chest radiograph is obtained.

Spontaneous pneumomediastinum usually presents as substernal chest pain. The differential diagnosis includes myocardial ischemia, gastroesophageal reflux, pulmonary embolism, and pneumonia.

Once the diagnosis of pneumothorax has been made, the physician should reevaluate the history and physical examination to ensure that there is no sign of blunt or penetrating trauma. An elderly person may have forgotten a recent fall that resulted in rib fractures and an underlying pneumothorax. A puncture site in the neck or supraclavicular area can easily be missed in an unsuspected drug abuser who has penetrated the pleural space.

ED EVALUATION

Physical findings are frequently not helpful in making the diagnosis of a small to moderate sized spontaneous pneumothorax. Patients often exhibit mild resting tachycardia and tachypnea. Depending on the extent of the pneumothorax, breath sounds may be diminished unilaterally. The presence of hypotension, tachycardia (>140 beats/min), or tracheal deviation should immediately alert the emergency physician to the possibility of a tension pneumothorax requiring emergent decompression.The diagnosis of pneumothorax is usually made by chest radiography, which reveals a peripheral lucent area containing no lung markings. It is unnecessary to perform inspiratory and expiratory films as they are equally sensitive for the diagnosis of a pneumothorax (13).

A chest CT is helpful in the detection of a small pneumothorax and pleural blebs. This can guide therapy, as video-assisted thoracoscopic surgery (VATS) may be considered in patients with PSP with visible blebs on CT. CT also allows for assessment of pleural blebs on the contralateral lung.

Bedside ultrasound as a diagnostic tool for pneumothorax has a higher sensitivity and similar specificity to chest radiography (14). It can be useful in the setting of patient who is too unstable to have an upright chest radiograph. Positive findings for pneumothorax include an absence of the lung sliding sign and the comet tail.

Patients with a significant (>25%) pneumothorax have an increase in the alveolar–arterial oxygen gradient, although an arterial blood gas is rarely necessary. The electrocardiogram is not helpful for diagnosis. Nonspecific changes, including T-wave inversion in the precordial leads, decreased amplitude of the R wave, and left axis deviation, are often noted.

The diagnosis of a spontaneous pneumomediastinum is often overlooked and requires a thorough examination and a high index of suspicion. Auscultation of the heart may reveal a “crunching” sound during systole (Hamman sign). Rarely, subcutaneous air may be present. A very thin lucent stripe can be seen outlining the heart and the mediastinum (Fig. 78.2). A lateral neck radiograph may reveal subcutaneous air. Up to 10% of clinically suspected pneumomediastinum will negative chest x-rays. CT scan is 100%

sensitive and specific in detecting pneumomediastinum (Fig. 78.3) (15). The electrocardiogram is useful only in helping to rule out ischemia in the patient presenting with substernal chest pain. Additional diagnostic testing, including esophagography, bronchoscopy, and esophagogastroduodenoscopy in nontraumatic pneumomediastinum is rarely indicated unless there is a high clinical suspicion of esophageal rupture (a history of recent instrumentation or forceful vomiting) (16).

FIGURE 78.2 Chest radiograph with pneumomediastinum.

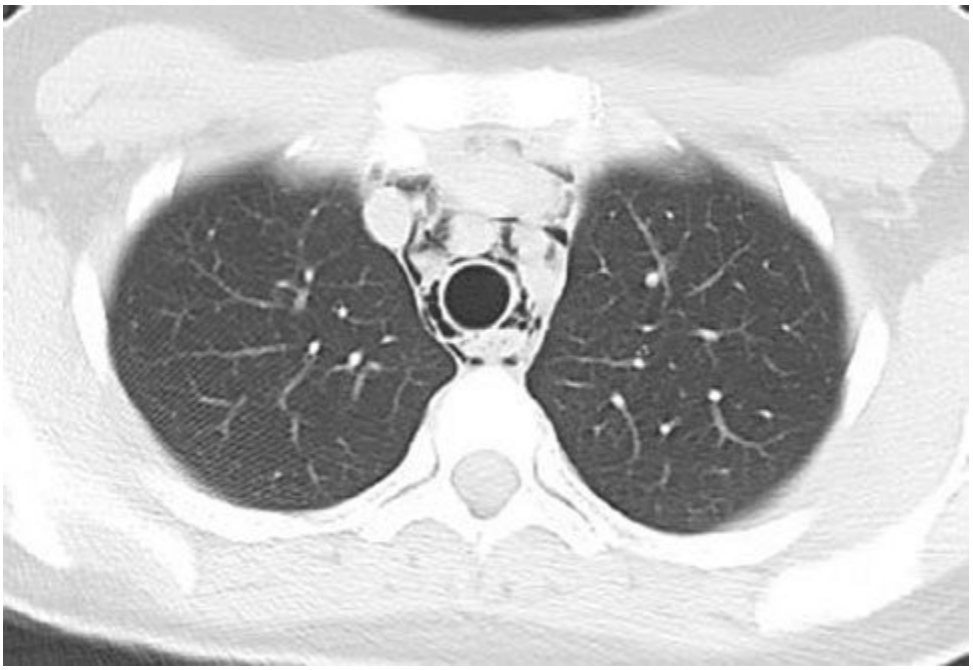

FIGURE 78.3 CT scan demonstrating pneumomediastinum.

KEY TESTING

- CXR
- CT chest—to detect small pneumothoraces/blebs and for diagnosis of pneumomediastinum
- Bedside chest ultrasound—for patients too unstable for upright CXR and more sensitive than CXR for small pneumothoraces

ED MANAGEMENT

Most patients with primary spontaneous pneumothorax do not have significant cardiopulmonary compromise. Any hemodynamic instability should suggest the presence of tension pneumothorax, which requires immediate needle decompression followed by tube thoracostomy.

Conservative treatment (observation) of a pneumothorax involving $<15\%$ of the total hemithorax volume is recommended by most experts. It is estimated that pleural air is spontaneously reabsorbed at a rate of 1% to 1.5% of the volume of the hemithorax

per day. Therefore, a small pneumothorax (<15%) would be expected to be reabsorbed within 10 to 15 days.

Evacuation of a larger pneumothorax by simple aspiration, pigtail catheter placement or tube thoracostomy is recommended. Surgical management is indicated in patients with recurrent spontaneous pneumothorax or a persistent air leak 5 to 7 days after placement of pigtail or chest tube.

A pneumothorax that occurs in the setting of chest wall trauma should be treated with a tube thoracostomy to drain a possible coexisting hemothorax. These patients require admission to the hospital and close monitoring.

Management of pneumomediastinum is conservative studies have shown that there is no need for antibiotics or further diagnostic testing unless there is a history of recent instrumentation or vomiting.

CRITICAL INTERVENTIONS

- Perform immediate needle decompression on patients with suspected tension pneumothorax.
- Insert a chest tube or pigtail catheter for patients with a moderate to large pneumothorax (>15%).
- Perform CT chest on individuals with suspected pneumomediastinum and negative chest radiograph.
- Perform an esophagoscopy on patients with pneumomediastinum and suspected esophageal rupture (e.g., history of recent instrumentation or forceful vomiting).
- Look for underlying trauma or needle penetration as a cause of the pneumothorax or pneumomediastinum.

DISPOSITION

Appropriate disposition of patients with spontaneous pneumothorax depends on the size of the pneumothorax, the therapeutic approach chosen, the reliability of the patient, and the availability of outpatient follow-up.

Patients with a small primary spontaneous pneumothorax (<15%) for which the physician has opted for conservative management (i.e., observation and spontaneous reabsorption) should have a follow-up radiograph within 6 hours to make sure the pneumothorax has not enlarged. If it has not, a follow-up radiograph should be performed in 7 to 10 days. Patients should be instructed to return for any increase in shortness of breath or chest pain or the development of fever.

Patients who have undergone placement of a pigtail catheter or a tube thoracostomy must be admitted to the hospital. The catheter or thoracostomy tube is connected to continuous suction. These patients do not require monitoring and do not require admission to an intensive care unit unless there is significant underlying pulmonary or cardiac disease.

Patients with spontaneous pneumomediastinum are usually admitted for 24 hours of monitoring, although patients with reliable follow-up could potentially be discharged. Studies indicate that, in the absence of risk factors for esophageal perforation, this is a benign entity with an uneventful course.

Common Pitfalls

- Failure to perform esophagoscopy in patients with spontaneous pneumomediastinum and suspected esophageal rupture.
- Management of spontaneous pneumothorax by observation alone can save hospitalization and healthcare costs only if employed in the appropriate circumstances and only if the patient is compliant and receives appropriate discharge instructions.

CHAPTER 79

Pulmonary Embolism

Prathap Sooriyakumaran and Jeffrey A. Tabas

Pulmonary embolism (PE) is a relatively common, life-threatening condition that presents a diagnostic dilemma for the emergency practitioner. The incidence in the United States is estimated at 650,000 to 900,000 patients per year, resulting in as many as 200,000 deaths per year (1). This makes PE the third leading cause of cardiovascular death. Correct diagnosis and treatment significantly decreases morbidity and mortality (2). Accurate diagnosis is essential, as a missed or delayed diagnosis is associated with increased rates of adverse outcomes (3), and over diagnosis subjects a patient to the risks of unnecessary anticoagulation as well as to the psychological and financial implications of carrying such a diagnostic label.

CLINICAL PRESENTATION

Pulmonary emboli may result from a myriad of causes. Most commonly, emboli arise from thrombi in the legs, but they may also originate from anywhere in the venous system proximal to the pulmonary arteries, such as pelvic veins, nonportal abdominal veins, upper-extremity veins, or right-sided heart valves. Other sources include fat emboli, usually in association with long-bone fractures, amniotic fluid emboli (in the setting of labor and delivery), air emboli, and septic emboli.

The signs and symptoms of pulmonary emboli result from the effects of obstructed pulmonary vasculature. This may result in local tissue ischemia or infarct, increased ventilation–perfusion mismatch that can cause increased alveolar dead space or increased alveolar–

arterial oxygen gradient, and increased pulmonary vascular resistance that can cause right heart strain or failure. The spectrum of presentation varies from asymptomatic patients to those with mild subjective complaints to hemodynamically unstable patients with severe hypotension, respiratory failure, or pulseless electrical activity. The terms “submassive” and “massive” PE both describe symptomatic PE, with a systolic blood pressure less than 90 typically used to distinguish “massive” hemodynamically unstable PE, from “submassive” hemodynamically stable PE that nonetheless has some degree of right ventricular dysfunction and increased pulmonary hypertension. Differences in size, quantity, and location of emboli as well as underlying patient characteristics (such as cardiopulmonary reserve) contribute to the wide spectrum of presentation.

The most common signs and symptoms associated with the presence of PE are listed in Table 79.1 (4). A prospective cohort study of 7,940 patients with diagnosed PE found that patient history of PE or deep vein thrombosis (DVT), unilateral leg swelling, surgery within the previous 4 weeks, current estrogen use and hypoxemia (saturation $<95\%$) were the strongest predictors of PE, with odd ratios (OR) between 2 and 3 (5). Common symptoms investigated include dyspnea (OR 1.26), pleuritic chest pain (OR 1.53), and symptoms of DVT such as unilateral leg swelling (OR 2.60). Although low-grade fever is not infrequent, temperatures $>38.5^{\circ}C$ are less common and suggest other causes (temperature $>38.5^{\circ}C$ had an OR of 1.13, but this was not statistically significant). Unfortunately, many of these signs and symptoms are manifestations of other conditions, and there is no combination of clinical findings that has been shown to be diagnostic for PE. In addition, the “classic” triad of hemoptysis, pleuritic chest pain, and tachypnea is uncommon.

TABLE 79.1
Relative Frequency of Presenting Symptoms and Signs in Patients with PE

Symptom	Sign
Dyspnea, 73%	RR >20/min, 70%
Pleuritic pain, 66%	Rales, 51%
Cough, 37%	Tachycardia, 30%
Leg swelling, 28%	Loud P2, 23%
Leg pain, 26%	Temp. >38.5°C, 7%
Hemoptysis, 13%	Wheezes, 5%

PE, pulmonary embolism; RR, respiratory rate; Temp., temperature.

Classic risk factors (Table 79.2) for thrombosis include Virchow's triad of hypercoagulability, venous stasis, and endothelial injury. Commonly acquired hypercoagulable states include cancer, pregnancy, and estrogen therapy. There is increasing understanding and discovery of heritable thrombophilias, but these risk factors are often unknown at the time of presentation. Venous stasis may result from prolonged immobilization, recent surgery, extended travel, or medical conditions such as paraplegia or previous stroke. Damage to the vascular endothelium may result from fractures, surgery, catheter placement, or other forms of trauma. Demographic factors, such as advanced age, should also be taken into consideration. However, up to 30% of patients with a diagnosed PE have no known risk factors. In summary, although the presence of risk factors increases suspicion for PE, lack of known risk factors does not exclude the diagnosis.

TABLE 79.2
Risk Factors for PE

Prior thrombus or thromboembolism
Family history of thrombosis
Cancer
Prolonged immobilization—paralysis, lower-extremity cast, travel
Pelvic or lower abdominal surgery, <6 mos
Cerebral vascular accident
Congestive heart failure
Lower-extremity or pelvic trauma/fractures/surgery
Obesity
Estrogen therapy—oral contraceptives, hormone replacements
Pregnancy or postpartum
Inflammatory bowel disease
Age >40 yrs
Smoking
Thrombophilias (e.g., Factor V Leiden, Protein C or S deficiency, etc.)

PE, pulmonary embolism.

DIFFERENTIAL DIAGNOSIS

Given the wide spectrum of signs and symptoms associated with PE, the differential diagnosis in most presentations is extensive. Other causes of dyspnea or chest pain include pulmonary and cardiac causes such as chronic obstructive pulmonary disease (COPD) or asthma, congestive heart failure (CHF), pulmonary infections, pericarditis, acute coronary syndrome, aortic dissection, pneumothorax, trauma, or musculoskeletal pain. Abdominal sources such as biliary colic or pancreatitis may mimic a PE. The evaluation can be complicated by the fact that conditions such as CHF can both mimic signs and symptoms of PE as well as be a risk factor for PE. Musculoskeletal pain and anxiety are always diagnoses of exclusion and should be made only after more life-threatening causes have been confidently eliminated.

ED EVALUATION

Initial management of PE consists of rapid assessment and stabilization for immediate life-threatening conditions. When appropriate, intravenous access should be established, and cardiac and pulse oximetry monitors should be placed. Laboratory testing,

electrocardiography, and chest radiography should be expedited. The probability of disease (see subsequent text) should be determined based on the patient's signs, symptoms, identifiable risk factors, and the presence of an acceptable alternate diagnosis.

A complete blood count and serum chemistry panel are usually indicated in the general assessment of any patient with chest pain or shortness of breath. A creatinine level is helpful if contrast administration is planned. All patients suspected of having a PE should undergo an electrocardiogram (ECG). The ECG is a nonspecific test for PE, and the primary purpose is to detect other disease processes such as pericarditis or acute coronary syndromes. The most common ECG findings in patients with PE are nonspecific ST and T-wave abnormalities. Other common findings include tachycardia and T-wave inversion in the anterior precordial leads (V1 to V4). The classic ECG finding of S1Q3T3, consisting of an S wave in lead 1, and a Q wave with a flipped T wave in lead 3, is neither sensitive nor specific for PE. In a secondary analysis of a prospective, observational cohort of 6,049 ED patients who were tested for PE and had an ECG, both the findings of S1Q3T3 and T-wave inversions in V1 to V4 had positive likelihood ratios (LR+) of 3.7 and tachycardia had a LR+ of 1.8 (6). These findings were infrequent overall, but were observed more frequently in patients with the final diagnosis of PE compared to patients who did not have PE.

A chest radiograph should be obtained for patients with suspected PE. Given the lack of specific findings for PE, the primary purpose is again to detect other disease processes, such as a pneumothorax, pulmonary edema, malignancy, or pneumonia. In one large study of patients with proven PE, the most common chest radiographic interpretations were cardiac enlargement (27%), normal (24%), pleural effusion (23%), elevated hemidiaphragm (20%), pulmonary artery enlargement (19%), atelectasis (18%), and parenchymal pulmonary infiltrates (17%). Cardiomegaly is a common associated finding with PE, given that CHF is a risk factor. Classic radiographic findings, which occur infrequently, include Westermark sign (a prominent central pulmonary artery with decreased pulmonary

vasculature distally) and Hampton's hump (a wedge-shaped, pleural-based opacity representing pulmonary infarct) (7).

Arterial blood gases are rarely helpful in the evaluation of PE. One analysis of more than 100 patients with PE who lacked prior cardiopulmonary disease revealed that 38% had a normal alveolar–arterial (A–a) gradient. Patients with prior cardiopulmonary disease who proved not to have PE, had an elevated A–a gradient 24% of the time (8). One potentially useful scenario may occur when a patient is found to have a large, unexplained A–a gradient. However, these authors rarely obtain arterial blood gases for suspected PE alone.

Based upon the history, physical examination, and preliminary laboratory evaluation, the clinician should categorize a patient into very low (<2%), low (2% to 15%), moderate (15% to 40%), or high probability (>40%) suspicion for PE. Several clinical decision rules have been developed in an attempt to improve implicit clinician judgment, however, they appear to be no better than gestalt assessment by experienced providers in predicting probability of PE (9,10). These rules appear to be most effective at improving risk stratification for the clinically inexperienced practitioner and to provide some uniformity of approach within a department. The Wells Criteria (Table 79.3) is the most extensively tested decision rule. A modified approach, in which patients with a score less than or equal to 4 are considered safe for D-dimer testing and those greater than 4 are not, has been shown to be safe and effective (11).

TABLE 79.3
Criteria of Wells et al. for Assessment of Pretest Probability for PE

Criterion	Points
Suspected DVT	3.0
An alternative diagnosis less likely than PE	3.0
Heart rate, >100 beats/min	1.5
Immobilization or surgery in previous 4 wks	1.5
Previous DVT/PE	1.5
Hemoptysis	1.0
Malignancy (on treatment, treated in the past 6 mos or palliative)	1.0
Score range (points)	Interpretation of risk
0–2	Low
3–6	Moderate
>6	High

DVT, deep venous thrombosis; PE, pulmonary embolism.

Evaluation for PE should be based on pretest probability. See Figure 79.1 for an algorithm summarizing our recommendations for how to proceed with the evaluation for PE. The results of diagnostic testing should be used to determine sequentially what further evaluation is needed to exclude or confirm the presence of PE. A posttest probability of 1% to 2% is a generally accepted risk level. This would presumably lead to a subsequent complication rate of $<0.7\%$. Some patients and physicians may be willing to accept more or less risk.

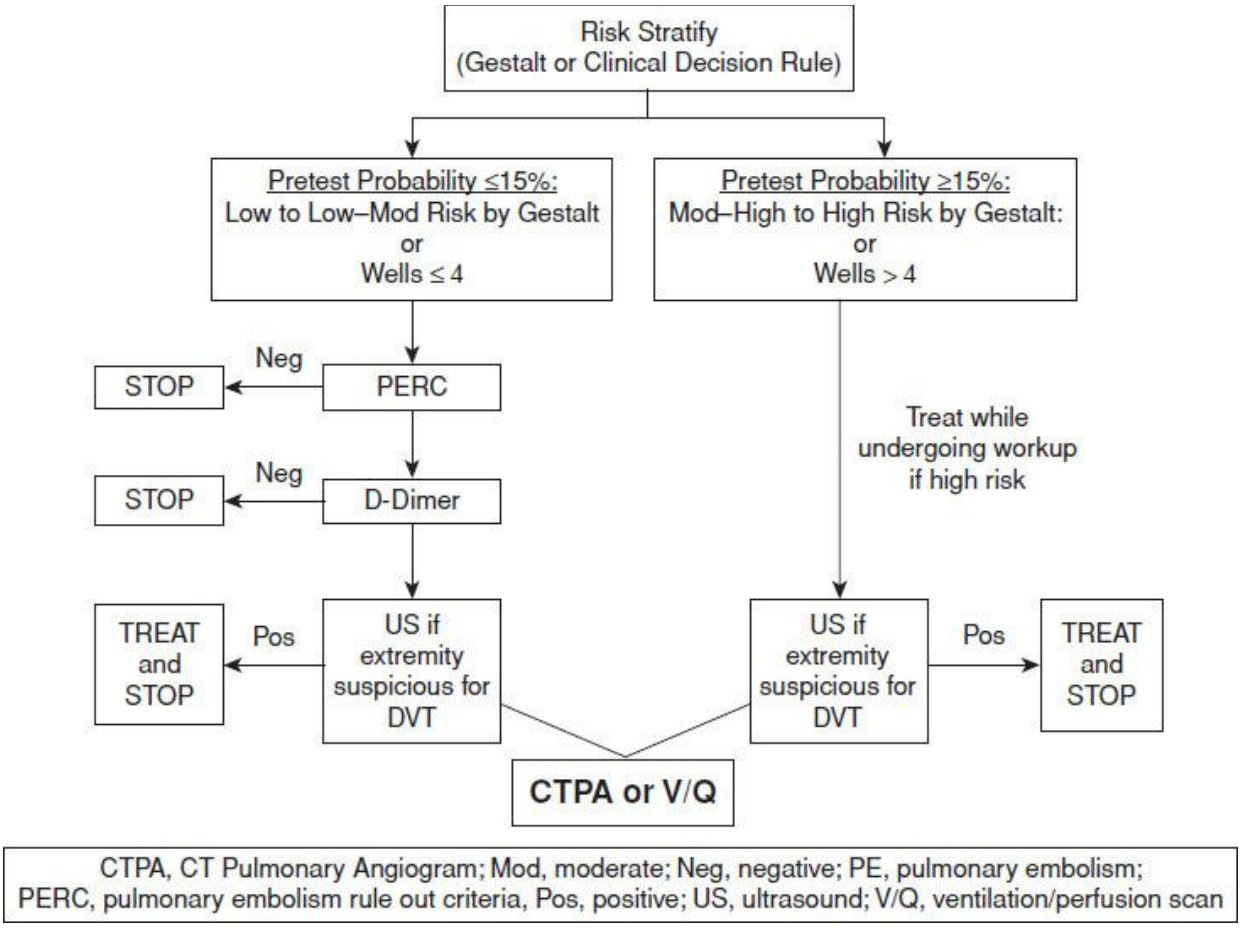

FIGURE 79.1 Workup of PE in the ED.

For patients who are low to low-moderate probability (less than 15%) stratified either by clinical decision rule or gestalt, Kline et al. (12) have demonstrated that patients with a zero score on the Pulmonary Embolism Rule Out Criteria (PERC) do not need further evaluation for PE. PERC consists of 8 criteria (Table 79.4). When none of these are present in patients with low to low-moderate pretest probability, the risk of PE or death is similar to that of patients with negative V/Q or CT pulmonary angiography. In a meta-analysis of 11 studies investigating the diagnostic performance of PERC for PE, the pooled sensitivity and specificity was 0.97 (95% confidence interval 0.96 to 0.98) and 0.23 (95% confidence interval 0.22 to 0.24), respectively (13). For patients with less than 15% pretest probability who are PERC positive, the next step in evaluation is a D-dimer test. D-dimers are degradation products of

cross-linked fibrin and are therefore elevated when there is activation of the coagulation pathway, as occurs in the setting of PE. Because of their nonspecific nature, D-dimers are also elevated in other conditions such as cancer, pregnancy, recent trauma, and even CHF. When used appropriately, a sensitive D-dimer assay is an effective screening test for PE, eliminating the need for further radiologic imaging. Most current assays show sensitivities as high as 90% to 95%. Bayesian analysis reveals that in a patient with 15% pretest probability (the upper limit of "low probability"), a negative likelihood ratio of 0.12 or less is required to provide a posttest probability of <2%. Most of the rapid, sensitive D-dimer tests demonstrate negative likelihood ratios within this range. Therefore, a negative result using currently available rapid, sensitive D-dimer assays is adequate to exclude PE in a patient with low to low-moderate pretest probability (14,15). Note that a positive D-dimer result has little impact on posttest probability.

TABLE 79.4
Pulmonary Embolism Rule-Out Criteria (PERC)

Criterion (All must be met to apply PERC)
Age ≤50
Heart rate <100
Oxygen saturation on room air >94%
No prior history of DVT/PE
No recent trauma or surgery
No hemoptysis
No exogenous estrogen
No clinical signs suggesting DVT

DVT, deep venous thrombosis; PE, pulmonary embolism.

For low to low-moderate pretest probability patients (<15%) with positive PERC and D-dimer testing, and for moderate to high risk patients, imaging is required. When discussing the diagnostic accuracy of radiographic imaging of patients with suspected PE, it is important to remember that the goal of imaging is to detect the presence of any venous thromboembolism (VTE) to guide the

initiation of treatment. Although patients with small or subsegmental pulmonary emboli may present with milder signs and symptoms, there is insufficient evidence to conclude that patients with "clinically insignificant" presentations are at a lower risk of recurrence than those with more clinically evident presentations (2).

Lower-extremity imaging for DVT in the assessment of suspected PE is most useful when there are clinical signs and symptoms in that extremity. Fifteen to twenty-five percent of patients with PE have clinically evident DVT (16). Bilateral lower-extremity imaging in a patient without clinical findings of DVT is probably of limited value except for unusual circumstances.

Ventilation/perfusion (V/Q) scanning involves low radiation exposure and displays high sensitivity. However, frequently indeterminate results and lack of information about other diagnoses have limited the use of the test in the evaluation of PE. Administration of an intravenous radioactive isotope is used to measure perfusion of the pulmonary vasculature, and administration of an inhaled radioactive isotope is used to measure pulmonary ventilation. A normal or near-normal result is 98% sensitive for the exclusion of PE. As with most tests, the V/Q scan should be interpreted within the context of pretest probability (Table 79.5). A low pretest probability with a low probability V/Q scan makes PE unlikely, and a high probability scan with a high pretest probability is considered diagnostic for PE. However, discordant results or intermediate probability scans, which account for a significant portion of results, mandate further studies. An indeterminate result is most common in patients with COPD, pre-existing cardiopulmonary disease, or markedly abnormal chest radiographs. V/Q scanning for assessment of suspected PE is appropriate when it is the only imaging modality available, in patients with a normal chest radiograph (and therefore likely to obtain a diagnostic result), or in patients who have contraindications to other imaging studies, such as contrast allergy or renal insufficiency. V/Q scanning is most likely to be diagnostic in patients with normal chest radiographs.

TABLE 79.5
Probability of Pulmonary Embolism Based on Clinical Suspicion and Results of Ventilation/Perfusion (V/Q) Scan

	V/Q Results			
Clinical Suspicion	High (%)	Intermediate (%)	Low (%)	Normal or Near-Normal
High	96	66	40	N/A
Intermediate	88	28	16	6%
Low	56	16	4	2%
All patients	87	30	14	4%

Adapted from The PIOPED Investigators. Value of the ventilation perfusion scan in acute pulmonary embolism: Results of the prospective investigation of pulmonary embolism diagnosis (PIOPED). *JAMA*. 1990;263:2753–2759.
NA, not applicable.

Computed tomography pulmonary angiography (CTPA) has high sensitivity and specificity for PE and, in about one-third of cases, demonstrates an alternative diagnosis, such as pneumonia, cancer, or aortic dissection. It is not particularly invasive and requires only a single breath-hold. Reported sensitivities for CTPA vary depending on scanner technology. A prospective multicenter study designed to assess the efficacy of multidetector CTPA (4, 8, and 16 row), reported a sensitivity of 83% and specificity of 96%. The addition of CT venography to CTPA increased sensitivity and specificity to 90% and 95%, respectively (17).

Pulmonary angiography, the traditional gold standard for the diagnosis of PE, is rarely performed. It has a false-negative rate of 1% to 2% and an indeterminate study rate of 3%. Significant complications include death in 0.5%, major nonfatal complications in 1%, and minor complications in up to 5%.

Transthoracic or transesophageal echocardiography may be helpful in the assessment of PE, especially in the unstable patient. Echocardiographic findings in patients with PE include right ventricular dilatation and hypokinesis, septal flattening and paradoxical motion, failure of the inferior vena cava to collapse during inspiration and, rarely, direct visualization of the thrombus.

Evaluation of the pregnant patient poses a particular challenge for the emergency department (ED) practitioner. Pregnancy increases risk of venous thrombosis up to fivefold. For women whose pregnancies result in a live birth, PE is the leading cause of death. Although exposure of the fetus to radiation is clearly undesirable, the safety of the mother takes priority. Evaluation of the stable pregnant patient with symptoms of PE may include a rapid sensitive D-dimer test in a low-suspicion patient (although specificity in pregnancy will be significantly decreased), ultrasonographic evaluation of the lower extremities (which if positive, will allow initiation of anticoagulation and deferral of further evaluation), and V/Q scanning or CTPA. Current literature suggests that radiation exposure from CTPA to the fetus, especially in the first or second trimester, is lower than radiation exposure from V/Q scanning (18).

ED MANAGEMENT

As with any critically ill patient, the emergency physician should start with the "ABCs." Intravenous access, cardiopulmonary monitoring, and oxygen therapy should be initiated. The patient's airway should be maintained and, if severely hypoxic, the patient should be emergently intubated. Hypotensive patients should be fluid resuscitated while more definitive treatments are being considered.

The goal of treatment in PE is primarily aimed at life-saving restoration of flow through occluded pulmonary arteries, or the prevention of potentially fatal early recurrences as well as long-standing damage from the initial insult (pulmonary hypertension and symptomatic right ventricular dysfunction). Anticoagulation remains the primary treatment for patients with PE. Anticoagulation should be initiated for high-risk patients while confirmatory studies are pursued. Typically patients are treated with 6 to 12 months of Coumadin, with initial treatment with heparin until a therapeutic INR is achieved. Intravenous unfractionated heparin or low-molecular-weight heparin (LMWH) has been shown to be equally effective in the treatment of pulmonary emboli. The advantages of LMWH are thought to include ease of use (subcutaneous instead of intravenous) and lack of need for laboratory monitoring, though the

disadvantages include cost. However, a trial comparing fixed-dose unfractionated heparin, delivered subcutaneously without laboratory monitoring (333 U/kg SC initial dose, then 250 U/kg SC every 12 hours), to LMWH (100 IU/kg every 12 hours SC) found them to be of equivalent safety and effectiveness in patients with VTE (20% with PE) (19).

The FDA has approved the use of enoxaparin and tinzaparin: the dosing for enoxaparin is 1 mg/kg subcutaneously every 12 hours and for tinzaparin 175 anti-Xa IU/kg subcutaneously once daily. Contraindications include renal insufficiency, obesity, or weight <40 kg. If intravenous unfractionated heparin is used, weight-based dosing has been shown to be superior to standard dosing, with more rapid time to therapeutic levels and decreased rates of recurrence and complications. Patients should receive an initial bolus of 80 U/kg and then an infusion of 18 U/kg/hr. The activated partial thromboplastin time is measured every 4 to 6 hours and should be maintained at 1.5 to 2.3 times the control, with adjustment based on an established nomogram.

New anticoagulants being developed may ultimately show improvement over unfractionated heparin and LMWH. These new agents include direct thrombin inhibitors, direct and indirect factor Xa inhibitors, activated protein C, and tissue factor pathway inhibitors. Some of their superior properties include once-daily dosing without monitoring, oral administration, and improved pharmacodynamic profiles. The FDA has recently approved rivaroxaban, a factor Xa inhibitor, for VTE prophylaxis and treatment. EINSTEIN-PE, a randomized, open label study with 4,832 PE patients, showed noninferiority of rivaroxaban (15 mg twice daily for 3 weeks, followed by 20 mg once daily) compared to standard treatment with enoxaparin followed by an adjusted-dose vitamin K antagonist for 3, 6 or 12 months (20). The advantages of rivaroxaban compared to vitamin K antagonists such as warfarin, which patients who are started on unfractionated heparin or LMWH are transitioned to, include more stable pharmacokinetic and pharmacodynamic profiles which allows for it to be prescribed in a fixed dose without the requirement of frequent monitoring. A significant disadvantage is

a lack of an antidote. Prothrombin complex concentrate (PCC) has been shown to reverse the effects of rivaroxaban on coagulation tests such as prothrombin time although the benefit in clinically reversing bleeding effects has not been studied (21).

For patients with hemodynamic instability resulting from PE, thrombolytic therapy is considered the treatment of choice. Despite this, in a modern cohort of ED patients with massive PE, analysis of the Emergency Medicine Pulmonary Embolism in the Real World Registry (EMPEROR) showed only 12% of these patients received thrombolytic therapy (22). Thrombolytics rapidly improve hemodynamic status by acutely reducing clot burden. The FDA has approved recombinant tissue plasminogen activator (r-TPA), streptokinase, and urokinase for the treatment of massive PE. The dosage used for r-TPA, which has been shown in several small studies to be associated with slightly better outcomes, is a 10-mg intravenous bolus and 90 mg over the next 2 hours. If streptokinase is used, the dosage is 250,000 IU over 30 minutes and then 100,000 IU an hour for 24 hours. Urokinase dosage is 4,400 IU/kg over 10 minutes followed by 4,400 IU/kg an hour for 12 to 24 hours. Before initiation of thrombolytic therapy, unfractionated heparin should be administered in full therapeutic doses (i.e., bolus followed by infusion). The heparin infusion should be suspended during delivery of thrombolytic therapy. The activated partial thromboplastin time should be checked immediately after completion of thrombolytic therapy and repeated until it is <80 seconds, at which point the heparin infusion should be restarted (without a bolus).

Current evidence is still insufficient to strongly support (or oppose) administration of thrombolytics to patients with acute right ventricular dysfunction or pulmonary hypertension from PE (i.e., patients with “submassive” PE). The Moderate Pulmonary Embolism Treated with Thrombolysis (MOPETT) trial tested the efficacy of half dose or “safe dose” thrombolysis in submassive PE. There is face validity that reducing the dose for PE would result in reduced complications while maintaining efficacy. Because the pulmonary vasculature receives the entire cardiac output, a given dose of drug would be expected to have greater effect than in the brain, which

receives 15% of cardiac output, or coronary arteries, which receive 5%. This treatment resulted in statistically significant benefit for the composite outcome of recurrent PE and death ($p = 0.0489$) (23). The Pulmonary EmbolIsm THrOmbolysis (PEITHO) study (24) compared full dose thrombolytics versus heparin therapy in 1,006 randomized patients with submassive PE over a 10-year period. Preliminary data presented at the American College of Cardiology 2013 Summer Sessions, showed significant benefit (absolute risk reduction of 3% in death or hemodynamic collapse) which was balanced by significantly higher rates of major bleeding.

Pulmonary embolectomy (catheter-directed or surgical) is an uncommon procedure, but it may be used as treatment for hemodynamically unstable patients with contraindications to thrombolytics or when thrombolytics are not available.

CRITICAL INTERVENTIONS

- Risk-stratify patients into low, moderate, or high probability for PE based upon the history, physical examination, and preliminary laboratory evaluation.
- Anticoagulate patients with a high clinical suspicion for thromboembolism before definitive studies are performed. Significant delays in initiation of anticoagulation can negatively impact outcomes.
- Administer thrombolytic therapy for patients with hemodynamic instability caused by PE.

DISPOSITION

Patients diagnosed with PE are generally admitted to the hospital. An RCT of outpatient versus inpatient treatment in low-risk PE patients found no difference in safety (25). However, the exclusion criteria were so stringent, including patients with BP <100 or hypoxia, patients deemed unreliable (broadly defined), patients who were obese and patients who received IV pain medication, that very few patients meet these criteria. If admitted, patients who are hemodynamically stable may go to a nonmonitored setting. If

unstable, they should be observed in the intensive care unit or a telemetry bed. Patients diagnosed with DVT who show no evidence of PE are routinely treated as outpatients, initially with LMWH and warfarin (see Chapter 96, "Deep Venous Thrombosis and Thrombophlebitis"). These patients transition off heparin in the outpatient setting.

Common Pitfalls

- Failing to consider PE in a patient presenting with pleuritic chest pain, dyspnea, or tachypnea in whom there is no convincing alternative diagnosis
- Failing to recognize that lack of risk factors does not exclude PE
- Failing to recognize atypical presentations, such as syncope, in the elderly
- Mistaking nonspecific radiographic findings of PE for an alternative diagnosis such as pneumonia in a patient with atelectasis on chest radiography
- Failing to apply PERC or D-dimer testing to avoid radiographic imaging in appropriate patients
- Failing to recognize that PE can recur in a patient who is adequately anticoagulated

CHAPTER 80

Hemoptysis

Sanjay Bhatt

Coughing up blood is a significant cause of concern to both the provider and patient. While a common symptom in adults, it is an uncommon presentation in children. The differential diagnosis can be diverse and includes pulmonary pathology as well as pseudohempotysis caused by ear, nose, and throat (ENT) or gastrointestinal pathology. Although typically indicative of primary pulmonary pathology, hemoptysis may result from numerous systemic illnesses. It is important to note that the severity of bleeding does not correlate with the gravity of the underlying disease.

Hemoptysis is attributed to multiple underlying pathophysiologic mechanisms. Bleeding sources include bronchial and pulmonary arteries. In general, bronchial arteries are under high-pressure systems whereas pulmonary are under low-pressure systems. Massive bleeding, which accounts for 1.5% of cases, usually arises from injury to the high-pressure bronchial arteries (1–3). The cause of bleeding depends on the underlying etiology. Exsanguination is rarely the cause of death in hemoptysis; rather, blood can obstruct distal alveoli thereby impairing gas exchange. In these cases, death can result from hypoxemia. There are several possible causes for bleeding; Table 80.1 lists the multitude causes of bleeding in a patient presentation to the emergency department (ED).

TABLE 80.1
Mechanisms of Bleeding in Hemoptysis

Malignancies: Invade vessels, or the tumor itself may become necrotic
Inflammatory and infectious problems: Vascular engorgement of the tracheo-bronchial mucosa
Bronchiectasis: Associated with abnormal vascular anastomoses between bronchial and pulmonary arteries
Lung abscesses: Bronchial ulceration and necrosis
Mycetomas of cavitary TB: Rupture and cause life-threatening hemorrhage
Left ventricular failure or mitral stenosis: Increased intravascular pressure with capillary and venous rupture
Pulmonary embolism: Infarction of lung parenchyma
Goodpasture syndrome: Breakdown of the alveolocapillary basement membrane
Aortic aneurysm: Erosion into adjacent vascular structures
Coagulopathy: Exacerbation of an underlying reason for bleeding
Cocaine: Intense vasoconstriction with cell injury

TB, tuberculosis.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Patients may present to the ED with a chief complaint of "coughing up blood." The extent of this bleeding can range from minor to copious. While the vast majority of patients have stable vital signs, those with pulmonary compromise may reflect some degree of tachycardia. Those with severe bleeding may show signs of hypoxemia, hemodynamic instability, and/or airway compromise. Patients with systemic diseases, such as Goodpasture syndrome, may present with hematuria and hemoptysis.

Pseudohemoptysis should be excluded before the pulmonary causes of hemoptysis are entertained. An appropriate history and physical examination can eliminate gastrointestinal and otolaryngologic sources. The vomitus of gastrointestinal bleeding tends to be darker in color and may contain food particles. In comparison, true hemoptysis is typically bright red and frothy. Mouth, throat, and nasopharyngeal sources of bleeding may be visualized with direct, indirect, or fiberoptic laryngoscopy.

The etiology of hemoptysis worldwide can vary by country (4). In the United States, the most common causes include infections, malignancy, bronchiectasis, bronchitis, and cardiovascular disorders

(5–7). Chronic obstructive pulmonary disease is an independent risk factor for hemoptysis (1). Worldwide, while tuberculosis (TB) is still the most common cause of hemoptysis, it is much less common in the United States (8). In areas such as New York City or Los Angeles that house a large TB population, this diagnosis must be considered.

While uncommon, patient with systemic lupus erythematous (SLE) may present with alveolar hemorrhage and resultant hemoptysis (9). Travelers or immigrants, especially those from Asia, the Middle East, and South America, may have parasitic infections (3). Catamenial hemoptysis, which is hemoptysis during menstruation, may occur in women with thoracic endometriosis (1,10). In those who are immunocompromised, bacterial pneumonia is a common diagnosis while in the HIV population, Kaposi's sarcoma must be considered (1).

Independent of coagulation parameters, patients on immunosuppressive medications, or those with a history of transbronchial biopsy or lung transplant, are at an increased risk for hemoptysis after bronchoscopy (11). It is important to note that the mortality rate among lung transplant patients who present with hemoptysis is high (12). Occult malignancy should always be considered, especially in those with a long-standing smoking history.

Three potential biologic weapons that may present with hemoptysis include plague, tularemia, and T2 mycotoxin (2). Table 80.2 lists the common causes of hemoptysis by category.

TABLE 80.2
Common Causes of Hemoptysis

- Inflammatory
  - Bronchitis
  - Bronchiectasis
  - Lung abscess
  - Pneumonia (viral, bacterial, and fungal)
  - Tuberculosis
  - Parasites (e.g., ascariasis and schistosomiasis)
- Neoplastic
  - Bronchial adenoma
  - Bronchogenic carcinoma
- Cardiovascular
  - Arteriovenous malformation
  - Arteriovenous fistula
  - Congestive heart failure
  - Aneurysm
  - Pulmonary thromboembolism
  - Primary pulmonary hypertension
  - Mitral stenosis
  - Vascular injury (e.g., foreign body)
- Congenital
  - Cystic fibrosis
- Immunologic
  - Collagen vascular disease
  - Vasculitis
  - Goodpasture syndrome
- Extrapulmonary Disease
  - Thrombocytopenia
  - Coagulopathies
  - Trauma
- Drugs
  - Anticoagulants
  - Cocaine
  - Thrombolytics

In pediatric patients, lower respiratory tract infections account for almost 40% of all presentations of hemoptysis. Other causes include cystic fibrosis (CF), foreign-body aspiration, bronchial adenomas, and trauma. All providers must be aware of accidental as well as deliberate trauma; bleeding caused by deliberate suffocation has

been described (1). CF may be associated with recurrent, severe bleeding in both children and young adults. Hemoptysis in children with CF occurs with increasing age and advancing disease and almost 60% of children will have at least one episode. Most of these episodes are not life-threatening (13). Although congenital heart disease and mitral stenosis after rheumatic fever are still reported causes of hemoptysis, corrective surgery for the former and decreasing incidence of the latter make them infrequent causes of bleeding (13). Other uncommon causes include bronchiolitis obliterans organizing pneumonia (7), pulmonary embolism, Wegener granuloma, primary pulmonary hemosiderosis, and arteriovenous malformations (AVMs) (5,13).

ED EVALUATION

Patients with massive hemoptysis require initial focus on the airway, breathing, and circulation (ABCs) of support; as noted above, especially given concern for asphyxiation and lesser so exsanguination. The ABCs take precedence to making a definitive diagnosis. While providers agree that massive hemoptysis describes the expectoration of a large amount of blood *or* a rapid rate of bleeding, the thresholds that define massive hemoptysis remain controversial. Thresholds range from 100 to 1000 mL (14) over 24 hours though none has been generally accepted. Some clinicians argue that abnormal gas exchange and hemodynamic instability, generally tachycardia or tachypnea, should be part of the definition.

Nevertheless, patients who present with what is termed “massive” hemoptysis have a mortality rate close to 50% (6). Similar to the adult definition, the pediatric definition of massive hemoptysis can vary; some sources define the rate of bleeding as 8 mL/kg/24 hrs (13). While massive versus submassive bleeding carries both diagnostic and prognostic implications, this differentiation is difficult to perform in the ED. Similar to adult presentation, mortality is primarily due to asphyxiation and lesser so exsanguination.

Most series list TB and bronchiectasis as the most common causes of massive hemoptysis; other diseases include lung abscesses, malignancy, Goodpasture syndrome, Behçet disease, AV malformations, trauma, coagulopathies, and aspergillomas (3).

As almost any amount of bleeding may prove detrimental to patients with limited cardiopulmonary reserve or significant underlying disease, baseline cardiopulmonary status, and overall physical condition must weigh into a physician's decision to pursue aggressive measures. History, physical examination, and laboratory studies can help evaluate the patient's ability to respond to the physiologic stress of hemoptysis and the therapy it necessitates.

Once a patient has been stabilized, efforts to determine the cause of hemoptysis should include a thorough history and physical examination. Laboratory studies should include: a complete blood count to determine the chronicity and magnitude of bleeding and the need for a platelet transfusion; a urinalysis and creatinine values in those whom pulmonary renal syndromes are being considered; arterial blood gas analysis and a pulse oximetry to determine oxygenation; coagulation studies to determine whether fresh-frozen plasma may be of benefit; and sputum evaluation in those whom TB is considered, radiograph studies should include a chest x-ray to evaluate for a multitude of diagnosis including neoplasm and focal infections. A chest computed tomography may better identify malignancies, infections, and pulmonary emboli. The combination of high-resolution CT scan and bronchoscopy is the standard by which a diagnosis is established (2,4,15). Definitive diagnosis may require sputum cytology, pulmonary function testing, angiography, or specialized sputum studies (2,15).

Aggressive management must occur at the same time as evaluation. Some diagnostic modalities, most notably bronchial artery embolization, are both diagnostic and therapeutic (4,16–18). Some centers are now using a new technique of bronchoscopic endobronchial sealing with cyanoacrylate (19).

Even after exhaustive study, 10% of cases will have no identifiable etiology (3). These patients are classified as having idiopathic or cryptogenic hemoptysis; in these cases, it is presumed

that subtle airway or parenchymal disease is the culprit. Close follow-up to exclude repeat presentation and malignancy is especially important (20).

KEY TESTING

- Pulse oximetry
- CXR
- CBC
- Coagulation studies

ED MANAGEMENT

The primary goals of therapy are threefold: airway control to prevent asphyxia and less likely exsanguination, termination of bleeding, and diagnosis and treatment of the underlying cause. As noted above, patients with massive hemoptysis require initial focus on the ABCs of support. Airway control and adequate oxygenation are the immediate priorities. Endotracheal intubation, which may be technically challenging especially in this setting, is the intervention of choice, especially in those with poor gas exchange, hemodynamic instability, rapid ongoing hemoptysis, and at physician discretion. Placing a large 8.0 lumen tube can facilitate suctioning and the passage of a fiberoptic laryngoscope. Bag-valve-mask ventilation may be difficult in the patient with massive bleeding as blood may further block the tracheobronchial tree. The provider should consider selective intubation and, if readily available may consider a double-lumen endotracheal tube. Unilateral intubation, often performed in conjunction with a localizing bronchoscopic examination, can ventilate the nonbleeding lung. A localizing bronchoscopic examination is essential because of the importance of ventilating the proper lung as well as ensuring that the right upper lobe bronchus is not blocked as a result of the procedure. Another option is selective intubation using a fiberoptic laryngoscope. If the suspected bleeding lung or pathologic lesion is on the left side, the right mainstem bronchus may be selectively intubated by advancing an endotracheal tube past the carina. Normal lung anatomy

frequently allows passage of the tube into the right mainstem bronchus. As noted above, given the potential problem that the right upper lobe bronchus may become blocked, it is imperative that direct visualization is performed during or soon after the intervention.

In addition, patients with massive hemoptysis should be placed in a dependent, lateral decubitus position. Thus, in a patient with massive bleeding from the left lung, the patient should be intubated into the right mainstem and placed in a left lateral decubitus position. This position may protect the uninvolved lung from filling with blood and, in so doing, maximize gas exchange.

Special care is given to IV fluids and blood and resuscitation measures. Isotonic fluids and blood products should be rapidly infused. In addition to intravenous isotonic fluids, packed red blood cells, platelets, and fresh-frozen plasma are imperative in the proper clinical situations. Coagulation and platelet abnormalities should be corrected with fresh-frozen plasma and platelet infusions, as indicated. Significant coughing may exacerbate the bleeding and can be reduced with small doses of intravenous morphine. Antibiotics should be administered for suspected infectious etiologies. Pulmonary, ENT, interventional radiology, and surgical consultants will assist in localizing the bleeding site. Bronchoscopy and angiography may be both diagnostic and therapeutic. Bleeding control may be achieved with selective bronchial artery embolization, topical vasoconstrictors, and catheter tamponade. Selective bronchial artery embolization is an effective nonsurgical treatment for massive hemoptysis but carries a risk of systemic and spinal artery embolization (3,16). Although high success rates are frequently cited, spontaneous recanalization may occur and result in a recurrence of bleeding. Flexible endoscopy may be done at the bedside and rigid endoscopy may be performed in the operating room. Bronchoscopically administered topical hemostatic tamponade with a cellulose mesh has been reported as effective (21). Finally, recombinant factor VII may be effective in select cases (22). Hemoptysis may be best controlled by addressing the underlying source. As an example, mitral valve surgery may be

considered in patients with severe stenosis. Bleeding associated with CF may respond to intravenous pitressin therapy and bronchial artery embolization (23).

Medical therapy is successful in most patients-–even those with massive hemoptysis. However, when massive bleeding is caused by AV malformations, aortic aneurysms, chest trauma, pulmonary rupture, bronchial adenomas, or fungal lesions that do not respond to medical therapy, surgical options should be considered (2,3).

CRITICAL INTERVENTIONS

- For massive hemoptysis, place the patient in a lateral decubitus position. This will protect the uninvolved lung from filling with blood and allow adequate gas exchange.
- Use large endotracheal tubes when intubating (8.0 in the average adult) to facilitate suctioning and a fiberoptic laryngoscope.
- Selectively intubate the left or the right mainstem bronchus in the proper setting.
- Adequately resuscitate patient with IV isotonic fluids and blood products as appropriate.

DISPOSITION

Most patients respond to medical treatment and require admission to an intensive care setting; a smaller number of patients will require emergent operative intervention. As in all situations of potentially exsanguination, the operating room must be readily available. When definitive care is not available at the presenting institution, a patient may need to be transferred. The transferring physician should optimize the hemodynamic and respiratory status before transfer. Personnel involved in transferring a patient must be competent in emergency airway management. Admission to the hospital is indicated for all patients who are at high risk for deterioration; that includes those with limited pulmonary reserve, respiratory compromise, mycetomas or cavitary TB, and immunocompromised patients with likely infectious etiologies.

Patients with minimal hemoptysis may be discharged after the initial ED evaluation and institution of therapy. Follow-up bronchoscopy is indicated, especially in men, smokers, patients over the age of 40, those with a localized abnormality on chest radiography or CT, and those in whom bleeding has lasted more than 7 days.

Common Pitfalls

- Hemoptysis must be recognized and differentiated from nasopharyngeal and gastrointestinal bleeding.
- The bleeding rate must be accurately estimated. Special concern is appropriate even with only a few ounces of hemoptysis,
- Cardiopulmonary reserve and clinical status must be evaluated. A small amount of hemoptysis may have potentially devastating consequences for a patient with significant underlying disease.
- Close monitoring is essential; clinical deterioration may respond to measures including repositioning the patient and endotracheal intubation.
- In situations requiring transfer to another facility for higher level of care, measures must be taken to assure airway and hemodynamic stability, including prophylactic intubation when indicated.
- Radiographic lesions may be subtle; the radiologist's final report must be followed-up closely in all patients with hemoptysis.

CHAPTER 81

Sarcoidosis

Sanjay Bhatt

Sarcoidosis is a multisystem, chronic granulomatous disease with diverse manifestations and a variable clinical course. It is characterized by a heightened cellular immune response at the site of disease activity; the lungs are the primary target organ and are involved in 90% of cases (1,2). Other organs of lesser involvement include the skin, lymphatic system, and eyes. While no single etiology has been identified, a number of them have been postulated. These include exposure to infectious agents, including *Mycobacterium tuberculosis, Propionibacterium acnes,* and HHV 8, and noninfectious occupational and environmental agents, including beryllium, and autoantigens. Until 1995, only nine patients infected with human immunodeficiency virus (HIV) had coexistent sarcoidosis (3,4) with a resulting postulation that a low CD4 count is "protective" against the granuloma formations seen in sarcoidosis (5).

In the United States, the prevalence of sarcoidosis is 10 per 100,000 in Caucasians and 40 per 100,000 in African Americans (6). Among African-American patients, women outnumber men two to one in the prevalence of disease. Curiously, sarcoidosis is virtually unknown on the continent of Africa, giving credit to an environmental etiology. While the peak incidence of diagnosis and symptoms are between 20 and 40 years of age, the disease has been reported in children and the elderly. Sarcoidosis has also been identified in twins, husband–wife pairs, and in coworker firefighters (7,8).

With or without treatment, most cases of sarcoidosis resolve spontaneously. Indicators of a favorable prognosis include acute manifestations of inflammation including erythema nodosum, polyarthritis, fever, and bilateral lymphadenopathy. Poor prognostic indicators include African-American race, lupus pernio, and chronic bone, lung, or nasopharyngeal involvement (2,6,7).

CLINICAL PRESENTATION

In the United States, approximately 50% of patients with sarcoidosis are asymptomatic and diagnosed on routine radiograph that shows hilar lymphadenopathy (6,7). Those with suspected sarcoidosis can be referred for follow-up and confirmation of the disease. In the emergency department (ED), however, the more important issue revolves around when to suspect and how to treat active disease (Table 81.1).

TABLE 81.1
Characteristics at Clinical Presentation

Characteristics	Incidence (%)
Age (yrs)	
<40	75
>40	25
May occur in children and the elderly	
Gender	
Male	60
Female	40
Race	
Black	90
White	10
Asymptomatic	10–20
Acute/subacute (fever, fatigue, malaise, anorexia, weight loss, respiratory symptoms)	20–40
Insidious (respiratory complaints without constitutional symptoms)	40–70

From Cox CE, Donohue JF, Brown CD, et al. The Sarcoidosis Health Questionnaire: A new measure of health-related quality of life. *Am J Respir Crit Care Med*. 2003;168:323–329.

In 20% to 40% of cases, acute sarcoidosis develops over a period of several weeks. The symptoms are usually mild and may include fever, malaise, anorexia, and weight loss (7,9). Those with chronic sarcoidosis develop a more indolent form over months. Most have vague respiratory complaints and are likely to have symptomatic relapses. It is the group with a slow evolution of symptoms that is more likely to develop chronic disease and organ damage.

As sarcoidosis is a multisystem disease, it can present as a multitude of symptoms. The lungs, however, are almost always (90%) involved, and the clinical presentation is consistent with the presence of interstitial lung disease. Patient often present with exertional dyspnea and a dry cough. The physical examination may reveal dry rales or wheezing, suggestive of reactive airway. Airway hyperreactivity is especially prominent in patients with endobronchial involvement (10). Ninety percent of patients have an abnormal chest radiograph and some may develop pulmonary hypertension related to decreased lung volumes (11,12).

There are four stages of sarcoidosis; these stages are classified by the Scadding scale. Radiographic evaluation is helpful to define pulmonary involvement and also stage the disease. These four stages of involvement are shown on chest films (Table 81.2). Stage I is defined by the presence of bilateral hilar adenopathy and can often be accompanied by right paratracheal node enlargement (Fig. 81.1). Stage II is characterized by bilateral hilar adenopathy and reticular opacities. Stage III consists of reticular opacities, which are generally distributed in the upper lung zones with shrinking hilar nodes. Finally, stage IV is defined by reticular opacities in the upper lung zones with general lung volume loss (2,8).

TABLE 81.2
Radiographic Stage and Prognosis in Sarcoidosis

Stage	% of Patients	Prognosis (Likelihood of Resolution) (%)
0	5–10	—
I	50	60
II	25–30	46
III	15	12

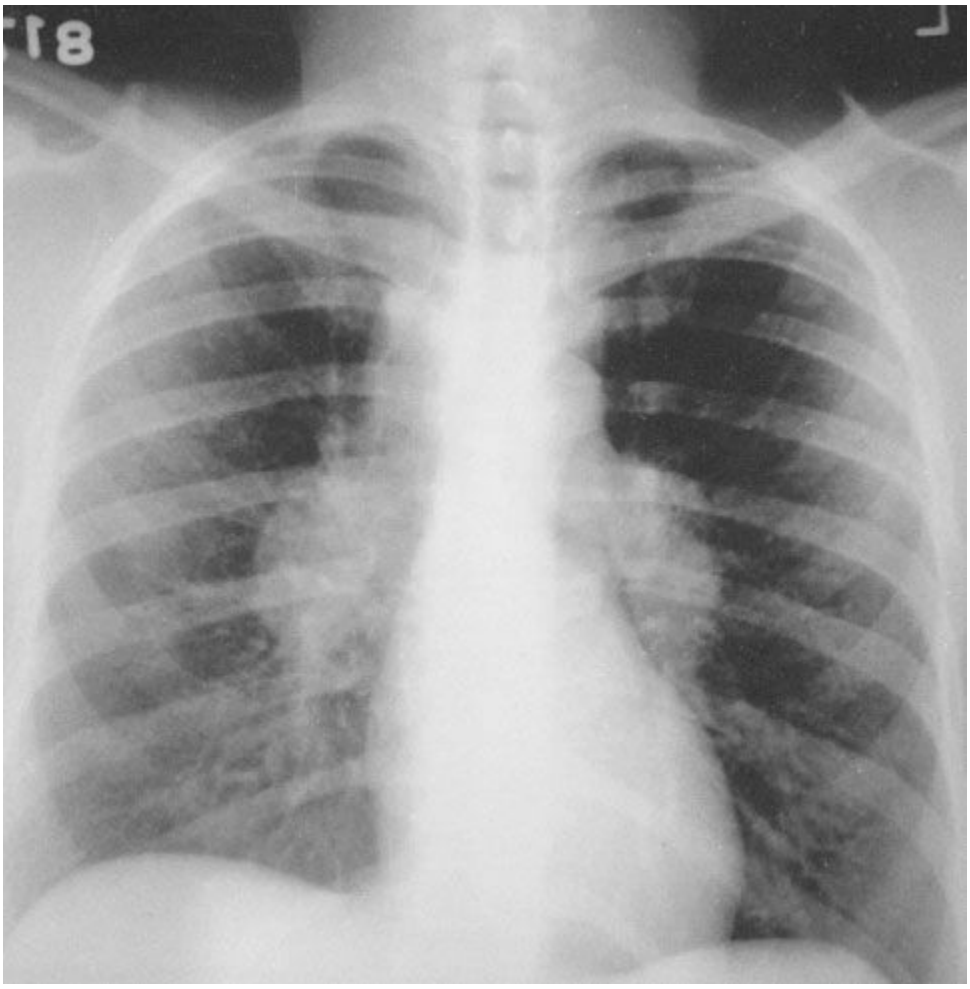

FIGURE 81.1 Typical type I radiograph. (Courtesy of Murray K. Dalinka, MD, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia.)

Radiographic staging has limited prognostic significance. While staging provides a guide to lung involvement, it does not assess functional ability or disease activity. Stage I changes of bilateral hilar adenopathy may resolve whereas changes in stage II to IV are generally chronic. It is important to recognize that these are not

stages of the disease but rather represent different radiographic manifestations (7).

While pulmonary manifestations of sarcoidosis account for 90% of disease, extrapulmonary manifestations account for the remaining 10%. These extrapulmonary manifestations can involve most organs including the skin, lymph nodes, and heart. Although myocardial involvement of sarcoidosis is found in 25% of autopsied cases, only 10% of those patients without cardiac symptoms have an abnormal electrocardiogram. Granulomatous involvement of the conduction system and ventricular walls can lead to dysrhythmias including complete heart block and sudden cardiac death. Life-threatening ventricular dysrhythmias may be related to QT prolongation (13). As many as 25% of patients with cardiac manifestations of sarcoidosis die as a result of congestive heart failure (CHF) (7). CHF may be due to local infiltration of the mitral valve or diffuse granulomatous disease (1). Myocardial magnetic resonance imaging may be a useful modality for tracking the clinical course of disease (14).

Abnormalities related to calcium are the most common renal and electrolyte abnormalities among patients with sarcoidosis. The defect in calcium metabolism is due to increased intestinal calcium absorption owing to overproduction of 1,25-dihydroxyvitamin D_3 by activated macrophages. Hypercalciuria (30%) and hypercalcemia (10%) are common presentations of sarcoidosis; patients may present with renal colic from nephrolithiasis, hypertension, and renal arteritis; primary renal infiltration with sarcoid granulomas is rare (7).

While severe hypercalcemia is unusual, corticosteroids can control hypercalcemia by inhibiting the action of 1,25-dihydroxyvitamin D_3. Before corticosteroids are considered, treatment begins with conservative measures including intravenous (IV) fluids and decreasing oral calcium intake (15).

Ocular involvement of sarcoidosis involves approximately 25% of patients; 5% of patients initially present with ocular symptoms. The most common ocular presentation is anterior uveitis. Uveitis may

develop rapidly and can become chronic eventually leading to glaucoma, cataracts, and blindness (9). Other ocular diagnoses include posterior uveitis, conjunctivitis, cataracts, and retinal hemorrhages.

Skin lesions occur in about one of every four patients. Cutaneous manifestations include lupus pernio (Fig. 81.2), plaques, and symmetric maculopapular eruptions. In addition, erythema nodosum is a hypersensitivity reaction that may be seen in women of childbearing age. While a nonspecific finding (7,8), erythema nodosum is often considered the hallmark of the disease (8).

FIGURE 81.2 Lupus pernio. (Courtesy of Gerald S. Lazarus GS, MD, Department of Dermatology, Hospital of the University of Pennsylvania, Philadelphia.)

Musculoskeletal presentations of sarcoidosis are common with 10% to 20% of patients presenting with chronic arthritis or acute polyarthritis. Acute polyarthritis is associated with erythema

nodosum and can be incapacitating, requiring corticosteroid therapy. Chronic arthritis is associated with chronic persistent disease and is most frequently seen in black patients (7).

Sarcoidosis that involves the upper respiratory tract should be suspected in all patients with systemic sarcoidosis and upper respiratory tract symptoms. The granulomatous disease can involve the larynx, pharynx, nares, and sinuses. Nasal and laryngeal involvement occurs in up to 16% of patients with sarcoidosis; extensive disease may cause severe airway compromise (9).

Less than 10% of patients have neural involvement. While the initial manifestations of neural involvement are central nervous system (CNS) related, peripheral nerve and skeletal muscle involvement is characteristically seen in the later stages. The granulomatous component of sarcoidosis can compress local structures. Patients can present with cranial neuropathy, especially seventh nerve palsy from brainstem compression, central diabetes insipidus from pituitary and hypothalamic lesions, and seizures from hydrocephalus. Neurologic symptoms usually improve with corticosteroid therapy (7,16).

Two other syndromes have been described. Löfgren syndrome includes the triad of erythema nodosum, bilateral hilar adenopathy, and arthralgias. Löfgren syndrome is associated with a good prognosis with over 90% of patients experiencing disease resolution within 2 years. A second syndrome, Heerfordt–Waldenström, also referred to as uveoparotid fever, is a rare presentation of sarcoidosis. The symptoms include chronic fever, anterior uveitis, facial nerve palsy, and parotid enlargement (9,17).

Symptomatic sarcoidosis is rare in children. It has been shown that children of African descent have more severe disease than Caucasian and Asian counterparts. There are two distinct forms of pediatric sarcoidosis. Children under the age of 4 years, those with an early onset of disease, are likely to present with the triad of rash, uveitis, and arthritis. Children between the ages of 8 and 15 develop multisystem disease similar to that described in adults with lymphadenopathy, pulmonary involvement, and the typical generalized signs and symptoms of fever and malaise (18).

DIFFERENTIAL DIAGNOSIS

While there is no classic presentation of sarcoidosis, a common presentation entails a young adult who presents with a fever, subjective shortness of breath, blurry vision, and erythema nodosum; the chest radiograph shows bilateral hilar adenopathy. Most cases, of course, are not this typical. As sarcoidosis is a multisystem disease, the differential diagnosis is broad. Sarcoidosis can be confused with tuberculosis, or other mycobacterial infections, lymphoma, and some fungal disorders including coccidioidomycosis. Other systemic diseases to be considered include leprosy, berylliosis, and hypersensitivity pneumonitis.

HIV infection must also be considered in patients suspected of having sarcoidosis. Patients with HIV commonly have several of the features found in sarcoidosis, including chest radiograph abnormalities and lymphocytopenia. Only a small number of patients with concurrent HIV and sarcoidosis have been recorded. It has been postulated because CD4 cells are required for clinical expression of sarcoidosis, they may be “protective,” against the viral illness. Although the clinical suspicion may be high, a definitive diagnosis of sarcoidosis cannot be made with certainty on initial clinical presentation. A patient who carries a diagnosis of sarcoidosis, however, may present with a complication of the disease.

ED EVALUATION

On presentation to the ED, a physician should direct the initial patient history to determine the duration and severity of symptoms, a previous diagnosis of sarcoidosis, and any previous need for corticosteroid therapy.

The major complications of systemic sarcoidosis include upper airway obstruction from laryngeal involvement (19,6), cardiac dysrhythmias and conduction disturbances including complete heart block, CHF, advanced pulmonary fibrosis with cor pulmonale (20), superimposed tuberculosis or bacterial infection (7), sudden loss of vision from ocular complications (1), incapacitating arthritis or

arthralgias (11), space-occupying lesions of the brain and hydrocephalus (21), and hypercalcemia with its cardiac, neurologic, and renal sequelae. In the proper clinical setting, abrupt corticosteroid withdrawal may cause signs and symptoms of adrenal insufficiency (15,22).

The physical examination should first focus on airway and cardiopulmonary systems. As sarcoidosis is a multisystem disease, attention should be given to all potentially involved organ systems. Ocular, neurologic, skin, and joint complaints necessitate more specialized examination and testing. Like all patients who present with altered mental status or abnormal neurologic findings, a funduscopic examination may be useful.

Diagnostic studies in the ED should be directed toward detecting both current and potential sarcoidosis-related problems. Patients may benefit from a 12-lead electrocardiogram and outpatient Holter monitoring. Chest radiography, pulse oximetry, and arterial or venous blood gas analysis may be indicated in those with respiratory complaints. Benefit may be realized from renal function studies, electrolytes, and calcium and platelet counts.

Strict criteria must be satisfied to diagnose sarcoidosis. They include compatible clinical and radiographic findings (6,19), histologic finding of noncaseating granulomas, and exclusion of other diseases with similar findings (20,21,23,24). It is unlikely that an emergency physician will establish that a patient meets these exacting criteria. A diagnosis based on only one of these features may be misleading. Definitive diagnosis requires specialty assistance.

Additional evaluation often includes cerebrospinal fluid (CSF) and isotopic imaging studies, extrapulmonary biopsy, and bronchoalveolar lavage. The ATS Sarcoidosis Consensus Group believes that transbronchial biopsy should be performed on patients suspected of sarcoidosis (2). Fine-needle biopsy is an important diagnostic tool (21), and bronchoalveolar lavage may be performed at the same time as biopsy. An elevated CD4:CD8 ratio in the fluid confirms the diagnosis and occurs in the majority of those with pulmonary disease (2,21,22). Advances in gallium scanning have

improved diagnostic accuracy; however, this test is not diagnostic of sarcoidosis. Likewise, although CT scanning may be helpful to rule out other diseases, it cannot establish a definitive diagnosis (21). Most patients will eventually have a 24-hour urinary calcium level (7) and serum and CSF angiotensin–converting enzyme levels.

KEY TESTING

- CXR and pulse oximetry for respiratory complaints
- ECG to detect conduction abnormalities
- Calcium level, electrolytes, BUN, creatinine, if suspected hypercalcemia
- CT head if altered mental status

ED MANAGEMENT

Most patients with sarcoidosis do not require treatment. This is especially true as most patients have asymptomatic disease. For those individuals who have more severe pulmonary or extrapulmonary symptoms, treatment is aimed at reducing the burden of granulomatous inflammation. While no specific treatment exists, oral glucocorticoids have been most widely used to control symptoms. Incapacitating disease that interferes with normal life activities merits consideration for corticosteroid therapy. Conversely, mildly symptomatic disease warrants conservative management without corticosteroids. In those who require treatment, systemic corticosteroids of prednisone 40 mg/d remain an effective and safe form of treatment (16,19).

Indications for treatment with corticosteroids in patients with pulmonary sarcoidosis include progressive and worsening radiographic imaging, pulmonary symptoms, and deteriorating lung function as measured by pulmonary function testing. Therapy is generally withheld in all asymptomatic patients despite the stage of therapy. Lung transplantation is a final option for end-stage pulmonary disease (7,23).

Treatment of extrapulmonary sarcoidosis is based on the affected organ and the degree of damage. As a general rule, treatment of

neurologic, ocular, myocardial, or renal sarcoidosis and hypercalcemia is indicated. Treatment is generally started to prevent further complication leading to loss of vision, sudden cardiac death and fatal arrhythmias, or renal failure.

Because of mortality rates approaching 10%, patients with neurosarcoidosis require treatment with prednisone 1 mg/kg/d followed by a taper. For severe or fulminant cases, IV steroids (1 g/d methylprednisolone) are administered for 2 to 3 days (16). Topical corticosteroids are used for anterior ocular and dermatologic disease (7,15,19).

Patients with cardiac conduction abnormalities resulting from granulomatous infiltration are usually refractory to conventional pharmacotherapy and often need to be admitted to the hospital to determine the most appropriate pharmacologic or electrical therapy. Cardiac transplantation has been performed successfully in younger patients with severe heart failure. Refractory dysrhythmias may require resection of a ventricular aneurysm (19,23). Hypercalcemia, if severe or symptomatic, may be treated as per conventional treatment. High-dose corticosteroid therapy may be required. Milder elevations of serum calcium levels may be treated with corticosteroids and frequent monitoring (15,19).

Although corticosteroids remain the mainstay of treatment, other agents have also been used. These agents include methotrexate, azathioprine, cyclophosphamide, chlorambucil, cyclosporine, nonsteroidal anti-inflammatory agents, chloroquine, infliximab, and hydroxychloroquine.

CRITICAL INTERVENTIONS

- Obtain a serum calcium level in patients with suspected or diagnosed sarcoidosis
- Treat hypercalcemia as an inpatient; aggressive treatment is warranted, especially in patients with significant signs and symptoms of hypercalcemia
- Obtain an electrocardiogram to diagnose cardiac conduction abnormalities

- Begin corticosteroid therapy in selected cases in conjunction with the appropriate primary care physician or consultant

DISPOSITION

The ED physician may require the assistance of specialty consultants in diagnosing and managing a patient with suspected sarcoidosis. Pulmonary, ophthalmologic, dermatologic, and neurologic consultation may be necessary before definitive therapy is undertaken.

In those patients who carry a diagnosis of sarcoidosis, hospital admission is indicated for patients with cardiac or neurologic symptoms, hypercalcemia, severe thrombocytopenia, or any degree of airway compromise.

Because long-term care is usually required, the family physician, internist, or pulmonary specialist is most commonly called on to provide primary outpatient therapy for sarcoidosis.

Common Pitfalls

- Sarcoidosis is frequently asymptomatic; it should be considered in patient with eye findings, suggestive skin lesions, hypercalcemia, persistent cough or dyspnea, or unexplained fever and weight loss
- The emergency physician should arrange follow-up so that a definitive diagnosis can be made and an appropriate treatment plan begun
- Specialty consultation should be obtained before treating with systemic corticosteroids and when dealing with cardiac, neurologic, or ocular disease
- Children can develop sarcoidosis
- The presence of wheezing may incorrectly suggest reactive airway disease. Corticosteroids may not be indicated in this setting

SECTION VIII
Cardiac Emergencies

Section Editor: JEFFREY J. SCHAIDER

CHAPTER 82

Acute Coronary Syndrome

Christopher Ross and Theresa Schwab

Acute coronary syndrome (ACS) is the leading cause of death and disability in developed nations and creates one of the largest economic burdens on the health care systems. More than 1 million deaths occur annually in the United States due to ACS, with many of these in patients younger than age 65 (1). Although millions of people are assessed for chest pain in emergency departments (EDs) in the United States each year, fewer than one-fourth are ultimately diagnosed with ACS. The case-fatality rate has dropped significantly owing to myriad factors, including societal education about risk factor modification, treatment of associated conditions such as diabetes and hypertension, current medical therapies, and the institution of reperfusion strategies. Despite aggressive workups and the use of several strategies for risk stratification, emergency physicians still discharge about 2% of patients with myocardial infarction (MI) (2), with an associated increase in short-term mortality. These patients tend to be younger, have atypical presentations, and have nondiagnostic electrocardiograph (ECG). Approximately 20% of all malpractice dollars are awarded to plaintiffs in cases involving ACS, and this fear often leads to altered decision making and an associated increase in testing and hospitalization in low-risk patients (3).

ACS encompasses three specific presentations of coronary artery disease (CAD): unstable angina (UA) pectoris, non-ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI).

UA is defined by its clinical presentation, usually a change in class as defined by the Canadian Cardiovascular Society (Table 82.1 and 82.2). The distinction between UA and NSTEMI is based ultimately on the detection of markers of myocardial necrosis in the blood, so the two entities are indistinguishable at presentation, and their management is initially the same. Neither UA nor NSTEMI have characteristic historical, physical examination, or ECG findings. STEMI is defined by the electrocardiographic findings and the need for initiation of emergent reperfusion strategies. Each of these conditions is due to a lack of perfusion of the myocardium, which causes an imbalance between oxygen supply and demand. Atherosclerosis of the coronary arteries with occlusion of the vessel is the most common cause of myocardial ischemia. Regardless of the specific etiology, the beneficial effects of therapy are greatest when performed soon after presentation to the hospital.

TABLE 82.1
Canadian Cardiovascular Society Grading of Angina Pectoris

Grade	Description
Grade I	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina is caused with strenuous or rapid or prolonged exertion at work or recreation
Grade II	Slight limitation of ordinary activity. Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or in cold, or in wind, or under emotional stress, or only during the few hours after awakening. Walking more than two blocks on the level and climbing more then one flight of ordinary stairs at a normal pace and in normal conditions
Grade III	Marked limitation of ordinary physical activity. Walking one or two blocks on the level and climbing one flight of stairs in normal conditions and at normal pace
Grade IV	Inability to carry on any physical activity without discomfort, anginal syndrome may be present at rest

Patients with stable angina usually have a smooth-surfaced atherosclerotic plaque that permits sufficient coronary arterial flow at rest or minimal exercise to meet the metabolic demands of the myocardium. During physical exertion or other increases in

metabolic demand, myocardial oxygen demand increases owing to elevation of both heart rate and blood pressure. Coronary perfusion cannot increase sufficiently to meet the augmented demands, and ischemia with classic symptoms of angina develops.

In contrast to stable angina, the pathologic substrate for ACS is a complex and irregular atherosclerotic plaque. Unstable plaques are prone to rupture, resulting in a cascade of inflammatory events, thrombus formation, and platelet aggregation that can cause acute obstruction of the arterial lumen and myocardial necrosis. Other etiologies of ACS include dynamic obstruction (coronary spasm such as in Prinzmetal's variant angina) and progressive mechanical obstruction, such as re-stenosis after percutaneous coronary intervention (PCI). The definition of myocardial infarction (MI) requires evidence of myocardial necrosis in a clinical setting consistent with myocardial ischemia. Specific examples include (i) a rise and/or fall of cardiac biomarkers with at least one of the following: symptoms of ischemia, ECG changes, or imaging evidence of new loss of viable myocardium or of wall motion abnormality; (ii) sudden, unexpected cardiac death accompanied by symptoms of myocardial ischemia or ECG abnormalities or autopsy findings; (iii) PCI and coronary artery bypass grafting (CABG), giving rise to elevated cardiac biomarkers with or without ECG findings. MIs can be classified according to Table 82.3.

CLINICAL PRESENTATION

The history is the most sensitive test for the ED detection of ACS, far surpassing both ECG and measurement of cardiac markers. The hallmark of ACS is chest pain, typically located in the substernal region or epigastrium that frequently radiates to the neck, left shoulder, and left arm. All patients presenting with chest pain should therefore have a detailed history and should be asked for particulars on onset of pain (abrupt or gradual), quality of pain (squeezing, sharp, pleuritic, etc.), radiation (can be either left or right shoulder/arm, neck, back, etc.), site of the pain (substernal, diffuse or poorly localized, chest wall, etc.), provocation (with exertion, breathing or spontaneously, etc.), and timing (episodic or constant,

duration of each episode, etc.). Anginal equivalents such as dyspnea, nausea, vomiting, and diaphoresis may also occur and compose up to 30% of presentations of ACS. These atypical symptoms are classically found in the elderly, in women, in non-Whites, or in those who have comorbid diseases such as diabetes, heart failure, prior stroke, or hypertension. Atypical presentations of ACS are associated with longer delays to presentation and ECG acquisition and a 3-fold increase in mortality associated with delay in the initiation of therapeutic interventions and a decreased intensity of treatment regimens (4). Classic ischemic chest pain associated with ACS usually occurs abruptly, increases in intensity over time, and reaches peak intensity within 2 to 5 minutes of onset. Anginal pain generally lasts for <15 minutes, whereas that associated with MI lasts longer. Certain chest pain characteristics have a low likelihood of representing ACS (seconds of pain or constant pain lasting hours to days, pleuritic pain, and reproducible chest wall pain), but this likelihood is not negligible and is one of the reasons why ACS is so difficult to diagnose (5). Patients may also present with a myriad of other symptoms like nausea, vomiting, diaphoresis, altered mental status, weakness, and even belching.

TABLE 82.2
Clinical Presentation of Unstable Angina

Angina at rest (usually >20 min) within 1 wk of presentation
New-onset angina of Canadian Cardiovascular Society Classification class III or IV within 2 mo of presentation
• Class III angina: pain when walking less than two blocks or climbing less than one flight of stairs
• Class IV angina: inability to carry out any physical activity without discomfort
Angina increasing in Canadian Cardiovascular Society Classification class to at least class III or IV

TABLE 82.3
Myocardial Infarction

Type 1

Spontaneous myocardial infarction related to ischemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring, or dissection

Type 2

Myocardial infarction secondary to ischemia due to either increased oxygen demand or decreased supply (e.g., coronary artery spasm, coronary embolism, anemia, arrhythmias, hypertension, or hypotension)

Type 3

Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumably new ST elevation, or new LBBB, or evidence of fresh thrombus in a coronary artery by angiography and/or at autopsy but death occurring before blood samples could be obtained or at a time before the appearance of cardiac biomarkers in the blood

Type 4a

Myocardial infarction associated with PCI

Type 4b

Myocardial infarction associated with stent thrombosis as documented by angiography or at autopsy

Type 5

Myocardial infarction associated with CABG

CABG, coronary artery bypass grafting; LBBB, left bundle branch block; PCI, percutaneous coronary intervention.

Reproduced with permission from Thygesen K, Alpert JS, White HD, et al. Universal definition of myocardial infarction. *Eur Heart J.* 2007;28(20):2525–2538. Kristian Thygesen, Joseph S. Alpert and Harvey D. White on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction.

Traditional risk factors (smoking, diabetes, hypertension, hypercholesterolemia, and family history) are weak predictors of the likelihood of ischemia in an acute presentation by an individual patient. These risk factors were developed retrospectively and are of limited utility in ED patients. These risk factors have no predictive value in the elderly, and even in those younger than 40 years of age, their predictive value is limited and should not dictate diagnostic and management decisions (6). The stronger risk factor for ACS is a previous history of ACS. Patients with a history of a positive stress testing or angiographically documented CAD have an extremely high likelihood of recurrent ischemic disease if they present with anginal or anginal-equivalent symptomatology.

Physical examination findings are nonspecific in the ACS patient, and the utility of the physical examination lies in identifying other etiologies for the patient's symptoms. Identification of acute cardiac dysfunction, in the form of shock or heart failure, mandates urgent initiation of treatment, but one-fourth of patients with ACS have a normal cardiac examination. Moreover, valvular heart disease, congenital heart disease, cardiomyopathy, and chronic ischemic heart disease have physical examination findings similar to those of the ACS patient, so care should be used in attributing these findings to other pathophysiologic processes. Thus, the physical examination is often not helpful in diagnosing ACS. Table 82.4 lists signs associated with the pathologic changes that occur with ischemia.

TABLE 82.4
Physical Signs That Occur During Myocardial Ischemia

Physical Sign	Underlying Pathophysiology
Soft S1	Decreased LV d*p*/d*t* or first-degree AV block
Paradoxically split S2	Prolonged LV ejection time
S3 and/or S4	Decreased LV compliance
Mitral regurgitation	Papillary muscle ischemia
Palpable precordial systolic bulge	Anterior or lateral dyskinesis
Bibasilar rales	Increased preload

AV, atrioventricular; LV, left ventricular; d*p*/d*t*, rate of pressure rise.

DIFFERENTIAL DIAGNOSIS

A detailed discussion of the differential diagnosis of chest pain is included elsewhere in the text. Cardiac, pulmonary, musculoskeletal, and gastrointestinal systems all give rise to symptoms of ACS. Life-threatening diseases which may be confused with ACS include aortic dissection, pulmonary thromboembolism, pneumothorax, mediastinitis, pericarditis, myocarditis, hypertrophic obstructive cardiomyopathy, and pericardial tamponade. Pneumonia and pleural diseases, valvular heart disease, pericarditis, takotsubo cardiomyopathy, gastroesophageal reflux disease, peptic ulcer disease, and chest wall pain (such as costochondritis and trauma to

the chest wall) should also be included in the differential diagnosis. Particular attention to the character of the pain, precipitating factors, associated symptoms, and the physical examination usually allows the clinician to rule out a number of these other causes of chest pain.

ED EVALUATION

The emergency physician must perform a rapid triage and assessment of patients with potential ACS. Risk stratification will need to be based on history, physical examination, ECG, cardiac markers, and potentially imaging. The estimation of risk is complex, but several investigators have proposed useful risk-stratification schemes (Tables 82.5 and 82.6).

Electrocardiography

The ECG is a mainstay of the initial diagnosis of ACS. It can dictate management, response to therapy, and appropriate admission disposition and is also predictive of the risk of subsequent major adverse cardiac events (MACE). In patients with suspected ACS, a standard 12-lead ECG should be obtained and interpreted within 10 minutes of presentation. Although the ECG remains the best immediate test for identification of AMI, a single ECG performed during the patient's initial presentation detects less than half of AMI. ECG abnormalities of myocardial ischemia or MI include characteristic changes in the PR segment, the QRS complex, the QT interval, and the ST segment or T waves. However, fewer than half of patients who are eventually discharged with a diagnosis of acute MI have a diagnostic initial ECG. Rather, "nonspecific" or "nondiagnostic" findings are more frequent. The ECG should be obtained when the patient is having symptoms, if possible, but a normal ECG obtained while a patient is having symptoms is no more likely to be associated with ACS than a normal ECG when there are no symptoms (7). Serial ECG recordings can aid in determining whether the patient's symptoms are due to ACS and have been shown to increase the sensitivity of identification of ACS to almost 90%, but the specificity remains poor at 50% (8). Whenever there is

a change in symptomatology or clinical status, a repeat ECG should be performed. Thus, if the ECG is either normal or nondiagnostic but there is still a high clinical suspicion of ACS, it is recommended that the ECG be repeated in 5- to 10-minute intervals to look for diagnostic changes (9).

TABLE 82.5
Likelihood That Signs and Symptoms Represent an Acute Coronary Syndrome Secondary to Coronary Artery Disease

Feature	High Likelihood *Any of the following:*	Intermediate Likelihood *Absence of high-likelihood features and presence of any of the following:*	Low Likelihood *Absence of high- or intermediate-likelihood features but may have:*
History	Chest or left arm pain or discomfort as chief symptom reproducing prior documented angina Known history of CAD, including MI	Chest or left arm pain or discomfort as chief symptom Age > 70 yr Male sex Diabetes mellitus	Probable ischemic symptoms in absence of any of the intermediate likelihood characteristics Recent cocaine use
Examination	Transient MR, hypotension, diaphoresis, pulmonary edema, or rales	Extracardiac vascular disease	Chest discomfort reproduced by palpation
ECG	New, or presumably new, transient ST-segment deviation (≥0.05 mV) or T-wave inversion (≥0.2 mV) with symptoms	Fixed Q waves Abnormal ST segments or T waves not documented to be new	T-wave flattening or inversion in leads with dominant R waves Normal ECG
Cardiac markers	Elevated cardiac TnI, TnT, or CK-MB	Normal	Normal

Reproduced with permission from Braunwald E, Antman EM, Beasley JW, et al. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction—summary article: A report of the American College of Cardiology/American Heart Association task force on practice guidelines [Committee on the Management of Patients with Unstable Angina]. *J Am Coll Cardiol.* 2002;40(7):1366–1374.

The electrographic manifestations of acute myocardial ischemia by the 2012 Joint ESC/ACCF/AHA/WHF Task Force include the following (10).

- For ST elevation: New ST elevation at the J point in two contiguous leads with the cut-points: ≥0.1 mV in all leads other than V2-V3 where the following cut-points apply: ≥0.2 mV in men 40 years; ≥0.25 mV in men <40 years, or ≥0.15 mV in women.
- For ST depression and T-wave changes: New horizontal or down-sloping ST depression ≥0.05 mV in two contiguous leads and/or T-wave inversion ≥0.1 mV in two contiguous leads with prominent R wave or R/S ration >1.

The 12-lead ECG shows the anterior myocardial wall well but is limited in identifying ischemic areas in the lateral, posterior, and right myocardium. Nonstandard surface ECG recordings are of value in some patients with ACS. The 15-lead ECG includes leads V4 r, V8,

and V9 to look for ischemic changes in the right ventricle and posterior portions of the myocardium. The addition of the 15-lead ECG increases the sensitivity for MI without sacrificing specificity. Although a 15-lead ECG should be obtained whenever there appears to be ischemia in the anterior or inferior leads, it can be used in every patient to increase the sensitivity of detection of MI. ECG with up to 192 leads has been utilized to improve sensitivity and to identify more patients who would benefit from reperfusion therapy. This body surface mapping has been shown to augment the traditional ECG in the identification of transmural infarction (ST elevation) and may get these patients to definitive therapy more readily. However, the vast majority of STEMI patients are picked up with the regular 12-lead ECG.

TABLE 82.6
Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Unstable Angina

Feature	High Risk *At least 1 of the following features must be present:*	Intermediate Risk *No high-risk feature but must have one of the following:*	Low Risk *No high- or intermediate-risk feature but may have any of the following features:*
History	Accelerating tempo of ischemic symptoms in preceding 48 h	Prior MI, peripheral or cerebrovascular disease, or CABG, prior aspirin use	
Character of pain	Prolonged ongoing (>20 mis) rest pain	Prolonged (>20 min) rest angina, now resolved, with moderate or high likelihood of CAD Rest angina (<20 min) or relieved with rest or sublingual NTG	New-onset or progressive CCS Class III or IV angina in the past 2 wk without prolonged (>20 min) rest pain but with moderate or high likelihood of CAD
Clinical findings	Pulmonary edema, most likely due to ischemia New or worsening MR murmur S_3 or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 yr	Age > 70 yr	
ECG	Angina at rest with transient ST-segment changes >0.05 mV Bundle branch block, new or presumed new Sustained ventricular tachycardia	T-wave inversions >0.2 mV Pathological Q waves	Normal or unchanged ECG during an episode of chest discomfort
Cardiac markers	Elevated (e.g., TnT or TnI >0.1 ng/mL)	Slightly elevated (e.g., TnT >0.01 but <0.1 ng/mL)	Normal

Reproduced with permission from Braunwald E, Jones RH, Mark DB, et al. Diagnosing and managing unstable angina. Agency for Health Care Policy and Research. *Circulation.* 1994;90(1):613–622.

ECG abnormalities have been classically divided into high- and low-risk criteria for MACE. High-risk abnormalities include ST-segment depression, pathologic Q waves, T-wave changes, left bundle branch block (LBBB), left ventricular hypertrophy (LVH), abnormal conduction, ventricular-paced rhythm, and any abnormality that is reversible or associated with the patient's symptoms. Abnormalities associated with a low risk of subsequent

cardiac events include normal ECG, nonspecific ST and T-wave changes, and absence of change from a previous ECG. Patients with a low-risk ECG still have more than a 10% chance of MI after presentation with ischemic symptoms. Patients with high-risk ECG findings have a 40% chance of MI and high risks of major cardiac events and mortality.

Early ECG signs of myocardial injury are ST-segment and T-wave changes that may also be seen with early or transient reversible ischemia. Nondiagnostic, new, or presumably new ST-segment elevation or depression of $\geq$0.5 mm (0.05 mV) or T-wave inversion to $\geq$1 mm (0.1 mV) observed during symptoms may indicate ACS. The magnitude of this ST-segment depression may be predictive for death and recurrent MI.

The presence of new nonspecific ECG changes increases the likelihood that chest pain is caused by myocardial ischemia; however, the predictive value is only about 50%. Any dynamic changes, including pseudonormalization of the ECG, should raise suspicion for ACS. New ST-segment deviations of $\geq$1 mm (0.1 mV) are more consistent with STEMI or NSTEMI and should prompt therapeutic intervention. It is important to note that the magnitude of the change is prognostic for morbidity and mortality from ACS. The greater the ST-segment depression on ECG, the more likely that the patient is having UA or a NSTEMI and worse the prognosis for outcome. A prominent R wave, or an R/S ratio $>$1, may also be indicative of myocardial ischemia, especially when it is seen in the anterior precordial leads. Patients with ST-segment elevation resulting from acute MI have either obliquely flat or convex-upward waveforms, whereas patients with noninfarction ST-segment elevation (i.e., early repolarization or LVH) tend to have a concave-upward waveform. ST-segment and T-wave changes are not always associated with ACS, so the differential diagnosis should be carefully considered before initiating treatment. Common nonischemic causes for ST-segment elevation or depression and T-wave inversions suggestive of ACS are listed in Table 82.7. Although a nonconcave ST-segment elevation pattern is more commonly encountered in acute STEMI than in other nonischemic causes of ST-elevation, the

sensitivity of the morphologic pattern, approximately 75%, precludes complete reliance on its presence or absence to make the diagnosis. The ECG can identify STEMI, but it is not sensitive or specific for the identification of other types of ACS.

TABLE 82.7
Nonischemic Causes of ECG Changes

ST-Segment Elevation	ST-Segment Depression	T-Wave Inversion
Left bundle branch block	LVH	Intracranial event
Left ventricular hypertrophy	Left BBB	Strain pattern
Pericarditis/myocarditis	Digoxin effect	Myocarditis
Paced ventricular rhythm	Hypokalemia	Early repolarization
Hypothermia (Osborne J waves)	Hypomagnesemia	Normal variant
Hyperkalemia		
Brugada syndrome		
Drug-induced (tricyclic antide-pressants)		
Left ventricular aneurysm		

BBB, bundle branch block; ECG, electrocardiogram; LVH, left ventricular hypertrophy.

Evidence of previous ischemic disease may be seen on the ECG. Q waves or QS complexes are usually pathognomonic of a prior MI. Q waves usually develop by 12 hours after the infarction and may be permanent ECG findings. The specificity of the ECG for diagnosing MI in the setting of previous MI is greatest when Q waves occur in anatomic groupings.

The degree of ST-segment changes is also predictive of the extent of myocardial disease, with higher mortality figures for both higher ST-segment elevation and deeper ST-segment depression.

T-wave inversions are a nonspecific finding and can occur in a normal ECG, especially in leads V1 and V2. They are more specific for ACS if they are narrow and symmetrically inverted, if they are associated with symptoms, or if they are reversible. Deep T-wave inversions across the anterior precordial leads or biphasic T waves in the same leads have an association with proximal left-sided coronary lesions. Wellens syndrome refers to this ECG finding, which is

associated with an increased incidence of sudden cardiac death during stress testing. These patients should thus undergo coronary angiography for definitive diagnosis.

STEMI is defined by distinctive changes on the ECG. The earliest finding of transmural ischemia may be prolongation of the corrected QT interval, then hyperacute T waves, followed by ST-segment elevation. The hyperacute T wave usually occurs within minutes of the interruption of blood flow. The T wave is often asymmetric, with a broad base. The height of the hyperacute T waves generally correlates well with the acuteness of the injury. There is no cellular death at this stage. The hyperacute T wave evolves rapidly to ST-segment elevation over a 5- to 30-minute period. It is important to note that ST-segment elevation in the setting of MI represents a region of the myocardium that is at risk for necrosis if blood flow is not restored; this has important implications for treatment. ST-segment elevation evolves from J-point elevation and maintenance of a concave configuration to a more pronounced elevation that becomes more convex or rounded upward. The ST segment may eventually become indistinguishable from the T wave and resemble a monophasic action potential (commonly referred to as *tombstoning*). The degree of ST-segment elevation correlates with the immediate risk for acute complications of infarction.

By definition, the diagnosis of STEMI is dependent on new ST elevation in two contiguous ECG leads. Specific criteria are new ST elevation at the J-point or dynamic ST-elevation in two contiguous leads, with cutoff points of $\geq$2 mm (0.2 mV) in men or $\geq$1.5 mm (0.15 mV) in women in leads V2-V3 and/or $\geq$1 mm (0.1 mV) in other leads. ST–T-wave depressions in leads oriented toward the presumably noninfarcted myocardium are termed *reciprocal changes.* These changes may also precede ST-elevation, emphasizing the importance of obtaining serial ECG. These ST–T wave depressions usually reflect more extensive infarction and a worse prognosis (Table 82.8).

TABLE 82.8
Anatomic Representation of Myocardial Ischemia by ECG

Findings

ECG Lead Changes	Infarct/Ischemia Location
V1–V6/I and aVL	Anterior wall
V1–V3	Anteroseptal or apical
II, III and aVF	Inferior wall
Right-sided precordial leads	Right ventricle
Posterior leads V7–V9 (ST depression in V1–V4)	Posterior wall

ECG, electrocardiograph.

Anatomic Localization of Ischemia by Electrocardiography

The localization of MI by ECG is important for immediate risk stratification for MACE.

Anterior and apical infarctions represent the large left ventricular wall, which makes up the greatest muscle mass of the heart. Infarction in this area is associated with the highest incidence of mortality and MACE. ST elevation or waves in one or more of the precordial leads (V1-V6) and leads I and aVL have classically been used to suggest anterior wall ischemia or infarction. Septal involvement classically refers to involvement solely in V1-V3 but this may represent an apical injury. Changes in V4-V6 suggest anterolateral ischemia or infarction. The reciprocal leads for anterior ischemia are the inferior leads. Anterior infarctions are due primarily to left-sided coronary lesions such as obstructions of the left main artery or the left anterior descending artery. Patients that have ST elevation in the anterior precordial leads and any of the following electrocardiographic findings are at risk of a proximal left lesion and thus have a higher risk of morbidity and mortality: presence of ST elevation in lead aVR, complete right bundle branch block (RBBB), ST depression in lead V5, an abnormal Q wave in aVL, and inferior ST elevation $\geq$1 mm plus ST elevation in aVL (11). ST elevation in lead aVR $\geq$ ST elevation in lead V1 may be indicative of a left main coronary artery obstruction (12).

Lateral infarctions may be associated with anterior, inferior, or posterior infarctions, depending on the dominance of the area by the left anterior descending, right coronary artery (RCA), or circumflex vessels. The ECG manifestations of lateral infarction are noted in

leads I, aVL, V5, and V6. The reciprocal leads for lateral infarctions can be seen in leads III, aVF, and V1.

Inferior infarctions are identified by ischemic changes in leads II, III, and aVF and may involve either the RCA or the circumflex artery. If there is ST elevation in lead III exceeding that in lead II, especially when combined with ST depression in I and aVL, there is a very high probability of involving the proximal or mid-RCA. If the ST-segment elevation in lead II is equal to lead III, especially combined with ST depression in leads V1-V3 or ST elevation in leads I and aVL, it is usually a circumflex arterial occlusion (13). The RCA supplies the atrioventricular (AV) node in 90% of patients (in the other 10% it is supplied by the circumflex). Thus, bradycardia and blocks are common with involvement in this region. When there is evidence of inferior myocardial ischemia and/or infarction, right-sided leads V3R and V4R should be placed to assess for possible right ventricular ischemia or infarction (see below for right ventricular infarctions [RVMIs]). The reciprocal changes can be seen in I, aVL, or both. Care must be taken in diagnosing anterior changes as reciprocal, as ST depression may be indicative of posterior infarction as well (see further).

True isolated posterior infarctions are rare, as the majority of posterior infarctions are extensions of either inferior or lateral infarctions (RCA or circumflex). Inferior and lateral MIs associated with posterior extension have a higher mortality than each in isolation, and posterior infarctions may be involved in up to 20% of all MI. The posterior wall is, however, poorly represented on the standard 12-lead ECG. A posterior MI should be suspected with any ST-segment depression in the anterior precordial leads or any inferior or right-sided MI. Posterior and inferior MIs can be differentiated from anterior wall ischemia by the presence of ST-segment elevations in the inferior leads (II, III, and aVF) and posterior leads V7-V9. Utilization of these posterior leads V8 and V9 improves diagnostic sensitivity. ECG criteria for posterior MI include a tall, upright T wave, a tall, wide R-wave ≥ 0.04 seconds in lead V1 (corresponds to the appearance of pathologic Q waves in the posterior leads), a R/S amplitude ratio of >1, and horizontal ST depression in the anterior

precordial leads. Posterior MI is amenable to reperfusion therapy, so identification has important implications.

The ECG diagnosis of RVMI offers special challenges. The right side of the heart is another poorly represented region on the standard ECG, and RVMI usually occurs in the presence of an inferior left ventricular infarction, which can mask the specific ECG manifestations. Because there are anatomic variations of the blood supply to the right ventricle, interruption of blood supply in any of the coronary arteries can lead to a right-sided infarction. Thus, right-sided infarction should be a consideration with all MIs and especially so in inferior infarctions. Thirty to fifty percent of inferior infarctions show extension to the right ventricle. RVMI is associated with higher mortality and in-hospital morbidity than patients without RV involvement. Although about half of RVMI have profound hemodynamic and electrical complications, the long-term prognosis is generally good for those who survive the event (14). The sensitivity of the ECG can be improved by utilizing right-sided chest leads (V1R-V6R), which are the mirror images of the left-sided leads. RV infarction is indicated by ST-segment elevation of ≥ 1 mm in lead V3R or V4R, or both. RV infarction is also suggested in an inferior MI with an isolated ST-segment elevation in V1, owing to the rightward axis of this lead. Although elevation of the right-sided limb leads is specific for RVMI, it is not sensitive. It is important to recognize right ventricular involvement on ECG, as these patients are dependent on preload for the maintenance of left ventricular outflow. Administration of agents, such as nitrates, that reduce preload can result in profound hypotension. RV contractile dysfunction becomes hemodynamically significant in only about 10% of patients; individuals with hemodynamically significant RV infarction typically present with arterial hypotension and jugular venous distention but clear lung fields. These patients are usually amenable to fluid resuscitation, as it will in essence improve hemodynamic parameters on these preload-dependent patients.

Bundle Branch Blocks

Bundle branch blocks (BBB) can make the interpretation of MI more difficult. RBBB usually does not interfere with the diagnosis of STEMI. A RBBB usually affects the terminal phase of ventricular depolarization, producing a wide R¿ wave in the right chest leads and a wide S wave in the left chest leads. This is due to the delayed depolarization of the right ventricle, while most of the STEMI involvement involves the LV and therefore ECG tracings will not be affected in this regard. In the setting of RBBB block, MI can be diagnosed relatively easily, with the ECG showing a wide QRS, a positive terminal deflection in lead V1, and a wide S wave in V6. In the presence of LBBB, ECG indicators of acute MI are much less reliable. No single or group of ECG criteria are completely sensitive for the detection of MI. Three ECG findings that have shown a specificity of 90% for MI include (i) ST-segment elevation of 1 mm or more in the same direction as the QRS complex, (ii) ST-segment depression of 1 mm or greater in leads V1 to V3, and (iii) ST-segment elevation >5 mm opposite to the direction of the QRS complex. A paced rhythm produces a pattern similar to that of LBBB, so ST-segment elevation of >5 mm in predominantly negative QRS complexes (usually the anterior precordial leads) is the only criterion that is useful in the setting of diagnosis of MI when there is a paced rhythm.

Biochemical Markers

After history and ECG, risk stratification continues with biochemical markers of cardiac injury. Disruption of normal cardiac myocyte membrane integrity by ischemia/infarction leads to biologically active intracellular contents such as troponin, creatine kinase (CK), and myoglobin to leak into the extracellular space. The patterns of appearance of these markers in the blood depend on their intracellular location and molecular weight, the local blood and lymph flow, and their rate of elimination from the blood. Cardiac markers are not only useful for diagnosis but can provide prognostic information as well. There is debate as to whether release of these markers is due solely to irreversible damage to the heart. This question arises because of the minor troponin elevations seen after

athletes that have run marathons or triathlons or rises of troponin with some patients with pulmonary embolism. These troponin elevations are transient and resolve much more quickly than troponin elevation from AMI (15).

CK, specifically the CK-MB fraction, has been historically used as the primary cardiac marker, but its diagnostic utility over time is in favor of troponin assays. CK-MB is far less sensitive and specific for myocardial infarction than troponins and should not be used in isolation to make the diagnosis of myocardial infarction. CK-MB usually begins to rise within 4 hours of an ischemic event, peaks at 18 to 24 hours, and returns to baseline by 36 to 48 hours. However, some CK-MB is normally present in skeletal muscle, limiting its specificity for cardiac ischemia. Its relatively short half-life assists in temporally identifying the ischemic event when used with other markers, such as troponins.

Cardiac troponins (TnI and TnT) are much more specific for cardiac muscle necrosis. These are proteins that are highly specific for myocardial tissue as they are immunologically distinct from skeletal muscle troponins. There is great variation in the sensitivity of the troponin assays currently in clinical use, from initially developed “standard” assays to the new “high sensitivity” assays that have come into use. Being able to rapidly diagnose ACS or to identify patients at high risk of events with cardiovascular disease is the premise of using “high sensitivity” troponins (16,17). There is little standardization of these assays against each other and there is only recommendation of utilizing an elevation above the 99th percentile, no matter what assay is being used. There are trade-offs between sensitivity and specificity, especially at the very low levels of troponin measurements in whatever troponin assay used. Using standard 99th percentile cut-off values, elevated serum cardiac Tn levels are detectable 2 to 3 hours after acute MI in 80% of patients with AMI (18). This sensitivity improves to 100% by 10 hours. Troponin reaches peak concentrations in approximately 12 hours and remains elevated for 3 to 10 days after an infarction. Even small troponin elevations that are accompanied by a normal CK-MB have been shown to correlate with focal myocyte necrosis. Troponin peak

values also correlate with size of infarct on scintigraphy and MRI (19,20). In patients presenting with chest pain who do not have ischemic changes on ECG, an elevated troponin is associated with significant increases in the incidence of CAD in those who undergo angiography and adverse cardiac events over the subsequent year. Troponins can thus be used as prognostic indicators in patients with ACS. NSTEMI is differentiated from UA on the basis of troponin elevation and is associated with four times the mortality in the first month and 2.5 times the mortality at 3 years. In STEMI patients, an elevated troponin has been shown to be an independent predictor of mortality in both the immediate postinfarction period and 1 month to 3 years after infarction (21). The degree of elevation of troponins also has significant prognostic value: Higher troponins are associated with progressively increased mortality, decreased TIMI flow, decreased LV function, and abnormal Q waves when compared with lower troponin elevations (22).

The demonstration of a rising or falling pattern is needed to distinguish myocardial injury from background elevated troponin levels. Troponins can also provide information about reinfarction. Patients with recurrent infarction have an increase in the troponin of more than 20% above the baseline elevation. Although elevations in troponins reflect myocardial necrosis, they do not indicate its mechanism. Thus, an elevated troponin in the absence of clinical evidence of ischemia should prompt a search for other etiologies of myocardial necrosis (Table 82.9).

TABLE 82.9
Etiologies of Elevated Troponins in the Absence of Ischemic Heart Disease

Cardiac Contusion (Trauma, Surgery, Pacing, etc.)	Congestive Heart Failure (Both Acute and Chronic)
Aortic dissection	Aortic valve disease
Hypertrophic cardiomyopathy	Tachy- or bradyarrhythmias
Rhabdomyolysis with cardiac injury	Renal failure
Pulmonary embolism	Acute neurologic disease (stroke or subarachnoid hemorrhage
Drug toxicity or toxins	Critically ill patients with respiratory failure or sepsis
Burns (especially if >30% body surface area)	Extreme exertion
Infiltrative diseases (amyloid, sarcoid, scleroderma)	Inflammatory diseases (myocarditis and pericarditis)

Alpert and Harvey D. White on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction.

Myocardial Imaging

Strong clinical suspicion and/or nondiagnostic ECG or laboratory findings have usually led to stress testing in the past to further risk stratify patients. Stress testing utilizes physiologic evidence to identify the relationship between coronary artery stenosis and symptoms, characteristic changes on the ECG, regional wall motion abnormalities on echocardiogram, and myocardial perfusion defects on nuclear medicine studies. If there are nondiagnostic stress test results or a strong clinical suspicion, anatomical assessment of the coronary artery may be required. Classically, invasive coronary angiography is then performed to assess whether significant coronary arterial occlusion has occurred. Recently, with the advent of improved coronary CT angiography (CCTA), multidetector CT scanning provides another option to assess anatomically the integrity of the coronary arteries. Multidetector CT scanning detects coronary artery calcification (CAC) and also offers direct imaging of the coronary arteries. Image quality and diagnostic accuracy have improved with each successive generation of scanners (23). Any CAC found on CT scanning is associated with an increased risk of death, infarction, bypass surgery, or PCI (24). Mortality increases linearly with increasing CAC score (calculated scores done by radiologist

specifically trained in CAC reading); patients with no detectable calcium have been reported to have a 12-year survival rate of 99.4% with regard to cardiac disease. The low specificity may lead to increased referral for invasive angiography in patients without significant obstructive disease. However, 64-slice CT angiography not only detects calcium but also has the ability to image the coronary arteries with a detail approaching that of invasive coronary angiography. In reviewing single-center studies of CCTA with classical angiography, there is a sensitivity for significant ($\leq$50%) stenosis of 98% and a pooled specificity of almost 90% (25). In multicenter studies, the sensitivity for significant stenosis is lower (85%) and specificity remains at 90% (26). Nevertheless, the negative predictive value of CCTA ranges from 95% to 100% (27). This has led some institutions to institute low-risk chest pain patients getting a "rule out" CCTA. This practice has not yet been adequately validated and cannot be recommended at this time. Both low-risk patients and high-risk patients do not benefit from CT angiography, because of false-positives and false-negatives, respectively. There is a lack of cost-effectiveness studies as well, and CCTA involves a much higher radiation exposure than the traditional ACS workup. So, although CT angiography and other newer imaging modalities may hold great promise for the future, it is premature to recommend their routine use at the current time.

KEY TESTING

- ECG—Repeat if initially non-diagnostic and there is on-going chest pain
- CXR
- Cardiac Troponin—Repeat at 2 to 4 hours if initial result is negative and recent onset of chest pain
- CBC
- Electrolytes, BUN, creatinine, glucose

ED MANAGEMENT

The initial management of all patients with chest pain and suspected acute ischemic heart disease should include immediate ECG, administration of oxygen, and establishment of vascular access, with laboratory assessment that includes cardiac markers, continuous cardiac rhythm monitoring and pulse oximetry, and close observation of vital signs.

Interventions in Patients with Chest Pain and Suspected Unstable Angina or non-ST-Segment Elevation Myocardial Infarction

ED interventions for intermediate- and high-risk patients with UA and NSTEMI are similar. Management is directed toward decreasing myocardial oxygen demand and stabilizing thrombogenic atherosclerotic plaques.

Anti-Ischemic Therapy

Nitroglycerin

Nitroglycerin (NTG) improves symptoms of myocardial ischemia by (i) reducing oxygen demand through venodilation (low doses: preload reduction; higher doses: preload and afterload reduction) and (b) enhancing oxygen delivery by dilating coronary arteries and arterioles. Despite extensive clinical use, there is remarkably little objective information documenting the effectiveness of NTG in NSTEMI. NTG can relieve anginal pain and may transiently improve LV function but has not been shown to lessen mortality (28,29).

To achieve rapid beneficial effects, NTG therapy should be initiated with sublingual tablets or sprays. Usual protocols include 0.4 mg as a starting dose, with repeated doses every 5 minutes to a total of three doses, based upon symptoms. IV NTG may be initiated by continuous infusion if there is inadequate resolution of symptoms with sublingual therapy or if titration of blood pressure is necessary. The goal of IV NTG therapy is relief of symptoms or a mean arterial blood pressure 10% below baseline in normotensive individuals and up to 30% reduction in hypertensive individuals. NTG should also be avoided in patients who have taken erectile dysfunction medications

such as sildenafil and tadalafil within the preceding 24 hours. Such administration can lead to profound hypotension, MI, and death. Hypotension due to administration of NTG should be treated with a crystalloid bolus infusion.

Morphine

Morphine (2 to 5 mg IV) is a reasonable addition for pain control in myocardial ischemia if symptoms do not resolve with NTG. Morphine has additional benefits beyond its analgesic and anxiolytic effects. It causes venodilation and reduced preload. It also has vagal effects, which reduce heart rate.

Beta Adrenergic Blockers

Beta blockers reduce myocardial oxygen demand by reducing contractility, sinus node rate, and AV nodal conduction. These agents also have antidysrhythmic properties and may counteract the effects of catecholamines on the myocardium. The primary immediate benefits are due to decreased myocardial oxygen demand. No randomized trials have specifically addressed the NSTEMI patient, but the multiple studies that show benefit of beta blockade of UA and STEMI can be extrapolated to the NSTEMI population (30). Beta blockers reduce the odds of death by 23% in the setting of acute MI.

Typically, a cardioselective beta blocker is preferred, such as metoprolol or atenolol or, if an ultrashort agent is required, esmolol (Table 82.10).

TABLE 82.10
Beta-Blockade Agents and Dosages

Agent	Dosage
Metoprolol	5-mg increments by slow intravenous administration (1–2 min) for a total initial dose of 15 mg. Oral therapy can be initiated after 15 min of IV therapy at 25–50 mg q6 h for the next 48 h
Atenolol	5 mg IV q10 min for two doses, then 50 mg 10 min after the last IV dose and repeat in 12 h, then 100 mg/d divided qd—bid
Esmolol	500 µg/kg/min IV bolus over 1 min, then 50 µg/kg/min IV with titration upward for control of heart rate or blood pressure but 50 µg/kg/min q4 min

Early aggressive beta blockade poses a significant hazard in hemodynamically unstable patients with STEMI and should be avoided; this philosophy is generally extrapolated to UA/NSTEMI patients as well (31). It has also been noted that there has been no mortality benefit in receiving IV beta blockers rather than oral preparations in the early stages of AMI.

Chronic oral therapy decreases long-term mortality and should be part of routine care. Carvedilol, begun in low doses with subsequent titration upward 3 to 10 days after MI in patients with left ventricular dysfunction, decreases subsequent death or nonfatal reinfarction when given in conjunction with other interventions for ACS.

The relative contraindications for beta blockers are well known: marked first-degree AV block; any form of second- or third-degree AV block; history of asthma; severe LV dysfunction with congestive heart failure; and marked sinus bradycardia or hypotension.

Calcium Channel Blockers

Calcium channel blockers (CCBs) reduce calcium flux into cells, which inhibits both myocardial and vascular smooth-muscle contraction. Some CCBs affect the cardiac conduction system to slow AV conduction and depress the sinus node. Decreased myocardial oxygen demand results from a reduction of afterload, contractility, heart rate, and improved myocardial flow. There are conflicting data as to whether CCBs are useful in NSTEMI. Trials in patients with UA found no difference in the incidence of MI or death in a comparison of CCBs to placebo (4). No CCB has been shown to reduce mortality

in MI, and in certain patients they may be harmful (e.g., those with heart failure, left ventricular dysfunction, or conduction disorders). CCBs can be used in patients who have ongoing symptoms despite adequate NTG and beta blocker therapy, inability to tolerate either NTG or beta blockade, or coronary artery spasm. The short-acting agent nifedipine must be avoided in the absence of concurrent beta blockade in ACS. Rate-controlling agents (verapamil and diltiazem) can be administered to patients who have no evidence of heart failure or in whom there are contraindications to beta blockers. Care should be used when administering a CCB to a patient already on a beta blocker, as the two synergistically depress LV function and both sinus node and AV node conduction.

Antiplatelet Therapy

Aspirin

All ACS trials evaluating aspirin in UA/NSTEMI have consistently demonstrated a striking benefit. Aspirin blocks the cyclooxygenase pathway that inhibits production of prostaglandins and thromboxanes from acarchidonic acid. Aspirin in conjunction with other medical therapy produces an almost 50% relative reduction in the combined endpoint of subsequent nonfatal MI, nonfatal stroke, or vascular death in UA patients and a 30% reduction in patients with myocardial infarction (32). One of every 11 patients treated with aspirin over 2 years avoided a cardiovascular event that would have occurred in the absence of aspirin therapy. These results were independent of time given, duration, and dosages. Aspirin should be given immediately upon presentation in doses of 75 to 325 mg and be continued indefinitely. It should be noted that the addition of a second antiplatelet agent significantly lowered the combined end point.

Adenosine Diphosphate Receptor Antagonists

Clopidogrel, prasugrel, and ticagrelor block the adenosine diphosphate receptor P2Y12 on platelets, thus inactivating platelet adhesion. The benefit of aspirin and adenosine diphosphate receptor

blockers was established with the CURE trial using clopidogrel. NSTEMI patients treated with clopidogrel have a relative risk reduction of 20% for death, MI, or ischemic stroke. The benefit of clopidogrel was seen both in patients treated with medical therapy alone and in those who underwent coronary catheterization. This reduction also led to a significant reduction in cardiovascular death, nonfatal myocardial infarction, or stroke at 9 months (33). The major disadvantage of clopidogrel is an increased incidence of bleeding. The actual risk of major bleeding is difficult to determine, as multiple studies have used different definitions of major bleeding. The risk of major bleeding (hemodynamic instability and/or requiring blood transfusions) is best estimated to be about 4%. Ideally, patients who subsequently require CABG should not receive clopidogrel for at least 5 days before their operation, so as to avoid excessive bleeding complications. Patients scheduled for elective PCI who had received clopidogrel prior to the procedure had a 70% relative risk reduction (1.9% absolute reduction) of major cardiac events versus placebo.

In general, NSTEMI patients should receive clopidogrel early. Even if clopidogrel is given prior to CABG, the benefits in terms of morbidity and mortality outweigh the risks of bleeding complications (34). The optimal loading dose of clopidogrel seems to be 600 mg rather than the previously accepted 300 mg dose. Although there was not a decrease in overall mortality, patients who received 600 mg and subsequently went on to get PCI had fewer deaths, MIs, and strokes, and fewer stent thromboses. However, the larger dose was associated with more major bleeding (2.5% versus 2.0%) (35). Aspirin therapy should continue with clopidogrel.

Prasugrel has a faster onset of action and has a greater degree of platelet inhibition than clopidogrel. In comparing prasugrel with clopidogrel in the form of a 300 mg loading dose, prasugrel has less cardiovascular death nonfatal MI and stroke irrespective if they had PCI or not. Prasugrel does appear to cause more major bleeding and life-threatening bleeding than clopidogrel after the first 3 days of therapy (36). Patients should not receive prasugrel in the ED, as patients with NSTEMI did not have a reduction in death, MI stroke,

urgent revascularization, and BPIIb/IIIa-inhibitor rescue therapy. In fact, pretreatment with prasugrel prior to PCI significantly increased bleeding risk (37). This recommendation is different than those for other agents in this class.

Ticagrelor not only has a faster binding time to platelets and inhibits platelets more than clopidogrel, but it also is a reversible. Ticagrelor showed a significant reduction in the rate of death from vascular causes, AMI, or stroke without an increase in the rate of overall major bleeding when compared to clopidogrel for patients that were schedule for coronary angiogram (38). In patients that were managed conservatively, ticagrelor once again outperformed clopidogrel with reduction of the same indicators as those above with only slightly nonsignificant bleeding rates (39).

In summary, outcomes after STEMI are better with aspirin and adenosine diphosphate receptor antagonists, with either conservative treatment or invasive management. In patients managed conservatively, ticagrelor has shown to be superior to clopidogrel and is therefore recommended. If ticagrelor is not available, then clopidogrel is recommended over prasugrel due to the reduced cost and less potential for bleeding complications. In patients who are being invasively managed, if the drug is being withheld until the coronary anatomy is known, ticagrelor and prasugrel are preferred over clopidogrel. If on the other hand a drug is given at the time of diagnosis, ticagrelor is recommended over clopidogrel. Prasugrel should not be used in this instance.

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein (GP) IIb/IIIa inhibitors act by occupying the receptor responsible for the binding of platelets to fibrinogen, the final common pathway of platelet aggregation. Platelets are then unable to bind together, and aggregation is avoided. The major benefit of this class of drugs is prevention of complications associated with PCI in UA/NSTEMI (40). Abciximab, eptifibatide, and tirofiban are the specific agents that have been associated with a reduction in death and subsequent MI in patients undergoing PCI. For NSTEMI patients that will be getting PCI and have heparin is the anticoagulant

chosen, GP IIb/IIIa inhibitors should be added if the patient is troponin positive. As GPIIa/IIIb are often now given intracoronary with very high platelet inactivation rates, GPIIb/IIIa inhibition is not needed in the ED setting (41,42).

Anticoagulants

Unfractionated Heparin

Unfractionated heparin (UFH) has been one of the mainstay treatments of UA/NSTEMI. An 89% reduction of subsequent MI and a 63% reduction in refractory angina have been documented. Meta-analyses have shown a reduction of death or recurrent MI by 56% in the first 5 days and 33% in the subsequent 2 to 12 weeks (43). These benefits do not continue over the long term; however, there may be a "rebound" phenomenon with increased thrombin activity after heparin is discontinued.

Most trials use a standard 5000-unit loading dose followed by a 1000 U/h infusion. However, this regimen has been found to be inferior to a weight-based formula of an initial bolus of 60 to 70 U/kg (maximum of 5000 U) to be followed by an infusion of 12 to 15 U/kg/h (maximum 1000 U/h). The therapeutic endpoint of adequate anticoagulation is a PTT between 60 and 80 seconds.

There are several disadvantages of UFH. The bioavailability is poor; frequent monitoring of the PTT is necessary; and severe heparin-induced thrombocytopenia occurs in 1% to 2% of patients.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) is an attractive alternative to UFH, as it addresses the shortcomings of UFH and is associated with a much lower incidence of severe heparin-induced thrombocytopenia.

Multiple studies have compared LMWH and UFH. The odds ratio for MI or death was similar with both UFH, and as with UFH, there was no benefit to long-term use of LMWH. Moreover, there is no difference in recurrent angina or major or minor bleeding between the two drugs. However, LMWH significantly reduced the risk of MI,

revascularization, and thrombocytopenia compared to UFH (44). Dosages and other information about LMWH can be found in Table 82.11.

TABLE 82.11
Low-Molecular-Weight Heparins in Treatment of UA/NSTEMI

Agent	Dosage
Enoxaparin	1 mg/kg subcutaneously every 12 h (maximum of 100 mg)
Dalteparin	120 international units/kg every 12 h (maximum of 10,000 international units)

Though patients on LMWH have overall more bleeding complications, most are minor and do not require treatment; major bleeding has not been shown to be statistically different from UFH.

Fondaparinux, a new LMWH that has FDA approval for the prevention and treatment of deep venous thrombosis associated with orthopedic procedures, may have an advantage over enoxaparin in terms of bleeding complications. Major bleeding was reduced by almost half when compared to enoxaparin with similar rates of death, recurrent MI, or refractory ischemia (45).

For NSTEMI patients who are managed with a conservative strategy, the recommendation is fondaparinux or enoxaparin over UFH or bivalirudin. Fondaparinux is preferred if there is a higher risk of bleeding. For NSTEMI patients who are managed invasively, fondaparinux would be recommended as the initial anticoagulant.

Bivalirudin

Bivalirudin is an example of a direct thrombin inhibitor that inactivates clot-bound thrombin. Clot-bound thrombin is a stimulus for thrombosis, so this inactivation will overcome some of the limits of standard heparin therapy.

Bivalirudin has been shown to be equivalent to GP IIb/IIIa inhibitors combined with LMWH in reducing death and recurrent MI and urgent need for revascularization in patients undergoing PCI. The main benefit is that the rate of major bleeding in these patients

is about half that associated with the GP IIb/IIIa inhibitor and LMWH group. Bivalirudin may be an attractive alternative to GP IIb/IIIa inhibitor and LMWH in light of the decreased bleeding rates and the simplicity of monotherapy (42). Bivalirudin has not been compared with fondaparinux.

Angiotensin-Converting Enzyme Inhibitors

The use of angiotensin-converting enzyme (ACE) inhibitors in the acute management of MI is a subject of debate. In the NSTEMI patient, indications for administration of ACE are clinical heart failure, pulmonary congestion, or a left ventricular ejection fraction $<40\%$. Outcomes appear to be best when administration occurs within the first 24 hours of ischemia. Oral medication is recommended owing to the risk of hypotension with IV administration. ACE inhibition in these patients results in a relative reduction of mortality by 7%, with a number-needed-to-treat of about 200 (46). Patients who have the greatest benefit are those with large anterior MI and clinically apparent heart failure. It is felt to be prudent to wait to administer this oral medication until few hours after presentation.

Reperfusion Therapy

Thrombolytics

There is no benefit to and there is strong recommendation against adding thrombolytic therapy to standard treatment in patients with UA/NSTEMI. Angiographic data show that the infarct-related artery in these patients is not occluded 60% to 85% of the time. The mechanism of ongoing ischemia and microinfarction is more likely to be embolization rather than complete vessel occlusion. Angiography after thrombolytic treatment has not shown a statistically significant improvement in flow compared to patients who did not receive thrombolysis. Furthermore, there was no difference in clinical parameters. Fatal and nonfatal MI occurred more frequently with thrombolytics and, not surprisingly, there was a trend more hemorrhagic complications (30).

Percutaneous Coronary Intervention

PCI therapy has shown tremendous promise, with a reduction of death, recurrent MI, and urgent need for revascularization in STEMI patients. There is limited data on PCI in NSTEMI patients.

UA/NSTEMI patients who should undergo immediate PCI include those with hemodynamic instability, refractory symptoms despite maximal medical therapy, refractory dysrhythmias secondary to ischemia, mechanical complications of ischemia (such as acute mitral regurgitation), and progressive symptoms in patients who had had prior PCI or CABG.

Patients without any of these high-risk characteristics can be managed in one of the two ways: an early invasive strategy that utilizes PCI or a conservative strategy that does not include PCI. Patients with ST depression, older than 65, and, most important, with troponin elevation seem to benefit most from an invasive approach, the primary benefit of which appears to be a reduction in subsequent MI (30).

A number of randomized clinical trials have compared the early invasive strategy to a conservative strategy in patients with a UA/NSTEMI. The rate of death or MI was 18% lower in the invasive group in these trials, primarily owing to the decrease in subsequent MI. There was a slight increase in immediate in-hospital mortality (procedural complication) that was more than compensated for by a significant reduction in mortality after discharge from the hospital. Several trials found that patients with an elevated troponin, with ST depression, and older than 65 derived particular benefit from the early invasive approach. Other studies have highlighted a strategy of selective invasive therapy in which patients are initially managed medically and stabilized before going for PCI. These trials found no difference in composite endpoints at 1 year between an early invasive and a selective invasive strategies (47).

In summary, patients with high-risk stratification for NSTEMI (see above) benefit from an early invasive approach, although optimal timing has yet to be determined.

Interventions in the Patient with ST-Segment Elevation MI

Acute STEMI is most commonly caused by abrupt thrombotic occlusion of a coronary artery at the site of an atheromatous plaque. Therapeutic interventions in this setting are directed toward reopening the occluded coronary artery (reperfusion) and decreasing myocardial oxygen demand.

Reperfusion Therapy

All STEMI patients should undergo rapid evaluation for reperfusion therapy and have a reperfusion strategy implemented promptly. The restoration of flow can be achieved by pharmacologic means (fibrinolysis or thrombolysis), by PCI with balloon angioplasty and coronary stent placement, or by surgical measures. The goal for all methods is rapid reperfusion to minimize myocardial necrosis.

Percutaneous Coronary Intervention

When it is available in a timely manner, high-quality PCI is preferred over thrombolytic therapy. Death, nonfatal reinfarction, and hemorrhagic stroke occur less often in patients receiving PCI, compared to those receiving thrombolytic therapy. PCI also has less short-term mortality at 30 days, less nonfatal reinfarction, and less hemorrhagic stroke. Should primary PCI occur with any acute STEMI, the patient can undergo the procedure in a timely manner by persons skilled in the procedure. Timely was defined as within 90 minutes or less from first medical contact for patients presenting or being transported to a PCI-capable hospital or 120 minutes or less for patients who present or are transported to a non-PCI-capable hospital with subsequent transport to a PCI-capable hospital (48). In the absence of contraindications, fibrinolytic therapy should be given to patients with STEMI and onset of ischemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact. Thrombolytics may even be given if there is clinical and/or ECG evidence of ongoing ischemia within 12 to 24 hours of symptom

onset and a larger area of myocardium at risk or hemodynamic instability.

In STEMI patients with delayed presentations of 12 to 24 hours, PCI is recommended over thrombolytics, especially if patients have symptoms of heart failure, ischemia, or malignant dysrhythmias (49).

The standard of care in STEMI patients presenting to the ED is to initiate PCI with balloon inflation within 90 minutes from arrival in the ED. Multiple measures can be instituted to lower the time for PCI (Table 82.12).

TABLE 82.12
Measures to Lower the Time for Percutaneous Coronary Intervention

Factors Shown to Reduce Door-to-Balloon Times in PCI	Time Saved (min)
Expectation of PCI team to arrive within 20 min	19.3
Use of prehospital ECG to activate PCI team	15.4
On-site cardiologist	14.6
Single call to activate PCI system	8.6
Weekly feedback to the emergency department and PCI lab	8.6
Emergency physician activation of the PCI team	8.2

ECG, electrocardiograph; PCI, percutaneous coronary intervention

Reproduced with permission from Bradley EH, Herrin J, Wang Y, et al. Strategies for reducing the door-to-balloon time in acute myocardial infarction. *N Engl J Med.* 2006;355(22):2308–2320.

Given the superiority of PCI over thrombolytics, consideration must be given to the issue of patient transfer from non-PCI-capable centers to PCI-capable centers. The impact of delay can be substantial. Each half-hour delay of reperfusion therapy is associated with an increase of 1.075 in the relative risk of 1-year mortality (49).

Facilitated PCI refers to a strategy of planned immediate PCI after administration of thrombolytic therapy. Despite the theoretical advantages of this two-tiered approach, facilitated PCI has not demonstrated any benefit in reducing infarct size or improving outcomes (50).

Rescue PCI refers to patients who have failed thrombolytic therapy. Patients who do not show a 50% reduction in ST-segment elevation within the first 1 to 3 hours have been shown to have decreased myocardial blood flow, increased infarct size, and a poorer prognosis. Patients with continuing symptoms of ischemia, or continued or new ischemic changes on the ECG, also have a worse prognosis. Patients who fail thrombolytic therapy have a 5-fold increase in mortality. PCI in this setting has resulted in higher rates of early infarct arterial patency, improved regional infarct-zone wall motion, and fewer adverse in-hospital events compared to a deferred PCI strategy or medical therapy alone. As time is an important factor, patients receiving thrombolytic therapy must be observed closely. If there has not been a reduction in ST-segment elevation within the first few hours, or if there is any hemodynamic or electrical instability or persistent ischemic symptoms, rescue PCI should be instituted.

Thrombolytics

Although PCI should be the primary reperfusion strategy, thrombolytics do improve survival in patients with STEMI and are indicated if PCI is unavailable. Intravenous thrombolysis improves coronary flow at 90 minutes after administration in 50% to 85% of patients. There is a reduction on average of 18 deaths per 1000 patients treated, and this survival benefit remains evident even after 10 years. The greatest benefits occur when thrombolytics are administered within 2 hours of symptom onset; there is a decline of approximately 1.6 lives saved per 1000 patients treated for every hour of delay beyond 2 hours, but beyond 12 hours from symptom onset, the benefit of thrombolytic therapy is minimal. This has led to extensive education, preparation, and continuous quality improvement measures to expedite thrombolytic administration (48).

Streptokinase is the prototypical thrombolytic and still has clinical utility to this day. The addition of streptokinase to STEMI treatment regimen reduced the relative risk of death by almost 25%. The adverse effects of streptokinase include bleeding, allergic reactions, and hypotension. Major bleeding is rather uncommon, and the risk of

hemorrhagic stroke is <1% in patients younger than 70 and 1.6% in patients older than 70.

Streptokinase induces a global lytic state within the body, whereas fibrin-specific thrombolytics act on the fibrin-rich organized clot. The most commonly used fibrin-specific thrombolytics are alteplase (tPA), reteplase, and tenecteplase. tPA has a short half-life (3 to 4 minutes) and is not associated with allergic reactions or hypotension. The difference in reduction in absolute mortality between tPA and streptokinase is about 1%.

All the fibrin-specific thrombolytics have similar rates of morbidity and mortality. Major hemorrhagic events occur in 2% to 3% of patients, and intracranial hemorrhage in about 1%. The intracranial bleeding usually occurs within the first 24 hours after administration. Of the patients who have a major bleeding event, there is a 20% mortality rate, and this accounts for 10% of all hospital deaths (51). Predictors of higher rates of intracranial hemorrhage are age older than 75, black race, female gender, prior history of stroke, systolic blood pressure >160 mm Hg, and weight <65 kg for women and <80 kg for men. If one or more of these factors are present and the patient does not have access to PCI, streptokinase should be strongly considered for reperfusion rather than fibrin-specific thrombolytics, as it is associated with a risk of hemorrhagic stroke that is about half as great as the fibrin-specific agents.

There are major limitations to thrombolytic therapy. Thrombolytics have their major benefit when they are given early in the course of STEMI, with a delay of <3 hours. Although the timely use of thrombolytics restores patency in up to 90% of infarct-related vessels, only 50% are restored to normal patency. After what appears to be successful treatment, early recurrence of ischemia or ST-segment shifts have been observed in 20% to 30% of patients, with complete coronary reocclusion and reinfarction in some individuals. Around 20% to 30% of patients have contraindications to thrombolytic therapy (Table 82.13).

TABLE 82.13
Absolute Contraindications to Thrombolytic Therapy

Active internal bleeding
CNS neoplasm, AV malformation, or aneurysm
CNS procedure or CVA within 2 mo
Severe uncontrolled hypertension (over 200/130 or complicated by retinovascular disease or encephalopathy)
Known bleeding diathesis
MI due to aortic dissection
Allergy to either streptokinase or anistreplase, if streptokinase or anistreplase will be used
Relative contraindications to thrombolytic therapy
Age older than 75
Cerebrovascular disease
Pregnancy or early postpartum
Recent major surgery (<10 d), noncompressible vessel puncture, or organ biopsy
Recent trauma, including CPR of over 2-min duration
Recent GI bleeding or active ulcer disease (<10 d)
Acute pericarditis or subacute bacterial endocarditis
Septic thrombophlebitis
High likelihood of left heart thrombus (e.g., mitral stenosis with atrial fibrillation)
Known coagulation defects, including anticoagulant therapy
Significant liver dysfunction
Conditions associated with bleeding risks, such as diabetic retinopathy.
Menstruation
Terminal cancer or other end-stage disease
Recent streptococcal infection, if streptokinase or anistreplase will be used

CVA, cerebrovascular accident; MI, myocardial infarction.

Anti-Ischemic Therapies

Nitroglycerin

Nitrates have an important role in the management of patients with STEMI, despite the absence of a mortality benefit. It can be of value in reducing pain due to myocardial ischemia, improving symptoms of pulmonary congestion, and lowering blood pressure in hypertensive patients.

Care should be taken in patients with systolic blood pressure <90 mm Hg, marked bradycardia, tachycardia, or known or suspected RVMI. The initial dose of NTG is 0.4 mg sublingually and repeated as needed, with conversion to an intravenous drip if there is continuing pain or a need to control hypertension.

Morphine

Pain management should be directed toward acute relief of ischemic symptoms and general relief of anxiety and apprehension, thus reducing circulating catecholamines. An initial dose of 2 to 4 mg can be administered and then titrated accordingly for symptom relief.

Beta Blockers

The current literature is far from unanimous regarding the use of beta blockers in STEMI. Early studies showed that in patients who had received reperfusion therapy, the rate of death, recurrent reinfarction, and intracerebral hemorrhage was less in patients receiving beta blockers. These earlier studies have come into question, however. Although early IV beta blockade has become an accepted ancillary treatment in patients undergoing thrombolysis for STEMI, there is no convincing evidence of a mortality benefit. The most recent data suggest that the benefit of beta blockade by reduction of ventricular dysrhythmias and recurrent infarction is completely offset by the incidence of cardiogenic shock associated with beta blockade (31). There are no studies evaluating beta blockade with primary PCI, but the general recommendations are the same as for patients receiving thrombolytics.

It is reasonable to administer IV beta blockers to STEMI patients with tachycardia and hypertension. Intravenous beta blockers should not be administered in patients with the following: (i) signs of heart failure, (ii) evidence of a low output state, (iii) increased risk for cardiogenic shock (age >70, systolic blood pressure <120 mm Hg, sinus tachycardia >110 bpm or heart rate <60 bpm, and increased time since onset of symptoms of STEMI), or (iv) other relative contraindications (PR interval >0.24 seconds, second- or third-degree heart block, active asthma, or reactive airways disease). Oral

beta blocker therapy should be initiated in the first 24 hours after presentation to the hospital with ACS, unless there are contraindications.

Antiplatelet Therapy

Aspirin

Aspirin should be given to the patient with suspected STEMI as early as possible and continued indefinitely, regardless of the strategy for reperfusion and regardless of whether additional antiplatelet agents are administered. The relative risk reduction of mortality for this easily administered intervention is 23%. Doses ranging from 160 to 325 mg have been shown to be effective in STEMI. Aspirin reduces reocclusion and reduces ischemic events after fibrinolytic therapy with either fibrin-specific or fibrin-nonspecific agents (48).

Adenosine Diphosphate Receptor Antagonists

This class of medications includes clopidogrel and prasugrel. There are currently no trials evaluating clopidogrel in addition to aspirin in the context of STEMI, but the NSTEMI trials have been extrapolated to STEMI patients. Clopidogrel has been shown to result in a relative risk reduction of 36% over placebo in STEMI patients (52). The impact of clopidogrel on STEMI patients is quite dramatic with a benefit showing that for every 1000 STEMI patients, pretreatment with clopidogrel prevented nine cardiovascular events (31).

For patients undergoing PCI, clopidogrel has been compared to prasugrel in STEMI patients and prasugrel has been shown to have less mortality, nonfatal MI, and nonfatal stroke primarily driven by the reduction in subsequent MI. There has also been shown to be less stent thrombosis with prasugrel with no increased risk of bleeding (53). The dosing for clopidogrel for patients receiving PCI is 600 mg, which is increased from the previous recommendation of 300 mg due to a reduction of MACE. Prasugrel is recommended to have a loading dose of 60 mg (54).

Ticagrelor differs from clopidogrel and prasugrel in that it binds reversibly rather than irreversibly and has a more rapid onset of

action. It is similar to prasugrel in that it has a more intense platelet inactivation than clopidogrel. Patients given a 180 mg loading dose of ticagrelor were less likely to die, have an MI or stroke than those given clopidogrel (38).

The timing for platelet inactivation is inherent to the agent chosen. Clopidogrel has been shown to take 8 hours for acceptable platelet inactivation, whereas prasugrel and ticagrelor are at 2 hours for similar parameters (55).

Therefore for patients receiving PCI for STEMI either prasugrel or ticagrelor have advantages compared to clopidogrel.

For patients receiving fibrinolytics, clopidogrel is recommended over prasugrel and ticagrelor simply because clopidogrel is the only medication that has been studied in this setting. The dosage in this setting is 300 mg for those who are less than 75 years and 75 mg for older patients (48).

In patients that are unable to receive either PCI or thrombolytics, ticagrelor is recommended over clopidogrel or prasugrel (48).

Glycoprotein IIb/IIIa Inhibitors

The major initial indication for the use of GP IIb/IIIa inhibitor therapy in STEMI was for patients that were having immediate PCI. These initial recommendations were made prior to the use of potent $P2Y_{12}$ inhibitors like prasugrel and ticagrelor. Prior to standard use of the $P2Y_{12}$ inhibitors GP IIb/IIIa inhibitors (primarily abciximab) did lower the absolute rate of death for PCI patients by 1%. Further analysis of many trials showed that although more patients achieved TIMI 3 flow (normal) at the time of PCI, final TIMI flow rates or any other major clinical outcomes were no different. The limited studies in patients with $P2Y_{12}$ inhibitors being utilized have given mixed results showing either no benefit or little benefit to the addition of GP IIb/IIIa inhibitors. It should be noted that, GP IIb/IIIa inhibitors, originally given systemically, are now given by the intracoronary route as this has been shown to reduce infarct size and mortality (56). The most recent recommendation for patients at low risk for bleeding getting primary PCI after being given heparin and either a

$P2Y_{12}$ inhibitor or not is the patients should have a GP IIb/IIIa inhibitor added but only after diagnostic angiography assures that the patient does not need immediate coronary arterial bypass grafting. Therefore, routine administration of GP IIb/IIIa inhibitors in the ED should be avoided. In the context of bivalirudin being used as a sole agent for ACS in patients at high risk for bleeding, it is a moot point, as heparin and GP IIb/IIIa is not recommended in this clinical context.

The addition of GP IIb/IIIa inhibitors to thrombolysis in the primary treatment of STEMI is not recommended due to no increase in survival and an elevated bleeding risk especially in patients over the age of 75 (48).

Anticoagulants

Heparin: Unfractionated and Low-Molecular Weight

Anticoagulant therapy is a mainstay in the management of STEMI due to its ability to prevent vessel closure in patients receiving PCI with or without stents. Several trials have compared UFH to LMWH. Enoxaparin and dalteparin are the two most studied LMWH. LMWH has been shown to have less death or recurrent MI but slightly more major bleeding at 30 days as compared to UFH (57). The weight-adjusted dose of UFH varies depending on the reperfusion strategy. For PCI, a weight-adjusted bolus of 70 to 100 U/kg (reduced to 50 U/kg if GP inhibitors have been instituted) should be given, followed by an infusion to keep the PTT at 250 to 350 seconds (200 seconds if GP inhibitors are also used) (48). For patients receiving the recommended LMWH, the dose of enoxaparin for patients younger than 75 years is an initial IV bolus dose of 30 mg followed 15 minutes later by subcutaneous injections of 1.0 mg/kg every 12 hours. For patients older than 75 years of age, the bolus dose is eliminated, and the subcutaneous dose is 0.75 mg/kg every 12 hours.

Fondaparinux, a newer agent in this class, has shown some promise, with reductions in death and reinfarction beyond that seen with other LMWHs and with UFH (58). The dose of fondaparinux in

STEMI is 2.5 mg IV, followed by subsequent subcutaneous injections of 2.5 mg daily.

In patients receiving thrombolytic therapy, the recommendation for heparin administration depends on which fibrinolytic agent is used. The nonspecific fibrinolytic agents (e.g., streptokinase) produce a systemic coagulopathy and are anticoagulants themselves, so heparinization is not required. For fibrin-specific thrombolytics (tPA, reteplase, and tenecteplase), there is less systemic anticoagulant activity and even less procoagulant activity of the breakdown products, which makes the rationale for heparinization evident. Patients undergoing reperfusion with fibrinolytics should receive anticoagulant therapy for a minimum of 48 hours, and preferably for the duration of the hospitalization, up to 8 days. If fibrin-specific thrombolytic therapy is utilized, a 60 U/kg bolus dose followed by an infusion of 12 U/kg/h (maximum of 4000 U bolus and 1000 U/h infusion) is recommended. The data for LMWH in STEMI shows that it is similar to UFH in safety and efficacy and is preferred for the above listed reasons.

Angiotensin-Converting Enzyme Inhibitors

Patients with STEMI in the anterior precordial leads, evidence of heart failure, or a left ventricular ejection fraction of $<40\%$ should receive an oral ACE inhibitor within the first 24 hours of therapy. Caution is necessary to avoid causing hypotension in the first few hours after the infarction. Oral ACE inhibitors should not be initiated in patients who have received vasoactive medications until hemodynamic parameters have stabilized after treatment. An angiotensin II receptor blocker can be given either alone, if the patient is intolerant of ACE inhibition, or in addition to an ACE inhibitor.

Complications of Acute Ischemia or Infarction

Dysrhythmias

Cardiac rhythm disturbances, most typically of ventricular origin, are common during UA or acute infarction. Ventricular tachycardia and ventricular fibrillation can occur without warning in ACS patients.

Premature ventricular contractions are noted in the vast majority of patients who experience AMI. In the past, frequent, multifocal, or early diastolic premature ventricular contractions were routinely treated with antidysrhythmic medications to reduce the risk of development of hemodynamically unstable rhythms such as ventricular tachycardia and ventricular fibrillation. However, pharmacologic therapy is reserved now for patients with sustained ventricular dysrhythmias. Prophylactic therapy has been shown to increase the risk of bradycardia and asystole in ACS patients but to have no impact on mortality.

Accelerated idioventricular rhythms occur in approximately one-fourth of STEMI patients, most commonly during reperfusion therapy, but with minimal hemodynamic effects. Sinus tachycardia is the most common supraventricular dysrhythmia; atrial flutter and atrial fibrillation can also be seen. Sinus bradycardia occurs in 30% of myocardial infarctions, especially when ischemia affects the conduction pathways; sinus bradycardia should be treated only if hemodynamic compromise is present, as a slow heart rate is protective in ischemia.

Conduction Disturbances

Mortality rates are markedly higher for patients who develop complete AV block. Heart blocks are usually related to ischemia of the conduction system, increased vagal tone, or a combination of the two. Patients with conduction disturbances may require emergent pacing to correct hemodynamic abnormalities. Transcutaneous pacing is the most readily available modality for rapid restoration of heart rate (Table 82.14).

TABLE 82.14
Indications for Placement of Emergent Transcutaneous Patches and Active Transcutaneous Pacing

Sinus bradycardia with symptoms of hypotension that is unresponsive to drug therapy
Symptomatic Mobitz II second-degree AV block
Symptomatic third-degree AV block
Bilateral BBB (alternating BBB, or RBBB and alternating left anterior fascicular block (LAFB), left posterior fascicular block (LPFB)[a]
Newly acquired or age indeterminate LBBB, LBBB and LAFB and LPFB[a]
RBBB or LBBB and first-degree AV block[a]

AV, atrial ventricular; BBB, bundle branch block; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; RBBB, right bundle branch block.
[a]Apply patches and attach to system but may only need to activate if sudden symptomatic or hemodynamic compromise.
Reproduced with permission from Yusuf S, Mehta SR, Chrolavicius S, et al. Effects of fondaparinux on mortality and reinfarction in patients with acute ST-segment elevation myocardial infarction: The OASIS-6 randomized trial. *JAMA*. 2006;295(13):1519–1530.

Ventricular Dysfunction

The left ventricle undergoes dynamic changes with any ischemic insult. AMI leads to dilation of the left ventricle, expansion of ischemic tissue, and thinning of the ventricular walls. These changes may result in heart failure and a subsequent poorer prognosis.

Cardiogenic Shock

The most severe form of ventricular dysfunction leads to inadequate forward flow and decreased perfusion of vital organs. Patients who develop cardiogenic shock usually have had a large anterior MI or have diffuse disease with multiple areas of myocardial dysfunction. Those younger than age 75 should immediately undergo PCI, as this has been shown to save 13 lives per 1000 patients (59). Patients older than 75 should also undergo PCI, provided they are suitable candidates for revascularization. Rapid transfer to a facility where PCI can be performed is indicated. In patients who present in cardiogenic shock within 3 to 6 hours of symptom onset and whose transport is expected to be delayed, fibrinolytic therapy may be initiated with close consultation from the accepting cardiology team (60).

Pericarditis

STEMI patients may develop pericardial friction rubs or pericardial pain. Infarction pericarditis occurs soon after AMI and is transient.

Most cases of infarction pericarditis have a benign course. The majority of rubs are audible in the first few days after an AMI. Postcardiac injury syndrome, often called *Dressler's syndrome,* is a late complication, developing weeks to months after an AMI. These patients develop pleuritic chest pain, a pericardial friction rub, fever, leukocytosis, and sometimes pulmonary infiltrates or pleural effusion. Most of the symptoms resolve with nonsteroidal anti-inflammatory drugs; rarely, corticosteroids may be required.

Left Ventricular Aneurysm

Local paradoxical expansile wall motion or dyskinesis has been termed *left ventricular aneurysm.* This occurs weeks to months after an AMI. Patients with large LV aneurysm are more prone to congestive heart failure, arterial embolism, and ventricular dysrhythmias.

Recurrent Chest Pain

Recurrent ischemic symptoms may develop in one-fourth or more of patients with AMI, especially when thrombolytics are used. The only way to determine whether medical or reperfusion therapy has failed is by prompt coronary angiography.

CRITICAL INTERVENTIONS

- Obtain an ECG quickly in patients presenting with symptoms consistent with myocardial ischemia.
- Initiate continuous cardiac monitoring to avoid missing significant cardiac dysrhythmias.
- Administer aspirin to all patients with potential ACS, unless there are specific contraindications such as aspirin allergy.
- Treatment decisions depend on risk stratification based on history and physical examination, ECG and serum cardiac markers, myocardial imaging, stress testing, and rest imaging.
- Recognize ST-segment elevation so that reperfusion therapy can be initiated promptly.
- Obtain informed consent for patients undergoing reperfusion therapy.
- Initiate anticoagulants and antiplatelet agents early in the course of ACS, as indicated.

DISPOSITION

Patients with suspected ACS should be admitted to the hospital. Patients with UA of MI should be admitted to an intensive care setting for close monitoring and treatment. When acute MI or refractory anginal symptoms are suspected, the consulting cardiologist should be contacted as soon as possible to facilitate medical management and, if indicated, interventional therapy. Patients often present with a low risk for ACS, however, and must be stratified for risk of short-term morbidity and mortality.

Low-risk patients are good candidates for admission into an observation unit for an accelerated protocol to determine whether ACS is present. Patients who have symptoms suggestive of myocardial ischemia but a nondiagnostic ECG and normal cardiac markers and no recurrent symptoms are candidates for stress testing. The safety of observation units for these low-risk patients has been established, and there is significant economic advantage to such an abbreviated hospital stay. Patients can be tested by standard treadmill exercise stress testing, myocardial scintigraphy at rest and during exercise, stress echocardiography, or CT coronary angiography. The sensitivities, specificities, and positive and negative predictive values of these test have been determined largely in the population of patients with a moderate-to-high pretest probability of CAD, so care must be used in their application to a low-risk population. Patients who have positive evaluations in the observation unit should be admitted to the hospital for further testing or management.

Stress echocardiography, to identify regional wall motion abnormalities, is another modality that can be used in low-risk patients. A negative dobutamine stress echocardiographic test is reported to have a negative predictive value of 99%.

Thallium and technetium sestamibi testing can be used for stratifying low-risk patients as well. These agents are taken up by the myocardium in proportion to regional blood flow and are capable of demonstrating myocardial perfusion defects. Negative tests in low-risk patients make them suitable for discharge, as they have less than a 1% chance of experiencing a cardiac event in the subsequent year.

Patients who are discharged from the ED with atypical or low-risk chest pain should have prompt follow-up arranged to further delineate and treat the etiology.

Common Pitfalls

- Failing to admit patients in whom the diagnosis of ACS is uncertain
- Failing to consider myocardial ischemia equivalents such as shortness of breath and syncope in the risk stratification of ACS patients
- Assuming that a negative or nondiagnostic ECG excludes ACS
- Assuming that negative biomarkers exclude ACS. Negative biomarkers can only exclude myocardial infarction. Cardiac markers are not released in UA.
- Failing to check posterior and right-sided ECG leads in patients with abnormal inferior and anterior precordial ST findings on ECG
- Failing to obtain serial ECGs to detect ACS in patients with a normal or nondiagnostic initial ECG
- Failing to appreciate that the 1-year mortality of STEMI and NSTEMI are the same
- Failing to consider the diagnosis of ACS in women. ACS is the leading cause of death in women.
- Failing to consider other potentially lethal diagnoses such as aortic dissection and pulmonary embolism in patients with chest pain

CHAPTER 83

Congestive Heart Failure and Cor Pulmonale

Christopher I. Doty

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is a complex clinical syndrome that represents a broad spectrum of disease stretching from stable pedal edema to fulminant cardiogenic shock. CHF can result from any structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood. Ultimately, CHF is the inability of the heart to pump enough blood to meet the body's needs. Often this manifests as increased left ventricular filling pressures. The common causes of CHF are listed in Table 83.1.

TABLE 83.1
Functional Classification and Causes of Left Heart Failure

Contractile Dysfunction
Ischemic heart disease
Idiopathic dilated cardiomyopathy
Myocarditis

Systolic Pressure Overload
Aortic stenosis
Systemic hypertension
Left ventricular outflow tract obstruction

Systolic Volume Overload
Aortic regurgitation
Mitral regurgitation

Restricted Diastolic Filling
Mitral stenosis
Left atrial myxoma
Hypertrophic cardiomyopathy

High-Output States
Hyperthyroidism
Anemia
Large arteriovenous fistula
Paget disease of the bone

Acute cardiogenic pulmonary edema or acute decompensated heart failure (ADHF) is characterized by the development of dyspnea associated with the rapid accumulation of fluid within the lungs' interstitial and alveolar spaces, which is the result of these acutely elevated left ventricular filling pressures (1).

The burden of CHF morbidity and mortality for the US health care system is staggering with over 6 million patients in the United States alone. The yearly incidence is over 500,000 new patients, making CHF a very deadly disease (2). The prognosis after the onset of clinical signs and symptoms of CHF has not changed substantially over the last 15 years; the 1-year mortality rate for severely symptomatic CHF (class III or IV) is about 45% (3,4). A new diagnosis of CHF carries a 5-year mortality risk of approximately 50%, which is worse than most solid tumors (1).

CHF continues to be predominantly a disease of the elderly. It is estimated that 80% of patients who present to the emergency

department (ED) with ADHF will be hospitalized, and repeat admissions are very common.

In CHF patients, there are three principal compensatory mechanisms that maintain systemic perfusion: (a) the Frank–Starling principle that relates preload to contractile force, (b) ventricular hypertrophy, and (c) central neural and peripheral neurohumoral responses to maintain systemic perfusion pressure and effective intravascular volume. These compensatory responses, unfortunately, are often maladaptive. These responses may further impede ejection of blood from the compromised ventricle. Therefore, manipulating the compensatory response to the fall in cardiac output (CO) (e.g., by the use of β-blockers, angiotensin-converting enzyme inhibitors [ACEIs]) has become a therapeutic focus in the management of chronic CHF (5).

The neurohumoral compensatory mechanisms for CHF actually result in an increase in systemic vascular resistance (SVR) and maintenance of effective intravascular volume through increased endogenous levels of biogenic amines, angiotensin, aldosterone, arginine vasopressin, B-type natriuretic peptide (BNP), prostaglandin E2, and prostacyclin. This increase in SVR and intravascular volume exacerbates the baseline pathology in CHF and worsen the patients symptoms. The pathophysiology of cardiogenic pulmonary edema is given in Figure 83.1.

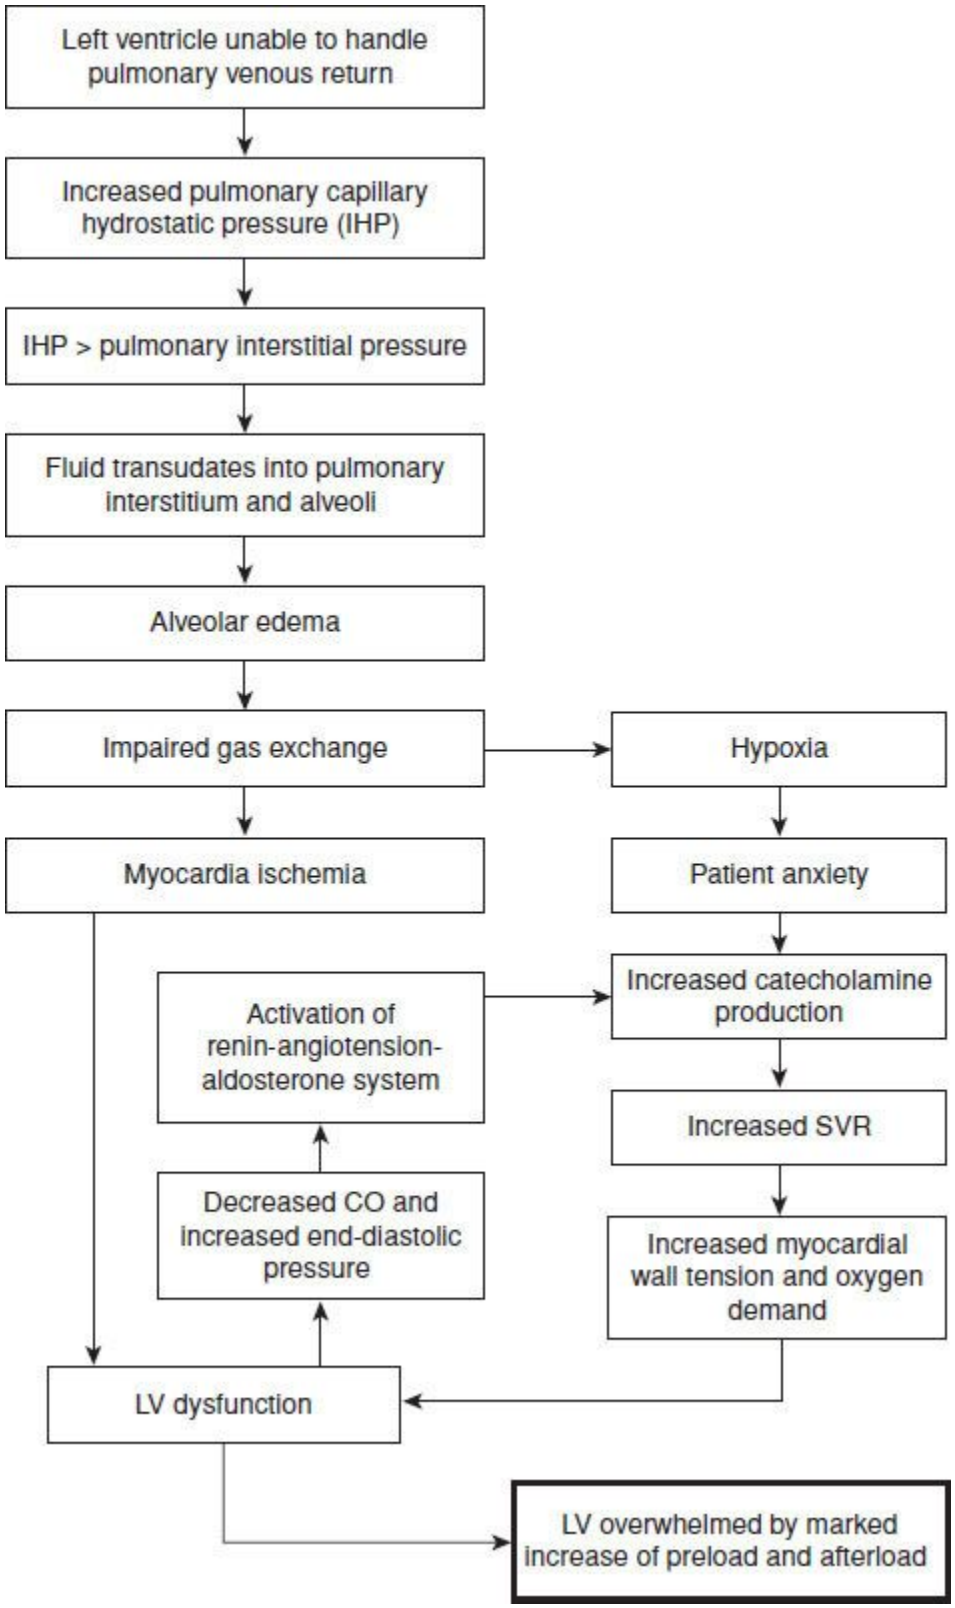

FIGURE 83.1 Pathophysiology of cardiogenic pulmonary edema.

CLINICAL PRESENTATION

The clinical symptoms of CHF usually present through one of two mechanisms. The first is by increasing of hydrostatic pressures in capillary beds. Often, this is in the capillary beds of the lung where the increased hydrostatic pressures in the capillaries lead to transudation of fluid into the alveolar air spaces. This inhibits effective gas exchange and leads to the feeling of dyspnea and to hypoxia. This increased hydrostatic pressure may also present in the capillaries of the systemic circulation. This would be most evident in dependent areas and is usually manifested by pedal edema, or in severe cases, ascites.

The second mechanism of clinical symptoms is through a decrease in CO or forward flow from the heart. This leads to the classic signs and symptoms of a low flow state. These include weakness, altered mental status, hypertension, and easy fatigue. Often these two mechanisms will often present simultaneously.

Patients with left-sided heart failure (LHF) usually present with dyspnea and exercise intolerance, whereas patients with right-sided heart failure often present with peripheral edema and ascites. No single feature or physical examination finding reliably distinguishes patients with CHF resulting from systolic dysfunction (decreased ejection fraction) from those with diastolic dysfunction (increased left heart filling pressures and pulmonary capillary wedge pressures [PCWPs]). It is important to remember that only a little over half of CHF patients have a systolic dysfunction (6). Patients with systolic dysfunction often have increased LV filling pressures owing to a decrease in compliance and a decrease in ejection fraction.

Rales, one of the classic findings in heart failure, may also be found in pneumonia, interstitial lung disease, ARDS, or chronic obstructive lung disease. Wheezing, or “cardiac asthma,” is caused by interstitial edema and is common in ADHF. However, wheezing has poor sensitivity for CHF as it is present in many other diseases.

Acute pulmonary edema is LHF in its most extreme form and is a life-threatening emergency. Dyspnea and respiratory distress are the major presenting symptoms. A past history of heart failure has a

specificity of 90% for the present dyspneic episode being caused by CHF, and patients with prior heart failure are approximately four times more likely to have ADHF when presenting to the ED with acute dyspnea (6). The typical patient is anxious, agitated, diaphoretic, in a tripod position, and will often appear as if they are in shock. There is usually hypertension caused by intense vasoconstriction, tachypnea hypoxia, and tachycardia. Clinical findings usually include (a) rales, (b) peripheral edema, (c) jugular venous distention, (d) a third heart sound, and (e) sometimes a fourth heart sound. Peripheral edema and hepatomegaly may not be seen when acute decompensation develops abruptly, unless it is superimposed on chronic fluid overload.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes pneumonia, asthma exacerbation, cor pulmonale, chronic obstructive pulmonary disease exacerbation, pulmonary embolism, and other conditions that cause dyspnea. Volume-overloaded states such as renal failure, nephrotic syndrome, and hypoproteinemia (e.g., due to liver failure) may also mimic heart failure. Table 83.2 outlines conditions that may precipitate or worsen heart failure.

TABLE 83.2
Precipitating Causes of Heart Failure

Cardiac	Noncardiac
Myocardial ischemia or infarction	Pulmonary embolism
Dysrhythmias	Increased metabolic demand (infection, trauma)
Noncompliance with therapeutic regimen (e.g., increased sodium intake, failure to restrict fluid intake, noncompliance with medications)	Systemic illness (e.g., severe hypertension, severe anemia, thyrotoxicosis, heavy alcohol consumption)
Acute or chronic valvular heart disease	Drugs: cocaine, amphetamines, excessiveness use of bronchodilators
	Pregnancy

ED EVALUATION

A thorough history and physical examination is the best diagnostic tool the emergency physician has in evaluating a patient for ADHF. ADHF often presents as a muddled picture in patients with the clinician having to weigh several diagnostic possibilities. However, there are several other diagnostic modalities that can help confirm the diagnosis. The chest plain radiograph (CXR) is readily available and often useful (7,8). Radiographic stages reflecting the severity of LHF have been described, but the classic radiographic progression is often not seen. In addition, the chest radiograph may not correlate temporally with the patient's immediate condition; that is, there may be a lag of as much as 12 hours from the onset of CHF to the appearance of diagnostic changes on X-ray. Similarly, after treatment of LHF, there may be a lag of up to 4 days from clinical resolution of CHF until radiographic resolution. The specificity of the CXR for CHF (67% to 78%) is low enough that it cannot exclude left ventricular dysfunction; however, it can often indicate other diagnoses, such as pneumonia or COPD (8). These causes of dyspnea can have very different appearances from CHF on CXR.

The earliest radiographic finding of increased preload is redistribution or "cephalization" of blood flow. Normally, there is more blood flow to the dependent portions of the lungs. As PCWP increases, flow to the lower lung fields is reduced because of the vasoconstriction and the flow to the upper lung fields increases. Cephalization is best detected on an upright film and is most commonly seen in the setting of chronic CHF. As PCWP continues to rise, fluid accumulates in the interstitial spaces of the lung, producing Kerley B lines. Often the radiographic shadows of the pulmonary vessels begin to blur. As PCWP rises further, the increased hydrostatic pressure causes alveolar edema, and a classic butterfly pattern of bilateral perihilar infiltrates is seen on CXR. In almost all patients with chronic CHF, the cardiac silhouette is enlarged (cardiothoracic ratio $>50\%$) and pleural effusions are common. The frequency of CXR findings that confirm CHF increases with the severity of diastolic dysfunction. A systematic review of the

utility of CXR in the diagnosis of LV dysfunction concluded that redistribution and cardiomegaly were the best predictors of increased and reduced ejection, respectively (7).

The availability of point-of-care ultrasound is quickly becoming ubiquitous in EDs. This modality allows the physician to rapidly and repeatedly assess the dyspneic patient without sending the patient to the radiology suite nor exposing the patient to ionizing radiation. There is increasing literature about the reliability and the ease of using point-of-care ultrasound in the evaluation of ADHF patients. Sonographic evidence of interstitial edema called B-lines or "lung comets" has been shown to be very sensitive for CHF and even predictive of PCWP (9). Liteplo et al. showed that rapid bedside thoracic lung sonography had very good likelihood ratios ($+OR = 4.7$, $-OR = 0.3$) for predicting or eliminating CHF if examined in two lung zones bilaterally (10). This evaluative technique for lung sonography has been shown to be easy to learn and very reproducible for novice ultrasound practitioners (11).

The electrocardiogram (ECG), although of limited diagnostic value, should be performed on every ADHF patient to rule out acute coronary syndrome as a precipitating cause, which requires CCU admission and a more aggressive approach to treatment. However, chronic ischemic changes are very common and can make new ischemia difficult to diagnose. In chronic CHF, the ECG usually shows enlargement or hypertrophy of one or more chambers.

Arterial blood gas analysis reliably shows hypoxemia caused by impaired gas exchange, but it is of no value in diagnosis and of limited use in guiding therapy. Other blood tests show typical but nondiagnostic abnormalities (e.g., abnormal liver function tests caused by passive hepatic congestion or hyponatremia caused by of excess free water retention).

BNP and NT-proBNP levels correlate well with the presence and severity of heart failure (HF). BNP is secreted by the myocardium in response to increased wall stretch and an increase in LV end-diastolic pressure (preload), both of which are hallmarks of ADHF. Pre-pro BNP is synthesized within myocytes and is cleaved to proBNP. ProBNP is released into the circulation and then cleaved to

the active BNP and an inactive N-terminal fragment, called NT-proBNP. The two peptides have a high degree of correlation (12). BNP is a compensatory peptide with venous, arterial, and coronary vasodilator properties but has no direct inotropic or chronotropic effects. Plasma BNP levels of <100 pg/dL and NT-proBNP levels of <300 pg/dL make HF highly unlikely; BNP levels >500 pg/dL and NT proBNP levels >1,000 pg/dL make HF very likely. In patients with a BNP level of 100 to 500 pg/mL, the baseline BNP level may be elevated owing to a stable underlying dysfunction, including right ventricular failure from cor pulmonale, acute pulmonary embolism, or renal failure. BNP level has been shown to be affected by age, gender, drug use, and several comorbidities such as liver cirrhosis or primary pulmonary hypertension. Conversely, BNP levels are lower than expected in flash pulmonary edema, obesity, and CHF secondary to mitral valve dysfunction. BNP levels should not, therefore, be used as the sole diagnostic tool in assessing patients with suspected heart failure (2). A plasma BNP >100 pg/mL diagnosed HF with a sensitivity and specificity of 90% and 76%, respectively (12,13).

Data from the BNP Multinational Study indicate that BNP levels can be used to improve diagnostic accuracy beyond clinical judgment. A rapid BNP immunoassay test is currently available and has been shown to be better than the clinical examination in detecting CHF in ED patients and identifying CHF as the etiology of dyspnea of unclear etiology (13). Coupling thoracic sonography with NT-proBNP has shown to increase the physician's diagnostic accuracy for ADHF tremendously (10). However, as BNP will not add significant diagnostic value in patients who have clear-cut findings, the test should not be used when the clinician has a very high or a very low pretest probability of ADHF.

Cardiac enzymes, including troponin, CBC, and a complete metabolic profile should be obtained in patients presenting with ADHF. Other testing may be indicated depending on the patient's medications and the patients past medical history.

KEY TESTING

- Chest radiograph
- EKG
- Transthoracic lung ultrasound
- Transthoracic echo
- NT-proBNP or BNP if unclear cause of dyspnea
- Troponin (I or T)

ED MANAGEMENT

All patients with ADHF should receive supplemental oxygen. An IV line should be placed, and the patient should be placed on a cardiac monitor with pulse oximetry. The treatment goals for treating ADHF have not changed significantly over the past 30 years. The pharmacologic goals of therapy are relief of pulmonary congestion by reducing preload and improvement in systemic tissue perfusion by improving myocardial contractility or reducing SVR (afterload) while maintaining or improving myocardial oxygen balance.

Patients presenting to the ED with ADHF can be treated in a stepwise manner and according to their underlying cause of heart failure. Recently we have begun to understand that there are several subtypes and pathways to heart failure.

There appears to be a “hypertensive” or “vascular pathway” to ADHF that is characterized by profound hypertension and relatively little peripheral edema. It is felt these patients are not truly volume overloaded but rather are in the state where the heart cannot empty its contents against the overwhelming afterload. The key step to treating these patients is aggressive vasodilation and afterload reduction to allow the heart to move the stroke volume forward. In these patients, fluid shifting to the vascular space, rather than total body water overload, is felt to be the culprit of the increased preload (2,14,15).

There is also a more gradual pathway that is characterized by a milder course and more progressive worsening of symptoms. This pathway, termed the “normotensive” or “volume overload” pathway, is marked by infrequent pulmonary edema but frequent hepatomegaly, peripheral edema, and jugular venous distention. In

this pathway, precipitating factors are commonly detected, which often include nonadherence to diet and medical plans, and concomitant pharmacologic therapy that exacerbates heart failure (14). As these patients tend to be truly volume overloaded, use of a diuretic is often useful.

TREATMENT OF MILD TO MODERATE ADHF

Initial ED therapy for patients in ADHF includes vasodilation with sublingual, oral, or transdermal nitroglycerin to increase venous capacitance and lower preload. Diuresis is not an efficient mechanism for preload reduction because ADHF patients have dramatically lowered renal blood flow secondary to vasoconstriction and therefore a relative inability to diurese. Furthermore, studies have shown that diuretics have several deleterious physiologic effects on CHF patients (2). However, patients that are clinically fluid overloaded and have peripheral edema can receive loop diuretics to assist in the reduction of total body water. Blood pressure (BP) should be monitored as many agents used for preload reduction can lower the BP (afterload) as well. Afterload reduction is required in patients with significant hypertension. This can be accomplished with high-dose nitrates, ACEIs, or direct vasodilators like nitroprusside (2,14).

Furthermore, the use of noninvasive positive pressure ventilation has been shown decrease mortality in several studies (16).

Tachydysrhythmias should be aggressively rate controlled to facilitate ventricular filling; this will decrease preload and improve CO. The most common supraventricular tachydysrhythmia (excluding sinus tachycardia) encountered in ADHF is atrial fibrillation. It is usually chronic; therefore, cardioversion is neither necessary nor likely to be effective. The ventricular response rate can be slowed quickly with an IV calcium channel blocker or amiodarone. Digoxin alone should not be used; however, it is a useful medication in concomitant CHF and atrial fibrillation, as it has positive inotropic and AV nodal blocking properties.

Treatment of Severe ADHF and Acute Pulmonary Edema

Nitrates

Nitrates are recommended as initial therapy for ADHF in the ED. At low doses, IV nitroglycerin induces venodilation; at high doses, it causes arteriolar dilation and dilation of coronary arteries. This simultaneously and efficiently lowers both preload and afterload.

Sublingual nitroglycerin at 400 μg per dose, repeated every 3 to 5 min as necessary, should be administered while IV nitroglycerin is being prepared for administration. High-dose sublingual nitroglycerin should be used in hypertensive patients with ADHF and is particularly useful in the prehospital setting. IV nitroglycerin should be initiated at 50 to 100 μg/min, with a range of 5 to 200 μg/min. Tachycardia and hypertension usually resolve as the patient gets symptomatically better, and the intravenous nitroglycerin dose can be titrated down gradually. The transdermal route is ineffective in these severe patients.

Despite the common use of nitrates, no prospective studies on their effects on mortality have been published. In a large randomized controlled trial involving patients with pulmonary edema, a regimen of high-dose nitrates and low-dose diuretics provided more consistent clinical improvement than a regimen of high-dose diuretics and low-dose nitrates. It was also associated with lower rates of mechanical ventilation and myocardial infarction (17,18).

Hypotension with standard nitrate therapy is generally mild and transient. Severe or persistent hypotension should raise suspicion for “preload-dependent lesions” such as aortic stenosis, cardiac tamponade, right ventricular infarction, hypertrophic obstructive cardiomyopathy, or for recent use of medications used for erectile dysfunction. All of these lesions result in hypotension when preload is suddenly lowered with nitrates.

Diuretics

Diuretics are a mainstay of long-term outpatient therapy for patients with systemic volume overload and chronic CHF. However, patients who present to the ED with ADHF are often not volume overloaded.

Historically, loop diuretics such as furosemide were administered IV to alleviate lung edema due to presumed fluid overload. Recent literature has suggested that this is not clinically useful in patients who are not edematous (14,15). There is often a 30- to 120-minute delay in the onset of actual diuresis. Moreover, patients with chronic pulmonary edema often have a significantly reduced renal blood flow owing to increased afterload, and diuretics may ultimately worsen renal function further; this effect is more pronounced in elderly patients. There is no convincing evidence of any immediate venodilatory effect, which might reduce preload quickly. In fact, furosemide produces activation of the sympathetic nervous system, which in turn increases pulse and SVR, and thus myocardial oxygen demand, all worsening ADHF (17,18,19). However, there is a set of patients with ADHF who benefit from diuresis. These patients will clinically appear fluid overloaded with the hallmark finding of peripheral edema. In these patients, moderate diuresis leads to decrease in total body water and eventual clinical improvement (19).

Nesiritide

Nesiritide is a recombinant form of BNP that is identical to the endogenous hormone produced in the ventricles and has identical hemodynamic effects. BNP binds to the guanylate cyclase receptor of vascular smooth muscle and endothelial cells, leading to increased intracellular cyclic guanosine monophosphate, which serves to dilate veins and arteries. It causes vasodilation and increases renal blood flow and urine output. It has also been shown to produce dose-related decreases in PCWP (preload), SVR (afterload), and increases in CO. These favorable effects in ADHF occur while also avoiding increases in heart rate or incidence of arrhythmias. However, nesiritide causes hypotension in a significant portion of patients and is also a very expensive medicine.

Nesiritide has been studied in several clinical trials, and studies have reported a trend toward increased 30-day mortality (7.2% mortality in nesiritide, 4% in those without nesiritide) and worsening renal function in ADHF patients receiving nesiritide (20).

Morphine

Morphine sulfate administered in small IV doses historically has been a classic therapeutic agent in ADHF. Although morphine does have venodilatory actions, its effects on venous capacitance have not been well established in the setting of acute pulmonary edema, and respiratory depression may occur at doses below those affect hemodynamic parameters. Morphine probably exerts mild indirect hemodynamic effects through anxiolysis by decreasing catecholamine production and causing vasodilation. Conversely, morphine produces many adverse hemodynamic effects (increases in left and right heart filling pressures and reductions in cardiac index, caused by a direct myocardial depressant effect on the already reduced contractile state of the ischemic heart). Several retrospective studies have found that ED administration of morphine to patients with ADHF increases the odds ratio of endotracheal intubation and ICU admission (21). The use of morphine in ADHF has dramatically decreased because of the superiority of nitroglycerin for preload reduction and low-dose benzodiazepines for anxiolysis.

Angiotensin-Converting Enzyme Inhibitors

ACEIs reduce both preload and afterload, improve renal hemodynamics, decrease sodium retention, attenuate sympathetic stimulation, and maintain or enhance left ventricular function. The data on the use of ACEIs for chronic outpatient CHF show a very clear mortality benefit; however, the literature for their use in ADHF is limited. There are several small studies showing safety and efficacy of ACEIs as vasodilators in the treatment of ADHF. ACEIs can be given in the form of a one-time dose of oral or sublingual captopril or IV enalaprilat as a bolus or by continuous IV infusion. Hemodynamic effects have been seen within 10 to 60 minutes. ACEIs can be used safely with IV nitroglycerin to provide a combination of preload and afterload reduction. However, more data are needed before the routine ED use of ACEIs can be recommended (18).

Positive Pressure Ventilation

The role of noninvasive ventilatory support (NIV) in the treatment of ADHF has been growing recently. In the past, NIV was reserved for patients that did not respond to standard therapy. However, more recent literature suggests a broader role for NIV. In patients with persistent hypoxia or signs of fatigue, NIV in the form of continuous positive airway pressure and bilevel positive airway pressure should be strongly considered. Patients with altered mental status are not good candidates for NIV.

NIV improves lung mechanics by recruiting atelectatic alveoli, increasing intrathoracic pressure, improving pulmonary compliance, and reducing the work of breathing. NIV improves hemodynamics by reducing preload and afterload, thereby enhancing left ventricular performance. Several studies have shown that NIV reduced the need for endotracheal intubation, and a meta-analyses of several small studies show decreased mortality in ADHF patients treated with NIV. Recent studies show no advantage of continuous positive airway pressure over bilevel positive airway pressure for patients with cardiogenic pulmonary edema (16).

Endotracheal intubation may be required if pulmonary edema is accompanied by severe hypoxemia that does not improve with pharmacologic therapy and NIV. The most reliable indication of life-threatening hypoxemia is a decreasing level of consciousness, although it is a relatively insensitive sign.

Inotropes

The use of inotropes is reserved for patients in whom vasodilators and noninvasive ventilation are ineffective or in hypotensive patients who are unable to tolerate vasodilators. This is because these medicines all increase myocardial oxygen demand and therefore acutely worsen the myocardial oxygen inbalance. When inotropes produce sufficient improvement in BP, IV nitroglycerin or nitroprusside can be added to provide the desired preload reduction to relieve pulmonary congestion. The choices of inotropic support include catecholamines (such as dobutamine, dopamine, or noradrenaline) and phosphodiesterase inhibitors. Dobutamine has the added advantage of inducing mild reductions in preload and

afterload and providing inotropic support. However, it occasionally causes a reduction in BP that requires it to be discontinued. Dopamine or norepinephrine can be used instead, but these improve BP by increasing SVR; thus preload and afterload-reducing medications are needed. To date, there have been no studies to demonstrate a mortality benefit of any particular pressor over others in the setting of ADHF treatment in the ED (14,18).

A newer class of medicines that are "calcium sensitizers," such as Levosimendan, have shown promise in certain subgroups as an alternative to catecholamine inotropes in the treatment of ADHF. A recent meta-analysis showed that there is a survival benefit as compared to conventional inotrope therapy in patients undergoing cardiac surgery in patients admitted to the cardiac ICU. Further trials are needed to clarify whether levosimendan has a role in the ED (22).

CRITICAL INTERVENTIONS

- Initiate high-dose nitrates as the initial therapy for acute pulmonary edema.
- Use of NIV decreases both intubation rates and mortality in hypoxic ADHF patients.
- Use of diuretics should be reserved for edematous patients with fluid overload (usually normotensive).
- Consider the use of bedside thoracic echocardiography for the rapid diagnosis and reevaluation of patients with ADHF.

DISPOSITION

The majority of patients with severe ADHF should be admitted to an intensive care unit unless pulmonary edema has been completely reversed and the patient does not have any evidence of ischemia on ECG. Invasive hemodynamic monitoring (PCWP) may be required in patients who do not respond to ED therapy. Patients with chronic CHF and a mild gradual worsening of symptoms who respond to IV diuretics may be managed in an observation unit or discharged after adjustments in their chronic drug regimen and arrangements for

early follow-up with a physician. Patients with more severe symptoms or other complicating factors (e.g., new rhythm disturbances, new onset CHF, uncontrolled severe hypertension, or suspected ischemic event) should be admitted for observation, evaluation, and optimization of drug therapy. Typical indications for admission are listed in Table 83.3 (14).

TABLE 83.3
Acute Exacerbation of CHF: Admission Criteria

Clinical or ECG evidence of acute myocardial ischemia
Pulmonary edema or severe respiratory distress
Oxygen saturation <90% (not caused by primary pulmonary disease)
Severe complicating medical illness (e.g., pneumonia)
Anasarca
Hypotension or syncope
Heart failure refractory to outpatient therapy
Inadequate social support for safe outpatient management

Common Pitfalls

- It is difficult to distinguish cor pulmonale with acute respiratory failure from ADHF. In some cases, it may not be possible to distinguish between these conditions by physical examination alone.
- Beware of hypotension with high-dose nitrate therapy. However, the hypotension is generally mild and transient. Severe or persistent hypotension should raise suspicion for "preload-dependant lesions."
- CXR is an imperfect test for the diagnosis of ADHF with different lag times between chest X-ray findings, symptomatology, and resolution of findings.
- Measurement of BNP levels for the diagnosis of LHF should be reserved for patients with dyspnea of unclear etiology.

CHRONIC COR PULMONALE (PULMONARY HEART DISEASE)

Chronic cor pulmonale is a syndrome resulting from restricted blood flow through the pulmonary artery circulation, resulting in increased pulmonary vascular resistance. This causes right ventricular hypertrophy and dilation. The syndrome is also known as pulmonary hypertension. Although cor pulmonale may be acute (most commonly caused by pulmonary thromboembolism), only the chronic form is discussed here. The usual cause of the increase of peripheral vascular resistance is loss of pulmonary vessel lumen cross-sectional size. This is usually due to vascular remodeling produced by excessive cell proliferation, reduced apoptosis, and often excessive pulmonary vasoconstriction (23).

Hypoxemia is a potent pulmonary vasoconstrictor, and concurrent hypercapnia and acidemia are synergistic. Most cases of cor pulmonale are accompanied by these abnormalities. The rise in pulmonary vascular resistance impedes RV ejection, and a compensatory response results in hypertrophy or dilatation and increased preload. Causes of chronic cor pulmonale are listed in Table 83.4. In the United States, chronic bronchitis and emphysema are the major causes of this disease.

TABLE 83.4
Causes of Chronic Cor Pulmonale

Diseases that Primarily Affect Air Passages
Chronic bronchitis/emphysema
Asthma
Pulmonary fibrosis (e.g., pneumoconiosis)
Granulomas and infiltrates (e.g., sarcoid)
Pulmonary resection
Congenital cystic disease
High-altitude hypoxia
Obstructive sleep apnea
Chronic daytime hypoxia

Diseases that Primarily Affect Chest Bellows
Kyphoscoliosis
Thoracoplasty
Pleural fibrosis
Chronic neuromuscular weakness
Morbid obesity

Diseases that Primarily Affect Pulmonary Vasculature
Primary pulmonary hypertension
Pulmonary embolism
Polyarteritis nodosa
Other arteritides

CLINICAL PRESENTATION

The underlying disease process largely determines the clinical manifestations of cor pulmonale, and symptoms of pulmonary dysfunction most often precede manifestations of right heart failure.

These symptoms include dyspnea at rest or with minimal exertion, weight gain, ankle swelling, and, in severe cases, ascites. Physical signs usually include bibasilar crackles and scattered wheezes (caused by lung disease, not interstitial fluid accumulation) on auscultation. The pulmonic component of the second heart sound may be palpable, and the jugular vein may fill paradoxically during inspiration or exhibit no respiratory fluctuation. Tricuspid insufficiency may be present, manifested by a systolic murmur heard best at the lower left sternal border and increasing with inspiration; this is often accompanied by the finding of a pulsatile liver edge.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms of cor pulmonale may mimic those of left heart failure (LHF), constrictive pericarditis, or cardiac tamponade. Severe and advanced mitral stenosis may present with predominant right heart failure or "silent mitral stenosis." When signs and symptoms of cor pulmonale are of abrupt onset, acute pulmonary thromboembolism should be considered.

ED EVALUATION

The CXR usually shows evidence of the underlying pulmonary disorder only, but it may be helpful in diagnosing the cause of an acute exacerbation (e.g., pulmonary infiltrate). The ECG is not a sensitive test for detecting RV hypertrophy or dilation, but some findings are reasonably specific. These include a P-pulmonale pattern (P-wave amplitude of at least 2.5 mm in lead II), right-axis deviation, R/S amplitude ratio in $V_1 > I$, low-voltage QRS, and right bundle-branch block pattern. The absence of radiographic or ECG evidence of RV hypertrophy or dilation does not rule out the diagnosis. Arterial blood gas analysis usually shows some combination of hypoxemia, hypercapnia, and acidemia. Liver function tests may be abnormal because of passive hepatic congestion. Pulmonary function tests are always abnormal, and the typical patient has a forced expiratory volume in 1 second of <1 L. The serum BNP level may also be elevated.

KEY TESTING

- Chest radiograph
- Electrocardiogram
- Arterial blood gas if need to determine degree of hypercapnia and acidemia

ED MANAGEMENT

Patients who present with acute exacerbations of chronic cor pulmonale usually have an exacerbation of the underlying lung disease. Superimposed additional physiologic stresses can

precipitate exacerbations of chronic cor pulmonale; however, thromboembolic disease should be considered if no other causes of exacerbation can be found. Therapeutic efforts should be directed toward improving oxygenation, decreasing hypercarbia, and normalizing pH (20,24). Therapy is directed at the underlying lung disease and often includes administration of low-flow oxygen, corticosteroids, antibiotics, and inhaled and systemic bronchodilators (25) (see Chapter 77, "Chronic Obstructive Pulmonary Disease").

DISPOSITION

Indications for admission for an exacerbation of chronic cor pulmonale are the same as for acute respiratory failure (see Chapters 1, "Airway Management" and 73, "Respiratory Failure").

ACKNOWLEDGMENTS

The author gratefully acknowledges the contributions of the authors of this chapter in prior editions of the text.

Common Pitfalls

- Administering high-flow oxygen to a patient with suspected LHF who has cor pulmonale may result in worsening of clinical status, because of the loss of hypoxic drive.
- The diagnosis of cor pulmonale cannot be excluded by the absence of ECG or radiographic findings of RV hypertrophy or dilation.
- ED treatment should be directed toward improving pulmonary function and decreasing pulmonary vascular resistance rather than toward alleviating the signs of right heart failure (e.g., aggressive diuresis, which may decrease RV preload and worsen left heart outflow).

CHAPTER 84

Bradydysrhythmias

David Hartman and David T. Overton

The cardiac conduction system consists of pacemaker cells, conducting cells, and contractile cells. Pacemaker cell possess the capacity to spontaneously depolarize (termed *automaticity*). The sinoatrial (SA or sinus node) is normally the predominant pacemaker of the heart, is located at the junction of the right atrium and the superior vena cava, and has an intrinsic basal rate of 60 to 100 bpm. The SA node is innervated by both sympathetic and parasympathetic nerves that alter its discharge rate. The arterial blood supply is either from the right coronary artery (55%) or the left circumflex artery (45%).

The atrioventricular (AV) node is located beneath the right atrial endocardium superior to the insertion of the septal leaflet of the tricuspid valve and can also function as a pacemaker, with an intrinsic rate of 45 to 60 bpm. The arterial blood supply of the AV node is from the posterior descending artery of the right coronary artery (90%) or the left circumflex artery (10%). This anatomy becomes clinically relevant in the AV nodal dysrhythmias associated with acute inferior myocardial infarction. The AV node fires in the absence of sinus node impulses, or it may usurp control from the sinus node. Other cells in the bundle branches and Purkinje network can function as pacemakers as well, but their intrinsic rate is quite low, approximately 30 to 40 bpm.

Electrical impulses in the heart travel over a network of conducting cells. Impulses normally originate in the sinus node. Passage through the AV node is relatively slow, accounting for a normal physiologic delay in ventricular depolarization. The AV node

blends into the bundle of His, which divides into bundle branches. The bundle branches arborize into a network of Purkinje fibers that transmit impulses to the ventricular myocardial contractile cells. Contractile cells in the atria and the ventricles do not depolarize spontaneously.

The electrocardiographic P wave represents atrial depolarization. The P–R interval (normally 0.12 to 0.20 seconds in the adult) reflects intra-atrial, AV nodal, and His–Purkinje conduction. The QRS complex, representing ventricular depolarization, has a normal duration of 0.04 to 0.10 seconds, and the following T wave represents ventricular repolarization. The U wave is seen in a variety of circumstances such as hypokalemia, although its electrophysiologic basis is uncertain. Two basic pathophysiologic mechanisms underlie the production of both tachydysrhythmias and bradydysrhythmias: (i) disorders of impulse formation and (ii) disorders of impulse conduction. Depressed automaticity may result in bradydysrhythmias, such as sinus bradycardia or sinus arrest. If SA node automaticity is sufficiently depressed, escape rhythms originating elsewhere in the heart may assume control. Depressed impulse conduction may lead to AV or fascicular blocks.

ED EVALUATION AND MANAGEMENT

When approaching patients with bradydysrhythmias, as with any patient, the priorities of airway, breathing, and circulation must be addressed first. The patient should be placed on a cardiac monitor, and an electrocardiogram (ECG) should be obtained expeditiously. The urgency and means of treating bradydysrhythmias depend on how symptomatic the dysrhythmia is, the clinical setting in which the dysrhythmia occurs, the propensity for the dysrhythmia to progress, and concurrent drug therapy. Bradydysrhythmias may produce hypotension, lightheadedness, dizziness, fatigue, mental status changes, angina, congestive heart failure, syncope, or even seizures. The elderly may be more susceptible to symptomatic bradycardia. Prompt therapy using electronic pacing or intravenous medications is required for these symptoms, which are caused by end-organ hypoperfusion. Many dysrhythmias are asymptomatic and

require no treatment. A dysrhythmia that occurs during an acute myocardial infarction often mandates a different treatment approach than a dysrhythmia incidentally discovered during a routine physical examination. Electrolyte imbalances and a wide variety of drugs (e.g., digitalis, β-blockers, calcium channel blockers, cocaine, methylprednisolone, fentanyl, and amiodarone) may cause bradydysrhythmias, and each case has its own implications for treatment (1–7).

Sleep apnea may also be a cause of bradycardia (8), as may seizure disorders (9). Propofol has also been implicated in causing acute refractory bradycardia especially at doses >4 mg/kg/h for a prolonged time (10). Many infectious diseases have been reported to cause a relative bradycardia, including typhoid, Legionnaires, malaria, and dengue fever (11). Symptomatic bradycardias are increasingly common with advancing age. General supportive measures such as oxygenation, ventilation, and correction of electrolyte abnormalities are usually the first step. Specific drug therapy or artificial cardiac pacing may also be required.

Among drug therapies, the cornerstone is atropine sulfate, a vagolytic agent that enhances sinus node automaticity and AV nodal conduction. The usual adult dose is 0.5 to 1.0 mg intravenous push every 3 to 5 minutes to a total maximum dose of 0.04 mg/kg (3 mg) in the adult. Atropine is also effective when administered via the endotracheal route. The suggested endotracheal dose is 2 to 2.5 times the recommended intravenous dose diluted in 10 mL of normal saline. Because atropine can increase myocardial oxygen consumption, it should be used with caution in the presence of myocardial ischemia. Adverse effects include sinus tachycardia, ventricular tachycardia, or ventricular fibrillation, as well as manifestations of anticholinergic toxicity. In patients with high-degree AV block, one may also see, in rare instances, a marked reduction in the heart rate after atropine use.

Glucagon has been found to be beneficial in treating bradydysrhythmias secondary to β-blockers and calcium channel blockers. The drug appears to be effective in both toxic and nontoxic patients. Glucagon stimulates the SA node, resulting in a modest

increase in the heart rate. Glucagon increases automaticity at the AV node, which may be helpful in slow junctional rhythms. Glucagon has also been shown to increase cardiac contractility, increasing coronary perfusion. The peak action of glucagon occurs approximately 5 to 10 minutes after intravenous administration. Suggested initial dosing ranges are 0.05 to 0.10 mg/kg in children and 0.05 to 0.15 mg/kg in adults. This dose may be repeated based on the clinical situation and the characteristics of the offending medication.

Isoproterenol, a β-adrenergic sympathomimetic drug with potent inotropic and chronotropic effects, is only used rarely currently, having been largely supplanted by the widespread availability of transcutaneous pacing. Still, isoproterenol may be useful as a temporary measure when other options fail. It is administered as an infusion at a rate of 2 to 10 mg/min. Isoproterenol markedly increases myocardial oxygen demand and may cause significant adverse effects, including ventricular tachycardia or fibrillation.

If drug therapy is ineffective, artificial pacing may be instituted. Transcutaneous pacing is more easily performed than internal pacing and should be attempted first. Emergent temporary pacing may improve organ perfusion and cognitive function (12).

Disorders of Impulse Formation

Atrial Bradydysrhythmias

Sinus dysrhythmia is a physiologic finding commonly seen in healthy young people. In it, the sinus discharge rate decreases with expiration and increases with inspiration. Sinus dysrhythmia is thought to be caused by changes in vagal tone during respiration. P wave morphology and P–R intervals are usually constant. No treatment is indicated.

Sinus bradycardia, arbitrarily defined as a sinus rhythm of <60 bpm, may be the result of organic heart disease and may cause symptoms, but it is also a common finding in healthy patients and particularly in conditioned athletes (13). The significance of sinus bradycardia depends on the clinical setting. It is common during

therapy with digitalis and β-blockers and may not warrant intervention. In contrast, the following findings should suggest nonphysiologic sinus bradycardia: (i) profound bradycardia in an individual not engaged in strenuous endurance training, (ii) sinus pauses longer than 3 seconds on a Holter monitor, or (iii) syncope or near-syncope at rest or after strenuous exercise. When sinus bradycardia is symptomatic, treatment with atropine is usually successful, although cardiac pacing is sometimes necessary.

The sick sinus syndrome encompasses a spectrum of conditions, including severe sinus bradycardia, SA block, sinus arrest, and the bradycardia–tachycardia syndrome. The latter refers to the intermittent occurrence of bradydysrhythmias and tachydysrhythmias (e.g., atrial fibrillation, flutter, or paroxysmal supraventricular tachycardia) in the same patient. The bradydysrhythmia typically occurs immediately after resolution of an episode of tachycardia. Symptoms such as syncope or chest pain may result from either the tachycardia or the bradycardia. Pharmacologic therapy that is effective for the tachycardia may exacerbate the bradycardia, so cardiac pacing may need to be initiated before proceeding with pharmacologic therapy.

Atrioventricular Nodal Bradydysrhythmias

An AV junctional rhythm may be a physiologic rhythm initiated by the AV node in the absence of an adequate sinus stimulus or may result from an abnormally rapid AV junctional focus that usurps control from the sinus node (e.g., accelerated junctional rhythm). Junctional rhythms usually exhibit a QRS morphology similar to the patient's sinus rhythm. The P waves are usually inverted if they are conducted in a retrograde manner. The P waves can fall before, during, or after the QRS complex, depending on the location of the focus within the AV junction and the degree of retrograde AV block. When the P wave occurs before the QRS complex, the P–R interval is usually <0.12 seconds. The absence of P waves may be caused by obliteration by the QRS complex or by retrograde block.

AV junctional escape beats occur singly or multiply in the absence of stimuli arriving at the AV node (Fig. 84.1). Their hallmark is

occurrence after an interval longer than the dominant cycle. The underlying disorder may be sinus bradycardia, sinus arrest, sinus exit block, or AV block. Digitalis or β-blocker therapy may also be responsible. Junctional escape rhythms may also be incidental findings in otherwise healthy people with increased vagal tone. Treatment is not indicated for asymptomatic patients with infrequent escape beats. If symptoms occur, the clinician should treat the underlying rhythm rather than attempt to obliterate the escape beats, as pharmacotherapy to obliterate the AV nodal escape beats may lead to asystole. Treatment involves withholding offending drugs or using atropine or artificial pacing.

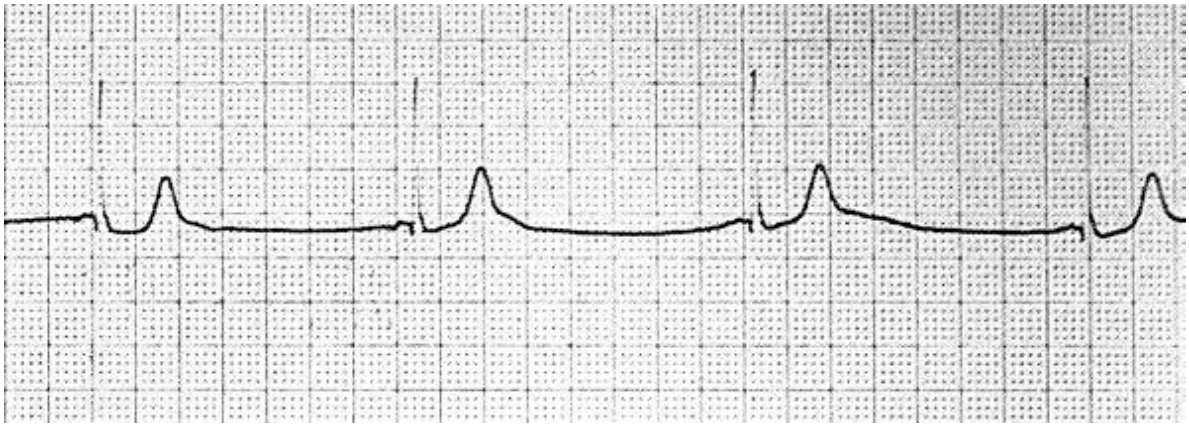

FIGURE 84.1 Junctional escape rhythm.

Ventricular Bradydysrhythmias

A ventricular rhythm with a rate of <50 bpm is termed a *ventricular escape rhythm* or *idioventricular rhythm.* Ventricular escape rhythm represents a physiologic safety mechanism that arises in the absence of stimuli from above, as in sinus bradycardia, sinus arrest, or, more commonly, AV block. Most patients with ventricular escape are symptomatic because the heart rate is low. Treatment is directed at the underlying dysrhythmia (i.e., atropine, or most often, cardiac pacing). Lidocaine, amiodarone, and other drugs that may abolish the ventricular rhythm are contraindicated because they have the potential for causing cardiac standstill.

Also known as idioventricular tachycardia or slow ventricular tachycardia, accelerated idioventricular rhythm has a rate of 50 to

100 bpm. Accelerated idioventricular rhythm is one cause of isorhythmic dissociation with occasional fusion beats demonstrating the continued presence of an intact AV node (Fig. 84.2). This rhythm may be associated with acute myocardial infarction (particularly after reperfusion), but it may also be seen in otherwise healthy patients. In the absence of symptoms, specific therapy is not warranted.

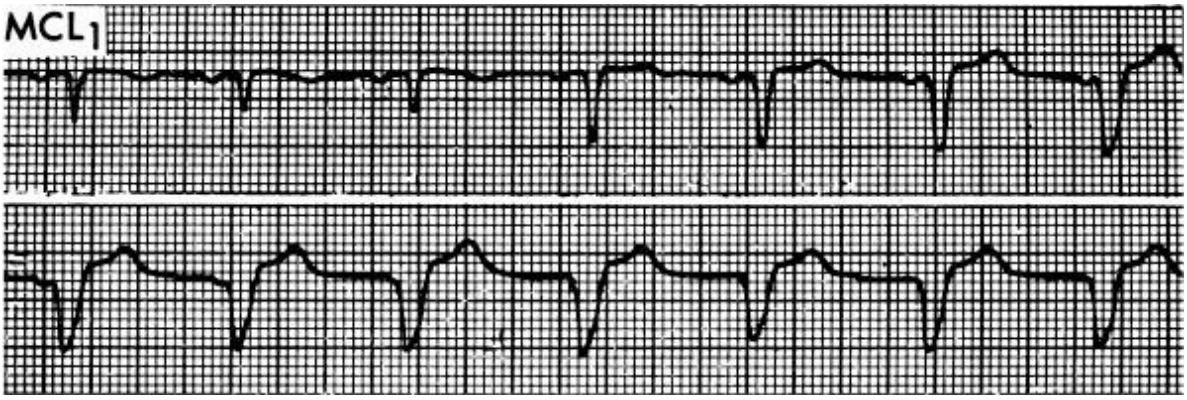

FIGURE 84.2 Idioventricular rhythm with isorhythmic dissociation and fusion beats.

Disturbances of Conduction

Disorders of Sinoatrial Conduction

The tissue surrounding the sinus node may delay or prevent conduction of sinus node impulses to the atria and AV node. Such conduction disorders are termed *SA block* and are classified in a manner analogous to AV block. Because of the limitations of the surface ECG, their precise diagnosis is more difficult than the varieties of AV block.

In first-degree SA block, there is a delay in the propagation of the sinus node impulse out to the atrial myocardium. Because every beat is transmitted, no abnormality is detected on the surface ECG.

Similar to AV block, second-degree SA block may be divided into types I and II. In type I (Wenckebach), there is, with each succeeding beat, a progressive delay in conduction from the sinus node to the atria, until conduction in totally blocked and a P wave is dropped (Fig. 84.3). The P–P interval shortens progressively before the

dropped P wave (analogous to the situation in second-degree AV block, in which the R–R interval shortens before the dropped QRS complex).

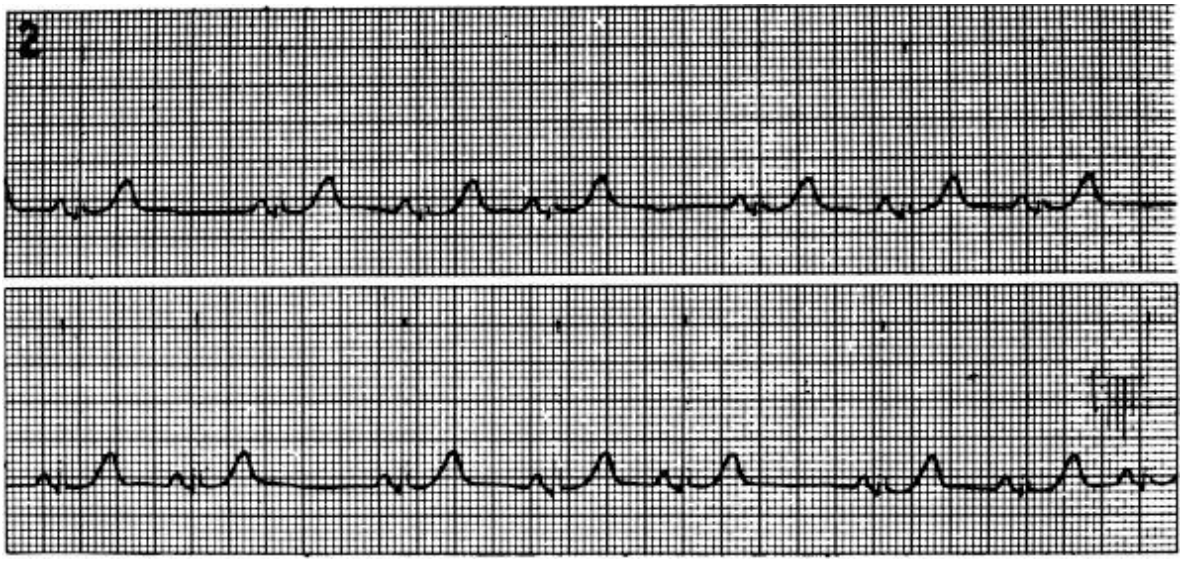

FIGURE 84.3 Type I (Wenckebach) SA block.

In type II second-degree SA block, there is intermittent failure of the sinus impulse to reach the atria, resulting in a missing P wave and a sudden lengthening of the P–P interval. The resulting P–P interval is usually a multiple of the previous one that is doubled in the case of 2:1 block (Fig. 84.4). This disorder can be mimicked by blocked premature atrial contractions, where the P wave is obscured by the preceding T wave (Fig. 84.5).

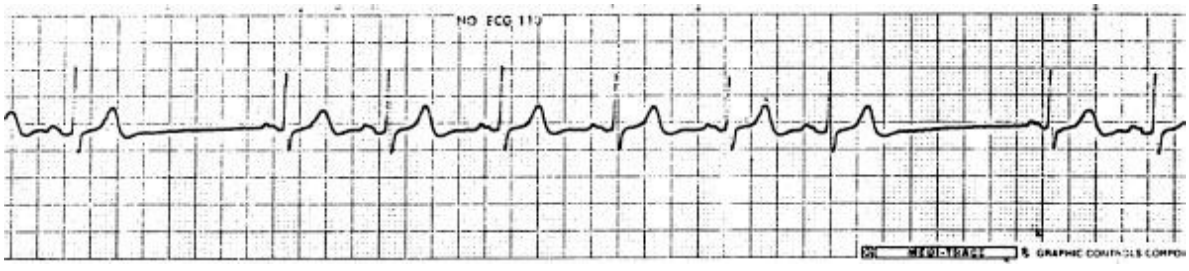

FIGURE 84.4 Type II SA block 2:1.

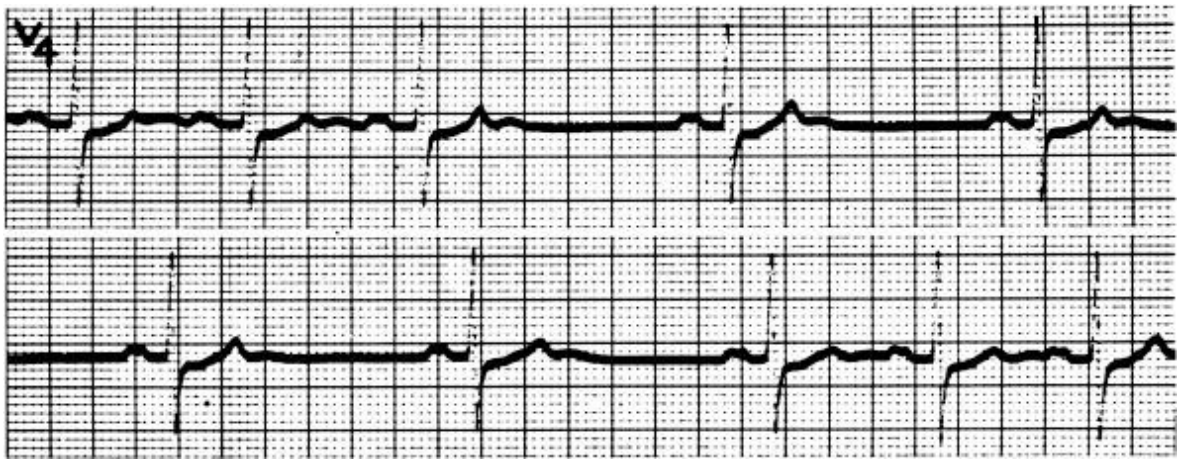

FIGURE 84.5 Blocked premature atrial contractions mimicking AV or SA block.

Third-degree SA block is where there is a failure of any sinus node impulses to be conducted to the atria (Fig. 84.6). Third-degree SA block is usually indistinguishable from sinus arrest, where there is a failure of impulses to arise from the sinus node.

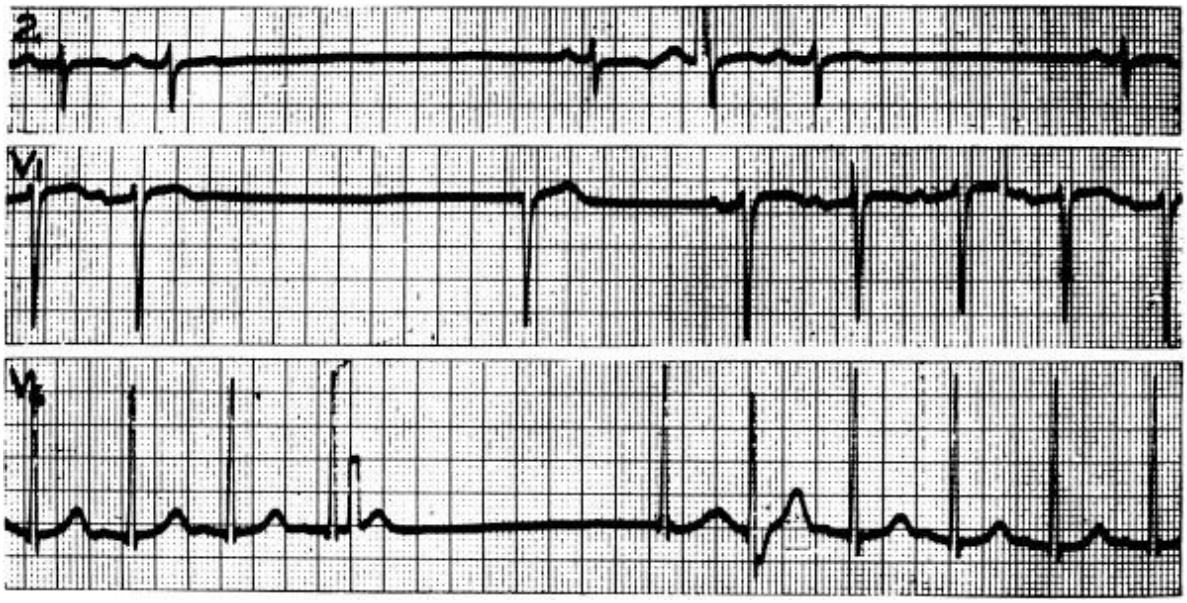

FIGURE 84.6 Third-degree SA block, with escape rhythm.

Disorders of Atrioventricular Conduction

Traditionally, AV blocks have been divided into first, second, and third degrees. However, AV block is a relative phenomenon, and the

physiologic delay normally present in the AV node is one end of a continuum. For example, in the patient with atrial flutter, “normal” AV conduction usually results in 2:1 block. In addition, the degree of block is rate dependent. One patient with mild AV disease may exhibit second-degree block at a particularly fast supraventricular rate, and another patient with more advanced AV nodal disease may exhibit 1:1 conduction if the supraventricular rate is slower.

A P–R interval of >0.20 seconds defines first-degree AV block. All P waves are conducted, 1:1 AV conduction is maintained, and the P–P and R–R intervals are consistent. Most commonly, the delay in AV conduction is within the AV node, and the QRS complex is of normal duration. Delays within the His bundle or His–Purkinje system are less common and are usually associated with widened bundle-branch block QRS patterns.

First-degree AV block may be associated with electrolyte disturbances or the use of digitalis, β-blockers, or calcium channel blockers. It becomes more prevalent as patients age. First-degree AV block may be seen during acute myocardial infarction, particularly inferior myocardial infarction. Treatment includes correction of electrolyte abnormalities or removal of the responsible drug. During acute myocardial infarction, close observation is warranted to detect progression to higher degrees of block. Otherwise, specific treatment is not indicated.

Second-degree AV block can be divided into Mobitz types I and II. Wenckebach distinguished between these two in the pre-ECG era, using only physical observation (14).

Mobitz type I second-degree AV block (Wenckebach) usually results from conduction delay in the AV node, although delays may occur in the bundle of His, bundle branches, or Purkinje system (Fig. 84.7). For this reason, the QRS complex in type I block is most often of normal duration and configuration. Mobitz type I AV block may be associated with inferior myocardial infarction or the use of digitalis, β-blockers, and calcium channel blockers. Mobitz type I AV block is usually transient, asymptomatic, and it has a good prognosis. If the patient is symptomatic, atropine can be given to enhance AV

nodule conduction. Pacing is usually not necessary. Offending drugs may need to be withheld.

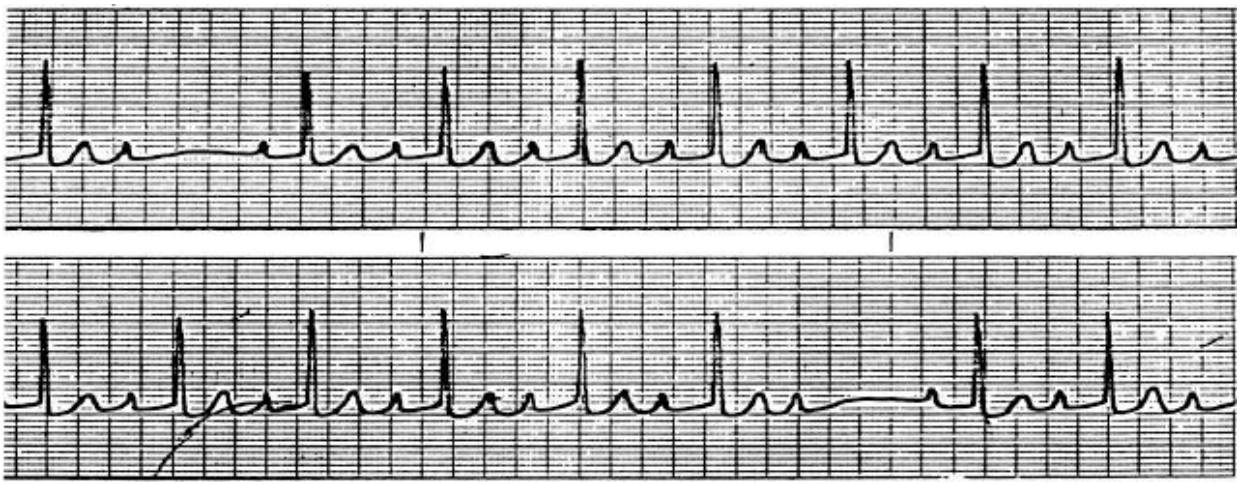

FIGURE 84.7 Mobitz type I (Wenckebach) second-degree AV block.

Mobitz type II second-degree AV block is less common. The site of block is usually within the His–Purkinje system, and a bundle-branch block QRS pattern is usually seen. In type II block, the P–R intervals are constant until single or multiple beats are suddenly dropped (Fig. 84.8). Type II block is usually symptomatic and has a higher likelihood of progressing to complete AV block. If associated with acute anterior myocardial infarction, type II block carries an ominous prognosis. Most authorities agree that Mobitz type II second-degree AV block requires permanent cardiac pacing. Because emergency drug treatment is often ineffective, temporary pacing may be necessary as a stabilizing measure.

FIGURE 84.8 Mobitz type II second-degree AV block.

A particular clinical problem is presented by the patient with 2:1 AV block. Although it is often assumed that such patients have type II block, type I block often presents as 2:1 block. The distinction is important given the difference in prognosis and treatment between the two entities. Although definitive proof may require intracardiac recordings, the following principles may aid in the clinical distinction:

- Type I block is more common than type II.
- A narrow QRS complex usually reflects type I block (although not all type I blocks have a narrow QRS complex). Type II block usually has a wide QRS complex.
- Coexisting acute inferior myocardial infarction suggests type I block, whereas anterior myocardial infarction suggests type II block.
- Digitalis, β-blocker, or calcium channel blocker therapy tends to be associated with type I block.
- In type I block, other areas of the rhythm strip may reflect other patterns of type I conduction such as 3:2 or 4:3.

In third-degree (complete) AV block, no atrial impulses reach the ventricles, and a subsidiary, escape pacemaker usually emerges. AV dissociation results with constant but independent P–P intervals and R–R intervals. The P–R intervals are variable, and P waves have no discernible relation to QRS complexes (Fig. 84.9). The site of block may be within the AV node, His bundle, bundle branches, or Purkinje system. In general, the lower the site of the block the more severe the symptoms.

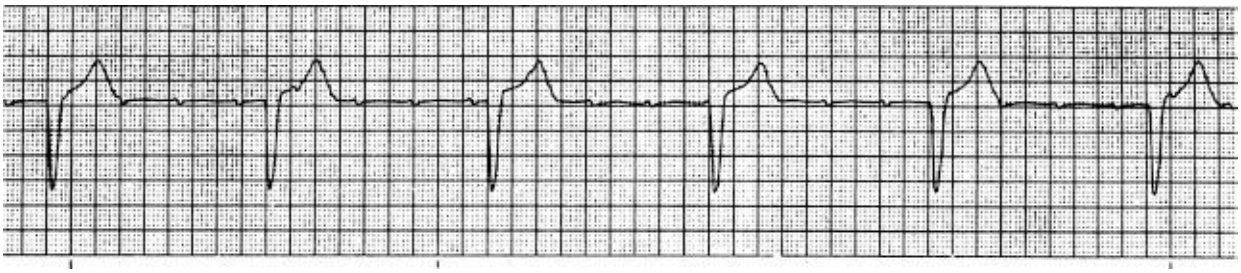

FIGURE 84.9 Third-degree atrioventricular block.

Third-degree AV block may be intermittent or self-limited. If the AV block is a complication of drug therapy, it usually resolves on withdrawal of the offending agent. Third-degree AV block may be associated with acute myocardial infarction but occasionally is an asymptomatic finding in an otherwise healthy person.

Like other bradydysrhythmias, the emergent treatment of third-degree AV block depends on symptomatology and clinical setting. Symptomatic patients may improve with atropine, particularly if the block is within the AV node. Symptomatic patients who are unresponsive to pharmacologic therapy require emergent pacing. Stable patients with acute inferior infarction may require only a prophylactic pacemaker. However, acute anterior infarction complicated by third-degree AV block is more ominous and requires emergent pacing.

The term *AV dissociation,* although commonly used interchangeably with the term *third-degree AV block,* encompasses a much broader range of rhythms. AV dissociation implies that the atria and ventricles are beating independently, a situation that includes not only complete AV block but also accelerated junctional and idioventricular rhythms (including ventricular tachycardia). In isorhythmic dissociation (Fig. 84.10), the sinus rate and the escape or ectopic rate are nearly identical, producing an electrocardiographic pattern characterized by varying P–R intervals as the sinus and ectopic foci slowly change their relative firing rates. Occasional fusion beats are an indication that the cause is not complete AV block.

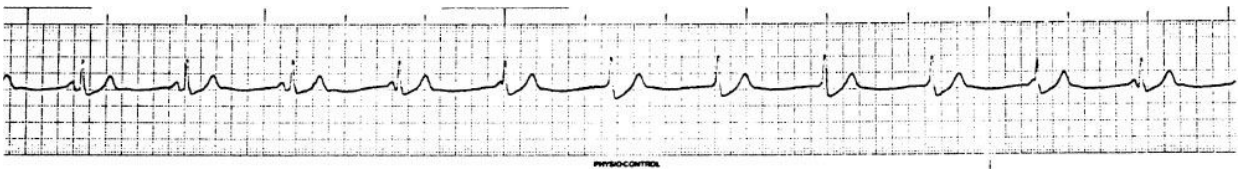

FIGURE 84.10 Atrioventricular dissociation with isorhythmic dissociation owing to a junctional focus.

Artificial Pacemakers

Temporary cardiac pacemakers are normally used in emergent or urgent circumstances, while most permanent pacemakers are placed electively. The emergency physician should be familiar with the indications and use of temporary pacemakers and with the principles of permanent pacemakers and their complications (see Chapter 86).

Temporary Pacemakers

Therapeutic emergency cardiac pacing is indicated in any hemodynamically unstable bradycardia that fails to respond to pharmacologic therapy. In addition, prophylactic emergent cardiac pacing may be indicated, even in the absence of symptoms, for patients with acute myocardial infarction in the following circumstances:

- First-degree AV block with new-onset bundle-branch block.
- Second-degree AV block type II.
- Third-degree AV block.
- Right bundle-branch block with left anterior fascicular block or left posterior fascicular block (either old or new).
- Left bundle-branch block (old or new) and placement of a Swan–Ganz catheter (because of the risk of inducing iatrogenic right bundle-branch block and then complete block).

Transcutaneous cardiac pacing involves the application of cutaneous electrodes to the chest and delivery of electrical impulses through the chest wall to the myocardium. Transcutaneous pacing is the technique of choice for emergent pacing in the emergency department and is the only option available for prehospital use.

The advantages of transcutaneous pacing are its ease and speed of use and the absence of serious side effects. The disadvantages include an inability to capture in some patients and the discomfort experienced by conscious patients because of chest wall contractions. The latter can usually be treated satisfactorily with analgesics or sedation. Transcutaneous pacing should be considered a stabilizing treatment, to be replaced with other pacing techniques, when possible.

Transvenous cardiac pacing involves the placement of the pacing electrode into the right ventricle by way of a central vein, often the

subclavian or internal jugular. Therefore, the procedure carries the risk of central venous catheterization but is the temporary modality that most closely approximates the function of a permanent pacemaker. Transvenous cardiac pacing does not involve painful muscle contractions or the hazard of direct cardiac puncture and can be used for relatively prolonged periods. Unfortunately, emergent transvenous pacemaker placement in the emergency department setting is often a lengthy and unsuccessful procedure associated with a high incidence of noncapture. Ideally, placement is performed under fluoroscopic guidance. Ultrasonographic guidance may make this procedure more effective, both in the initial placement of the central line and also in the correct placement of the pacing wire in the right ventricle. With the advent of transcutaneous pacing, transvenous pacing has been relegated to those situations in which fluoroscopy is available, stabilization has not been achieved by another modality, or attempts at transcutaneous pacing have been unsuccessful.

Transthoracic cardiac pacing is now rarely performed. It involves the placement of a pacing wire through the skin directly into the right ventricular cavity. Because of significant complications such as pericardial tamponade, pneumothorax, and coronary vessel injury, transthoracic pacing should usually be considered only in unusual circumstances.

Once capture has been achieved, regardless of the device used, the pacemaker settings will be dependent on the clinical situation. An initial rate of 80 to 100 bpm is appropriate for the majority of the patients. The initial output setting should be at maximum and decreased once capture is achieved. The mode should initially be asynchronous (sensitivity off) in those patients requiring emergency pacing for cardiac arrest. The mode should be set to synchronous in patients with bradydysrhythmias, as ventricular fibrillation may occur if the pacemaker fires during the vulnerable period (T wave).

CRITICAL INTERVENTIONS

- Initiate artificial pacing in unstable patients if drug therapy is ineffective.

DISPOSITION

Virtually all patients with symptomatic bradydysrhythmia require admission to the hospital. Patients with type II second-degree AV block and complete AV block usually warrant admission even if asymptomatic. Admission should be to a monitored bed in a unit with the capability of initiating emergent pacing.

If transfer to another facility is necessary, pacing should first be initiated if indicated and available. En route, the patient should have continuous cardiac monitoring and access to advanced cardiac life support. Transcutaneous pacing capability en route is also desirable.

Common Pitfalls

- Assuming that a 2:1 second-degree AV block is of the Mobitz type II variety, potentially leading to unnecessary treatment and intervention.
- Failing to take rate into account when evaluating AV blocks and fascicular blocks.
- Misdiagnosing blocked premature atrial contractions as significant AV block, potentially leading to unnecessary treatment and intervention.
- Blocking an escape rhythm, with the potential for causing cardiac standstill.

CHAPTER 85
Tachydysrhythmias

Scott R. Votey and Eric Silman

The axiom that we must treat patients and not electrocardiograms (ECGs) or laboratory results is perhaps nowhere more relevant than in the emergency management of tachydysrhythmias. Decisions must be guided principally by the clinical presentation, and exact rhythm identification should be subservient to the goal of prompt appropriate management.

The acute and chronic management of tachydysrhythmias differ importantly. Acute management focuses on stabilization and typically involves emergent administration of intravenous (IV) medications or external electrical cardioversion, while chronic management increasingly relies on more advanced interventions which are beyond the scope of emergency medicine. This chapter focuses almost exclusively on acute management.

TACHYDYSRYTHMIA PATHOPHYSIOLOGY

Under normal circumstances, the sinoatrial (SA) node is the pacemaker for the heart. Depolarization is initiated in the SA node, and the impulse is conducted through the atrium to the atrioventricular (AV) node. Atrial depolarization corresponds to the P wave on the ECG. Conduction to the ventricles is slowed in the AV node, which provides a measure of protection against hemodynamically unstable tachycardias. The normal slowing in the AV node is seen on the ECG as the PR interval. After the impulse traverses the AV node, it is conducted first down the His bundle, followed by the left and right bundle branches, and then dispersed to the ventricular myocardium via the Purkinje fibers. Ventricular

depolarization corresponds to the QRS wave on the ECG. Normal impulse conduction produces a narrow QRS complex.

Tachycardias can be generated from any focus in the heart, because essentially all myocardial tissue has intrinsic pacemaker activity. There are two principal mechanisms by which tachydysrhythmias arise: reentry and enhanced automaticity. Reentry is a phenomenon in which an initial depolarizing impulse travels a closed-loop path that returns cyclically to its point of origin and, in doing so, generates a regular sustained tachydysrhythmia. The requirements for a reentrant tachydysrhythmia are (a) a closed-loop conduction path; (b) slower conduction and prolonged refractoriness in one limb of the loop; (c) propagation of the initiating impulse down the faster limb of the loop, with antegrade conduction down the slower limb blocked; and (d) retrograde excitation of the initially blocked slower limb, returning the impulse to its point of origin, where depolarization is reinitiated. Repetition of this cycle sustains the dysrhythmia with a premature beat as the typical precipitant.

Enhanced automaticity is an increase in the rate of the spontaneous depolarization of myocardial cells above their electrical threshold. Sinus tachycardia is the physiologic response to enhanced automaticity of the SA node. When enhanced automaticity results in more rapid depolarization of extranodal myocardial cells, these foci can produce ectopic tachydysrhythmias. Examples include paroxysmal atrial tachycardia (PAT) and junctional tachycardia. Enhanced automaticity often occurs as a result of increased sympathetic tone (e.g., with fever, thyrotoxicosis, or sympathomimetic overdose). Treatment of these dysrhythmias generally should be directed at removing the underlying stressor.

CLINICAL PRESENTATION

Patients with tachydysrhythmias can present with wide-ranging signs and symptoms, from palpitations to cardiac arrest. Most, however, complain of some constellation of palpitations and dizziness. Syncope is an important presenting complaint of patients with any arrhythmia and should prompt cardiac rhythm evaluation in the

emergency department (ED). Up to 70% of patients with tachydysrhythmias complain of chest pain, but it important to remember that not all chest pain in this situation reflects myocardial ischemia. Chest pain in a young otherwise healthy patient with a supraventricular tachycardia (SVT) rarely signifies ischemia, whereas the chest pain of an older patient with reasonable likelihood of coronary artery disease should be taken seriously. Other symptoms due to the dysrhythmia such as nausea and diaphoresis also overlap with those of myocardial ischemia. Symptoms of tachydysrhythmias depend on the hemodynamic consequences of the rate and rhythm, with those patients who are hypoperfused presenting with severe symptoms such as syncope, chest pain, or cardiac arrest. Hypotension and poor perfusion are more typically dependent on the heart rate produced by any dysrhythmia than they are on the source of dysrhythmia. Ventricular tachycardia (VT), for example, conjures up images of imminent catastrophe, and SVT is usually assumed to be benign. However, some patients with VT are relatively stable, at least in the short run; whereas, in other patients, SVT can be acutely life-threatening.

ED EVALUATION

In the ED, where diagnostic data are often limited and the patient's condition warrants prompt action, tachydysrhythmias are most successfully managed using an algorithmic diagnostic and therapeutic schema that is easily remembered and applied. The following approach is broadly applicable to the emergency management of tachydysrhythmias.

Step 1. Be Prepared for a Cardiopulmonary Arrest

Any patient with a tachydysrhythmia is at risk for deterioration, because of either the dysrhythmia or its treatment. Being prepared for a cardiopulmonary resuscitation by having advanced airway equipment and a defibrillator at the bedside is essential.

Step 2. Determine Stability

Determine what hemodynamic effect the rhythm is having on the patient. In this context, *unstable* is defined as a heart rate and blood pressure inadequate to maintain vital organ perfusion and function, manifested clinically by significant chest pain, pulmonary edema, altered mental status, syncope, or severe hypotension. Categorizing a patient as stable or unstable is complicated by the innumerable gradations on the continuum from asymptomatic health to cardiopulmonary arrest. Altered mental status and ischemic chest pain with ECG changes of ischemia are convincing evidence of instability. Electrical cardioversion should be used to treat unstable patients with any tachydysrhythmia except sinus tachycardia and multifocal atrial tachycardia (MFAT).

Blood pressure is one of the most commonly used determinants of patient stability. It is important to remember that arbitrary blood pressure cutoffs for defining stable or unstable do not take into account the patient's baseline blood pressure. A systolic blood pressure of 90 mm Hg is of far more concern in a hypertensive elderly patient than in a young and healthy 20-year old. It should be emphasized that stability is subject to change on a minute-to-minute basis, and therapy must be adjusted accordingly.

After clinical stability is assessed, the ECG should be rapidly and systematically evaluated. Although most therapeutic decisions can be made on the basis of a rhythm strip, it is prudent to obtain a 12-lead ECG as soon as it is feasible. A 12-lead ECG can help determine if myocardial ischemia is present and can aid in differentiating among tachydysrhythmias, especially between sinus tachycardia and other regular SVTs.

Step 3. Determine the Rate

The more extreme the ventricular rate, the more likely the patient is to become unstable. Sinus tachycardia rarely exceeds 160 to 180 beats/min in adults. Although SVTs typically have rates slower than 180 beats/min, they can be faster in the presence of a bypass tract. VT is not slowed by passage through the AV node and can thus be much faster (250 to 300 beats/min) but is usually less than 220 beats/min.

Step 4. Determine the QRS Complex Width

When emergent cardioversion is not required, subsequent decisions can be based on the duration of the QRS complex. In an adult, a QRS width of greater than 0.12 ms is considered "wide." In many adults with a wide-complex tachydysrhythmia, the QRS duration is substantially greater than 0.12 ms. In children, the QRS duration is age dependent, but any QRS duration >0.10 ms is considered prolonged. It is usually possible to determine if a rhythm is wide or narrow from a rhythm strip alone, but if there is uncertainty, the widest QRS complex in the 12-lead ECG should be used as the measure.

Narrow-complex tachycardias can be assumed to be supraventricular. Wide-complex tachycardias are the result of any of three distinct pathophysiologic processes:

1. The rhythm originates in the ventricle and does not use the normal conduction pathway.
   The origin of the tachycardia is supraventricular, but there is a block of the normal conduction pathway below the AV node (bundle-branch block), often referred to as "aberrancy."
2. The origin of the tachycardia is supraventricular, but there is an accessory conduction pathway that bypasses the normal conduction pathway.

With rare exceptions, a wide-complex tachycardia should be treated as VT for three reasons: (a) VT is the most common cause of a wide-complex tachycardia; (b) despite the existence of diagnostic criteria, VT cannot be reliably distinguished from SVT with aberrancy in the clinical setting (1), and treating VT as SVT can be fatal (although treating SVT as VT is not harmful); and (c) even if the tachycardia has a supraventricular origin, there may be an associated bypass tract, in which case, some standard SVT treatments (e.g., verapamil) are contraindicated. It is never safe to assume that a wide-complex tachycardia is caused by aberrancy.

Step 5. Assess the Regularity of the RR Intervals

An irregular narrow-complex tachycardia is usually caused by atrial fibrillation (AF), although it can occasionally be caused by MFAT or atrial flutter with variable AV block. Because VT is usually regular except during the first few beats, an irregular wide-complex tachycardia should also raise the suspicion of AF with a bundle-branch block (AF-BBB) or a bypass tract. Distinguishing which patients have AF with a bypass tract is important, because the treatment of choice for these patients is cardioversion, even if they are stable. Although this differentiation can be difficult, two characteristics are helpful. In contrast to patients with AF-BBB, patients with AF with a bypass tract may have (a) very rapid conduction, with some RR complexes intervals equivalent to >250 beats/min, and (b) bizarre morphology QRS complexes resulting from fusion and partial fusion of beats from normal AV and bypass-tract conduction.

Step 6. Determine the Presence or Absence of P Waves

Determine whether P waves are present, their morphologic characteristics, whether they are regular, and how they are related to the QRS complexes. Regular uniform P waves preceding the QRS complex help distinguish sinus tachycardia from other SVTs. A normal P wave axis is one with an upright P wave in lead II and negative in aVR. This axis strongly suggests the atrial activity is coming from the SA node and is indeed sinus in nature. Although similar P waves may be present with the much rarer PAT, an abnormal P wave axis or morphology should alert one to the ectopic origin of that rhythm. An irregular narrow QRS-complex rhythm with more than three P wave morphologies is indicative of MFAT. One should, in addition, look for the regular sawtooth deflections of the ECG baseline that characterize atrial flutter waves.

Application of this scheme organizes dysrhythmias into four major categories based on the ECG appearance, with the additional distinction of clinically stable or unstable. The four categories are (a) narrow complex, regular, P waves present or absent; (b) narrow complex, irregular, P waves present or absent; (c) wide complex, regular, no P waves; and (d) wide complex, irregular, no P waves.

Generally, each of the specific dysrhythmias that fall into each of these categories is treated in the same fashion, thus the simplicity of the approach. Occasionally, unstable patients need treatment initiated before analysis of the rhythm can be completed. In addition, once the rhythm is stabilized, the patient may require additional pharmacologic treatment to prevent recurrent dysrhythmias.

*In select patients based on particular dysrhythmia and underlying comorbidities and risk factors.

DIFFERENTIAL DIAGNOSIS AND ED MANAGEMENT

Narrow-Complex Tachycardias

Narrow Complex, Regular, P Waves Present

Sinus tachycardia makes up the vast majority of these cases. Tables 85.1 and 85.2 outline the medical and electrical therapy for patients presenting with a wide variety of tachydysrhythmias. PAT is a rare alternative diagnosis. Therapy for sinus tachycardia is directed at the rhythm's underlying cause rather than at the rhythm itself. For example, patients with sepsis and sinus tachycardia or those with tachycardia due to hemorrhage require volume resuscitation and those with alcohol withdrawal or sympathomimetic intoxication benefit from benzodiazepines. There are a few conditions in which pharmacologic slowing of sinus tachycardia are beneficial. For example, β-blockers are important in thyroid storm to counteract the adverse consequences of extraordinary increases in sympathetic drive. While it was once standard to administer β-blockers to tachycardic patients with myocardial ischemia to decrease myocardial demand, routine early IV β-blockers are no longer

recommended in select ACS patients because of a lack of clear mortality benefit and an increased risk of cardiogenic shock in some patient groups (2).

TABLE 85.1
Selected Drugs for Tachydysrhythmias

Drug	Dosage	Contraindications	Side Effects	Comments
Adenosine	6 mg IV rapid push, followed by a saline flush Repeated doses of 12 or 18 mg may be used	• Known VT • AV node block • AF with WPW syndrome	Hypotension; transient Prolonged AV block (rare) Chest pain Flushing	Reduce dose in patients taking carbamazepine or dipyridamole (start at 3 mg), heart transplant patient, or administration via central line (start at 1–2 mg)
Amiodarone	150 mg over 10 min; 1 mg/min for 6 hrs; 0.5-mg/min maintenance infusion; 150-mg boluses for breakthrough VT/VF. 300 mg IV push in pulseless VT or VF	• AV block • Renal failure	Hypotension Bradycardia AV block Torsade de Pointes	Amiodarone has many side effects when given chronically but not acutely
Metoprolol	5 mg IV over 1–2 min; repeated every 5 min up to 15 mg if required	• Asthma/COPD • Hypotension • AF with WPW syndrome • AV node block	Hypotension High-degree AV block Bradycardia Bronchospasm	Secondary choice for most tachydysrhythmias because of negative inotropic effects. Atenolol is dosed identically
Diltiazem	5–10 mg IV slowly for AF Repeated to total of 50 mg in first 30 min, if required Infusion; 5–15 mg/hr	• Regular wide-complex tachycardias • AV node block • Hypotension • Digoxin toxicity • AF in WPW syndrome • Age <2 yrs	Hypotension High-degree AV block Bradycardia	Consider calcium pretreatment Use in patients with AF and class IV heart failure was safe in a small case series
Esmolol	0.5 mg/kg bolus over 1 min; followed by 0.1–0.3 mg/kg/min infusion titrated to effect	• As for other β-blockers	Hypotension High-degree AV block Bradycardia	A very short half-life makes this a good choice when it is unclear whether the patient can tolerate β-blockers
Lidocaine	1 mg/kg IV, repeated at 0.5–0.75 mg/kg IV to a total of 3 mg/kg, if required. Infusion of 1–4 mg/hr	• AF (increases AV conduction)	Seizures, confusion, lethargy, but only in overdose Bradycardia Asystole	Used for stable VT, but efficacy is poor. May reduce recurrent VT/VF but not helpful for primary prophylaxis
Magnesium	2–4 g IV over 5 min Infusion of 1–2 g/hr	• AV block • AF with WPW syndrome • Renal failure (infusion)	Hypotension Flushing Respiratory muscle weakness, bradycardia, and asystole with high doses	Patients with infusions running should be checked every few hours to determine respiratory status and reflexes. Decreasing reflexes suggest magnesium toxicity, and infusion should be stopped
Procainamide	17 mg/kg loading at no more than 50 mg/min	• Hypotension (relative contraindication)	Hypotension; give IV fluids, slow rate of infusion QRS widening QT prolongation	Effective in SVT with aberrancy. Reduces conduction though accessory pathways but may increase conduction through the AV node
Verapamil	5–10 mg IV at 2 mg/min for PSVT	• As for diltiazem	As for diltiazem	May cause more hypotension than diltiazem. Not extensively studied in patients with congestive heart failure

IV, intravenous; VT, ventricular tachycardia; AV, atrioventricular; AF, atrial fibrillation; WPW, Wolff–Parkinson–White; TdP, torsade de pointes; COPD, chronic obstructive pulmonary disease; VT, ventricular tachycardia; VF, ventricular fibrillation; SVT, supraventricular tachycardia; PSVT, paroxysmal supraventricular tachycardia.

TABLE 85.2
Electrical Therapy of Tachydysrhythmias

Rhythm	Biphasic Dose (J)	Notes
PSVT	50	Synchronized
Atrial flutter	50	Synchronized
Atrial fibrillation	50–200	Synchronized
Ventricular tachycardia	120–200	Synchronized
Torsade de Pointes	200	Unsynchronized (defibrillation)
Wide complex AF	50–200	Synchronized
Ventricular fibrillation	200	Unsynchronized, monophasic 200–360 J

Narrow Complex, Regular, No P Waves

The differential diagnosis includes paroxysmal supraventricular tachycardia (PSVT) and atrial flutter with a consistent AV block. Generally all these reentrant rhythms are treated in the same way with blockade of the AV node.

Paroxysmal Supraventricular Tachycardia

PSVT (Fig. 85.1) makes up the majority of cases in this category. The two main types of PSVT are atrioventricular nodal reentrant tachycardia (AVNRT) and atrioventricular reentrant tachycardia (AVRT), the differentiation of which is not important in the ED.

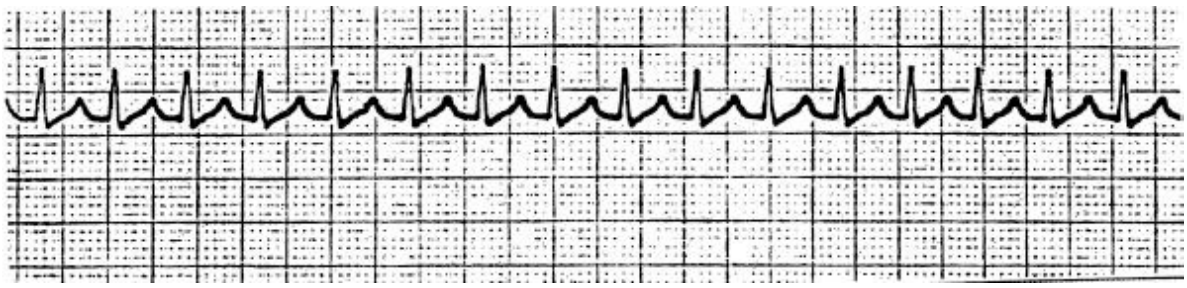

FIGURE 85.1 Paroxysmal supraventricular tachycardia.

Patients with PSVT who have severe signs of end-organ hypoperfusion should be cardioverted; more than 90% convert with small doses of electrical energy ($\leq$50 J). Pharmacologic treatment of PSVT, typically a reentrant tachycardia in which the AV node is part of the circuit, is directed at blockade of the AV node. Vagal maneuvers may be tried first: carotid massage, the Valsalva maneuver, and ice-water immersion work well in many patients.

However, because many patients with recurrent PSVT are familiar with vagal maneuvers, they often present for treatment only when these maneuvers have failed; therefore, these maneuvers are only occasionally effective in the ED.

Treatment options include adenosine, verapamil, diltiazem, and β-blockers. Adenosine, because of its brief duration of action and its resultant lack of sustained hemodynamic effect, is the drug of choice. The recommended initial dosage of adenosine is a 6-mg bolus over 1 to 3 seconds, followed by a rapid saline flush. If there is no response in 1 to 2 minutes, a 12-mg dose can be administered in the same manner. The use of doses of adenosine upward of 24 mg as a bolus have been reported in the literature, but are only marginally more effective than 12 mg. It is important that the drug be given as a rapid bolus to achieve high levels in the heart. In fact, adenosine is degraded so rapidly in plasma that the most proximal IV access possible (usually an antecubital vein) is desired.

In the absence of any of the standard contraindications to calcium channel blockers (hypotension, congestive heart failure, SA or AV nodal disease, or the previous use of IV β-blockers), diltiazem is a safe and effective alternative to adenosine. The standard initial dose is 10 mg IV and most patients convert to sinus rhythm within about 2 minutes. Incremental doses up to a total of 50 mg in the first 30 minutes are usually successful in those who do not. Verapamil is also effective. There is a substantial incidence of adverse effects when contraindications are present, so they should not be ignored. Many pediatric cardiologists consider it unsafe to use verapamil in children younger than 1 year of age and use adenosine exclusively in this age group.

Esmolol, an extremely short-acting β-blocking agent with a half-life of <10 minutes, is moderately effective in treating PSVT, although success rates are significantly lower than with either adenosine or verapamil and the incidence of hypotension is higher. Esmolol is, therefore, a secondary drug in the treatment of PSVT.

Atrial Flutter

Atrial flutter is a macroreentrant arrhythmia in which the circular current flow produces characteristic “sawtooth” waves, best seen in leads V1 and II, III, and aVF (Fig. 85.2). Atrial rates between 260 and 300 beats/min are typical, and the most common AV block of 2:1 produces ventricular rates of approximately 150 beats/min. Variable AV block can cause an irregular narrow complex rhythm. The ED management of atrial flutter is similar to that of AF. The decision to perform electrical cardioversion or attempt chemical rhythm control versus rate control must be made in the context of many factors: clinical stability, patient comorbidities and associate stroke risk, as atrial flutter carries a similar risk of stroke and many patients in atrial flutter also suffer from AF.

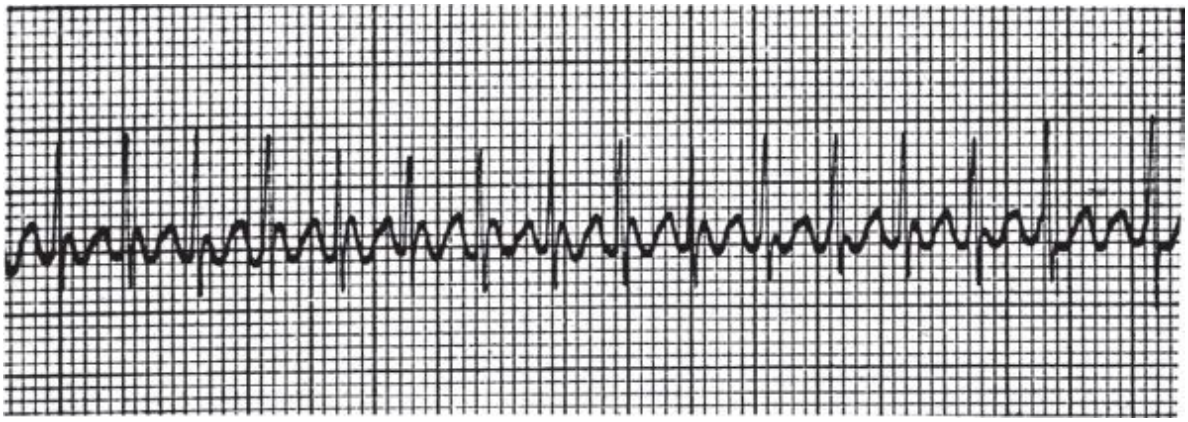

FIGURE 85.2 Atrial flutter.

The calcium channel blockers (verapamil and diltiazem), as well as digitalis, are capable of slowing the ventricular response in atrial flutter. Adenosine, although capable of slowing conduction for a few seconds, rarely results in cardioversion and has no role in the management of atrial flutter; however, it can occasionally be of diagnostic value in distinguishing atrial flutter and PSVT. Vagal maneuvers can sometimes slow the ventricular rate enough to bring out flutter waves (if they are present), but adenosine is particularly effective in this regard. Most authorities advocate electrical cardioversion given the high electrosensitivity of atrial flutter. Most patients convert with doses of 30 to 50 J. Despite the efficacy of electrical cardioversion, chemical cardioversion has advocates and

practice varies. As with AF, amiodarone and procainamide are currently commonly used agents in the ED.

Although the diagnosis of atrial flutter is often fairly easy, some patients with flutter at first glance appear to be in other rhythms. Therefore, it is important to consider and exclude flutter before using any drug (such as procainamide) that speeds conduction through the AV node. This is because atrial activity in flutter is typically much faster than the ventricular response and such drugs can change the conduction from 2:1 or 3:1 to 1:1, with serious hemodynamic consequences.

Since atrial flutter may increase the risk of systemic embolization, and since many patients with atrial flutter also have AF, anticoagulation is generally recommended in patients with atrial flutter in a similar manner as for AF (see section on *Atrial Fibrillation*) for risk assessment and anticoagulation recommendations.

Narrow Complex, Irregular, P Waves Present

Multifocal Atrial Tachycardia

MFAT is characterized by P waves of varying morphologies and by changing PR intervals. Because MFAT originates in the atria, it is associated with narrow QRS complexes, except in the presence of underlying bundle-branch block. MFAT occurs primarily in patients with chronic lung disease, and within this group, MFAT was most common in patients with high or toxic levels of theophylline. As the use of methylxanthines for the treatment of lung disease has declined, so apparently has the incidence of MFAT. Although MFAT is seldom life-threatening, the ability to control it can provide symptomatic benefit. Several small series have demonstrated slowing or conversion of MFAT with magnesium or verapamil (3). β-Blockers are probably less effective and should be used with caution in MFAT associated with chronic obstructive pulmonary disease (COPD).

Narrow Complex, Irregular, No P Waves

An irregular narrow-complex tachycardia is almost invariably AF or atrial flutter with variable block (Fig. 85.3). Occasionally, the P waves of MFAT are overlooked, and that rhythm is confused with AF.

FIGURE 85.3 Atrial fibrillation.

Atrial Fibrillation

AF is the most common arrhythmia treated in the ED and is marked by rapid disorganized atrial activation, often accompanied by rapid ventricular response (RVR). ED management of AF is both complex and controversial due to the heterogeneity of patients and their clinical presentations, and the lack of sufficient guiding evidence. When choosing therapy it is important to consider the ventricular response rate, hemodynamic consequences, duration of AF, presence of underlying heart disease, and precipitant of the patient's presentation.

In the majority of patients presenting with AF and RVR, the tachycardia itself (which profoundly decreases the time available for diastolic filling of the ventricles as well as coronary artery perfusion), rather than the loss of atrial systole, is responsible for the hemodynamic consequences. Patients with hypertrophic cardiomyopathy as well as other patients with significant diastolic dysfunction are an exception, because their stiff ventricles fill slowly and they thus rely on active atrial systole for an inordinate proportion of their end-diastolic ventricular volume.

At the other extreme, a slow ventricular response in new-onset AF is worrisome unless the patient is already taking medications that slow conduction in the AV node. Such patients may have AV node dysfunction, are rarely unstable, and often need to be admitted for consideration of long-term measures. Attempted cardioversion may lead to asystole or prolonged bradycardia and should be avoided.

Many patients seen in the ED with AF, particularly in circumstances in which AF is an incidental finding, have chronic AF, are taking medications for rate control, and are hemodynamically stable. Digitalis has long been used for chronic rate control.

Cardioversion in patients taking digoxin is a risk because of the potential for asystole. If cardioversion is required because of extreme hemodynamic compromise, it should initially be attempted at lower energy levels, such as 50 J. The calcium channel blockers diltiazem or verapamil, or a β-blocker are now preferred to digoxin for chronic rate control because these agents control rate not only at rest but also during exercise (4). Patients with chronic AF should be admitted to the hospital if they have signs of hemodynamic decompensation that requires cardioversion or if hemodynamic effects and RVR are not easily controlled.

Anticoagulation is an important management issue for patients with AF. Not only are patients with chronic AF at risk for systemic embolization, but evidence suggests that even shorter periods of AF may carry a risk of embolization, particularly following conversion to sinus rhythm, regardless of whether cardioversion is electrical or pharmacologic. All patients with chronic AF, except perhaps those <60 years old who have no other evidence of heart disease, should be on maintenance anticoagulant therapy unless there are substantial contraindications (5). Chronic anticoagulation may also benefit patients who experience recurrent paroxysmal AF (5,6). Even if accurate, a history of a brief duration of AF may fail to preclude the possibility of embolization caused by intra-atrial clot formation during the period of atrial standstill that can follow conversion to sinus rhythm. For this reason, some authorities suggest that in the absence of contraindications, patients with AF of >48 hours' duration be anticoagulated prior to electrical or chemical cardioversion, and for a minimum of 4 weeks after conversion to sinus rhythm. Other strategies involve risk stratification based on known risk factors for clot formation and a selective approach to anticoagulation in acute AF.

On the other hand, studies of transesophageal echocardiography (TEE) used to rule out an intra-atrial thrombus prior to conversion of AF suggest that a negative TEE reduces the risk of embolization enough to obviate the need for anticoagulation before cardioversion. Additional studies will be needed to more fully define the risks and benefits of these management strategies, and resolve this

controversy. Of course, if it is necessary because of hemodynamic instability, cardioversion should never be withheld.

For stable patients presenting with AF of >48 hours' duration and RVR treatment is directed at slowing the ventricular rate, and conversion to sinus rhythm is, at best, a secondary consideration. Prior to initiating rate control therapy it is important to consider what is precipitating the RVR. Just as an acute physiologic stress will increase catecholamine levels and result in sinus tachycardia in patient with a healthy heart, elevated catecholamines may precipitate an acute paroxysm of AF with RVR in a patient with an at-risk heart, or induce RVR in a patient with chronic AF. Consequently, an elderly patient with a history of chronic AF presenting with a fever, tachycardia, and evidence of urosepsis is better treated with IV fluids, antibiotics, and antipyretics than with pharmacotherapy directed at rate control.

Diltiazem has supplanted digoxin as the drug of choice for acute rate control of AF with RVR in stable patients. This change in practice is the result of evidence that, although digoxin is no more effective than placebo in slowing ventricular response in the first few hours, calcium channel blockers slow ventricular response within the first few minutes of IV administration (4). Neither diltiazem nor digoxin are particularly effective at producing cardioversion to sinus rhythm. In stable patients, diltiazem can be given at a dose of 5 to 10 mg IV over 2 minutes, repeated as necessary every 5 minutes to a total dose of 50 to 60 mg in the first 30 minutes. Following bolus injection, rate control can be maintained with an IV infusion of 5 to 15 mg/h. Although occasionally used to mitigate the hypotensive effects of diltiazem, IV calcium preparations are not supported by the literature in this regard.

Alternative rate control agents include β-blockers, digoxin, and magnesium. β-Blockers such as atenolol or metoprolol can be given in doses of 5 mg IV, repeated up to a total of 10 mg and 15 mg, respectively. β-Blockers are nearly as effective as diltiazem for rate control but may have a higher incidence of hypotension (7). Digoxin may be given as 0.5 mg IV or orally, followed by 0.25 mg, 4 and 8 hours later. Even when using these loading regimens, rate control is

no better than with placebo for at least several hours. Diltiazem may be given IV at the same time as digoxin, in the absence of other contraindications. Calcium channel blockers should be avoided in the presence of digitalis toxicity. There is evidence that IV magnesium is effective for rate control in AF, but although it is rarely used alone for this indication, it may be a useful addition to other therapies (8).

The ED management of stable patients with recent onset AF or flutter (RAFF) is controversial. RAFF, defined as <48 hours of symptoms, has many causes ranging from the benign to the life-threatening. It has long been standard practice to admit patients with RAFF to evaluate the possibility of serious underlying disease (e.g., acute myocardial infarction, mitral valve disease, pulmonary embolism, thyrotoxicosis, or drug effect) as its cause. However, 80% to 95% of stable patients with RAFF do not prove to have an acutely critical etiology, and those who do almost always have other worrisome clinical findings in addition to the dysrhythmia itself. Given the drive for cost-effective resource utilization and the emerging data, consideration may be given to discharging a reliable, hemodynamically stable, RAFF patient with no indications of serious underlying etiology, and prompt outpatient follow-up.

A second key management decision is intertwined with the decision to admit or discharge the patient with RAFF, whether to attempt cardioversion to sinus rhythm in the ED or merely control the ventricular response rate.

Rate control and admission is appropriate for high-risk but stable patients with RAFF. Rate control followed by discharge home on an oral rate control agent may be appropriate for low-risk patients for whom prompt follow-up can be arranged. Although this approach is widely used, evidence to support or refute its safety and efficacy is lacking. If this strategy is used the emergency physician should speak directly with the physician providing follow-up care to and agree on the time of the follow-up visit and the plan for rate control and anticoagulation.

In support of cardioversion of RAFF patients are several ED-based studies demonstrating a high success rate of cardioversion and an extremely low risk of stroke. In the largest prospective study of ED

cardioversion of RAFF patients, the authors observed no cases of stroke in over 600 patients discharged from the ED (8), albeit in a short follow-up period.

Pharmacologic agents that have been the subject of at least limited testing in the cardioversion of RAFF include amiodarone, clonidine, dofetilide, flecainide, ibutilide, magnesium, procainamide, propafenone, sotalol, and vernakalant. Rates of successful cardioversion and adverse effects vary. Of these procainamide has been more extensively studied for the cardioversion of RAFF. Procainamide has a 50% to 58% effectiveness rate and an acceptable safety profile when used in the ED (8,9).

The possible benefits of higher rates of earlier conversion using these drugs must be weighed against prodysrhythmic effects, a higher incidence of hypotension, and the fact that by 8 hours there is little difference from placebo in conversion rates. The spontaneous conversion rate of such patients is high, reaching 60% at 24 hours and 80% at 48 hours.

With the widespread adoption of safe and effective procedural sedation in the ED elective synchronized electrical cardioversion of PAFF has emerged as a viable therapeutic option. Often utilized following failed chemical cardioversion, success rates for electrical cardioversion are approximately 85% in selected patients with or without a preceding attempt at chemical conversion (10). Large ED case series have demonstrated a favorable safety profile (8).

Because of concerns about thromboembolic stroke, patient selection is important if either chemical or electrical cardioversion is to be attempted in the ED. Patients with AF >48 hours or of uncertain duration, and those at high risk of stroke (including a mechanical valve, rheumatic heart disease, prior stroke, and congestive heart failure) should not undergo elective ED cardioversion. To further reduce risk of stroke some centers perform TEE before elective cardioversion of RAFF.

In summary there is insufficient evidence to clearly guide the choice between rate versus rhythm control in stable patients with RAFF. The particulars of the specific patient and the local standard of

care will serve as a better guide for the practitioner than a blanket statement in support of either approach.

The therapy for unstable patients with AF and RVR is one of the most challenging situations in all of dysrhythmia management. Many of these patients have dilated atria and decreased ejection fractions. They do not easily cardiovert to sinus rhythm or remain in sinus rhythm if converted. In addition, cardioversion to sinus rhythm does not produce mechanical atrial contraction for hours to days. For this reason cardioversion should be considered a form of rapid rate control and not a therapy that immediately restores atrial systole. Finally, if the patient has been in AF for more than 2 days, intra-atrial thrombus may have formed and may embolize following cardioversion. For these reasons, cardioversion is considered by many a therapy of last resort, but if the patient is truly unstable, electrical cardioversion is required. The current American Heart Association (AHA) advanced cardiac life support (ACLS) recommendation is to cardiovert with a 120 to 200 J biphasic shock. Although traditional practice has been to cardiovert with an initial energy of 100 J, higher energies yield a somewhat greater success rate, and additional adverse effects appear to be minimal. Amiodarone has been used in unstable AF in a number of small case series and in one randomized trial in which it was found to be inferior to magnesium (11). Amiodarone slows ventricular rate and marginally increases the frequency of conversion to sinus rhythm. In rare cases, the cautious use of a vasopressor may be required to maintain blood pressure. The seriousness of this clinical situation cannot be overemphasized, and no therapy is without significant risk.

WIDE-COMPLEX TACHYCARDIAS

Wide Complex, Regular, No P Waves

Diagnostic possibilities include monomorphic VT, PSVT with aberrancy (bundle-branch block), and the antidromic SVT of WPW syndrome. Several clinical and ECG criteria have been devised to enable clinicians to distinguish between VT and SVT when the QRS

complex is wide. Useful indictors that make VT more likely include a history of heart disease, fusion and capture beats, and the presence of AV dissociation. Although such criteria are relatively accurate in predicting the source of tachycardia in series of patients, no single sign or combination of signs can definitively identify the origin of tachycardia (1). For this reason, wide-complex tachycardia should virtually always be treated as VT. Thus, drugs contraindicated in VT (e.g., verapamil) are almost never used to treat wide-complex tachycardia (12). Adenosine may be used to treat regular wide-complex tachycardia of uncertain etiology, because it is probably safe (if only very rarely effective) in VT and will convert most episodes of PSVT, including antidromic tachycardia associated with WPW syndrome.

Ventricular Tachycardia

VT (Fig. 85.4) is a macroreentrant rhythm that usually causes a life-threatening medical emergency. Although some patients have intermittent asymptomatic bouts of VT (usually episodes of <10 beats), patients who present to an ED with sustained VT are usually either suffering from significant hemodynamic effects or experiencing other acute cardiac problems—including, particularly, myocardial ischemia—that require emergent treatment.

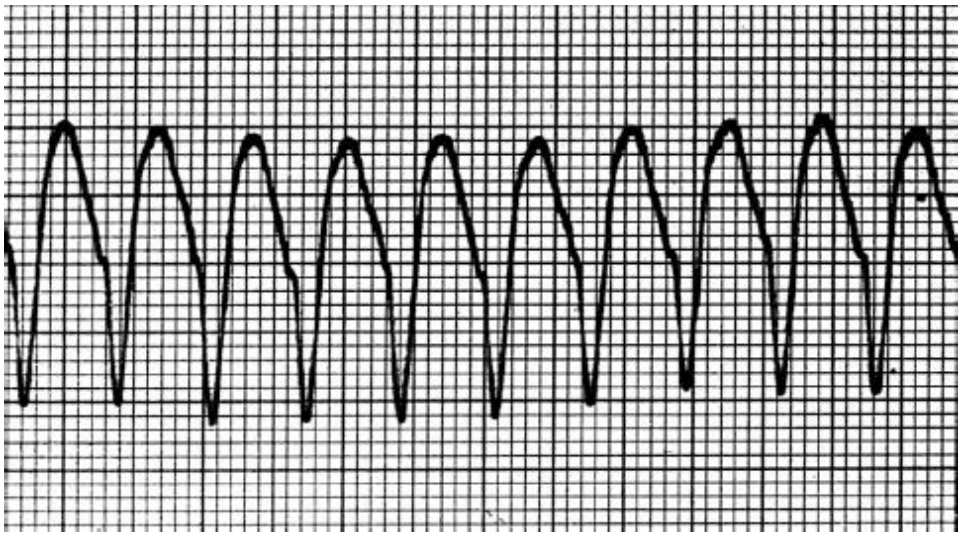

FIGURE 85.4 Ventricular tachycardia.

The very rapid heart rate of sustained VT usually causes hemodynamic deterioration. Such patients require emergent electrical cardioversion. Fixed dose single shocks have replaced the older “3-shock” protocol, and most guidelines recommend biphasic shocks of between 120 and 200 J (13). Cardioversion is performed in the synchronized mode to avoid precipitating VF. Amiodarone, procainamide, lidocaine, and magnesium are used to prevent recurrence of VT after successful cardioversion or to treat patients with recurrent VT. Despite a long history of use for this indication, lidocaine is of limited utility.

Sometimes, patients with sustained VT show no signs of hemodynamic instability in the short term. These patients can be treated with amiodarone, procainamide, or lidocaine, or magnesium. The medical literature does not provide a definitive basis for preferring one agent instead of another. Amiodarone is a common choice, but its efficacy has been questioned (14). Amiodarone can cause hypotension (treated with fluid bolus), AV nodal block, and rarely QT prolongation leading to torsade de pointes (TdP). Procainamide, an effective therapy for both VT and PSVT, should not be given at a rate of not more than 50 mg/min to avoid causing hypotension. Lidocaine is at best only moderately effective for the treatment of VT, and the literature in support of the use of magnesium for this indication is sparse. Failing pharmacologic conversion to sinus rhythm, synchronized cardioversion should be performed urgently, following appropriate sedation and analgesia. Essentially all patients with VT require consultation with a cardiologist and admission after ED therapy for the dysrhythmia.

Wide-Complex Paroxysmal Supraventricular Tachycardia

PSVT can manifest with wide QRS complexes when BBB (either underlying or rate-related) is present. The duration of the QRS complex in this circumstance is not likely to exceed 0.14 second, and heart rates usually range between 130 and 200 beats/min. Nevertheless, it is virtually impossible to be certain that a wide-complex tachycardia represents PSVT with bundle-branch block,

rather than VT; therefore, treatment should almost never be based on this assumption.

Wide QRS complexes are also seen in PSVT in association with the WPW syndrome when anterograde conduction occurs down the bundle of Kent and retrograde conduction occurs through the AV node. It may be possible to make this diagnosis from the ECG in patients with known WPW syndrome, although confusion with VT may still occur. When faced with a stable patient with a regular wide-complex tachycardia of uncertain etiology, adenosine is the preferred antiarrhythmic agent. Verapamil, diltiazem, β-blockers, and digoxin should be avoided in this circumstance.

When adenosine fails to convert regular wide-complex tachycardia or when VT is considered more likely, procainamide is a rational choice. Procainamide has antiarrhythmic effects on atrial and ventricular tissue, and it is generally safe and useful in most cases of wide-complex tachycardia, whether VT or PSVT with anterograde conduction through the bundle of Kent. Wide-complex tachycardia in the setting of possible drug overdose suggests cyclic antidepressant toxicity, in which case procainamide is absolutely contraindicated. Lidocaine can occasionally speed conduction through bypass tracts in experimental models and is therefore less attractive when wide-complex tachycardia is suspected to result from WPW syndrome-related PSVT.

Wide Complex, Irregular, No P Waves

Diagnostic possibilities include AF with bundle-branch block, AF with the WPW syndrome, polymorphic VT of which torsade de pointes is a subset, and VF.

Wide-Complex Atrial Fibrillation

A few patients with AF present with wide QRS complexes (Fig. 85.5), caused by an underlying or rate-related bundle-branch block or by the WPW syndrome. In the presence of known underlying bundle-branch block, treatment can be similar to that for routine narrow-

complex AF (i.e., cardioversion for severely unstable patients and diltiazem for rate control in stable patients).

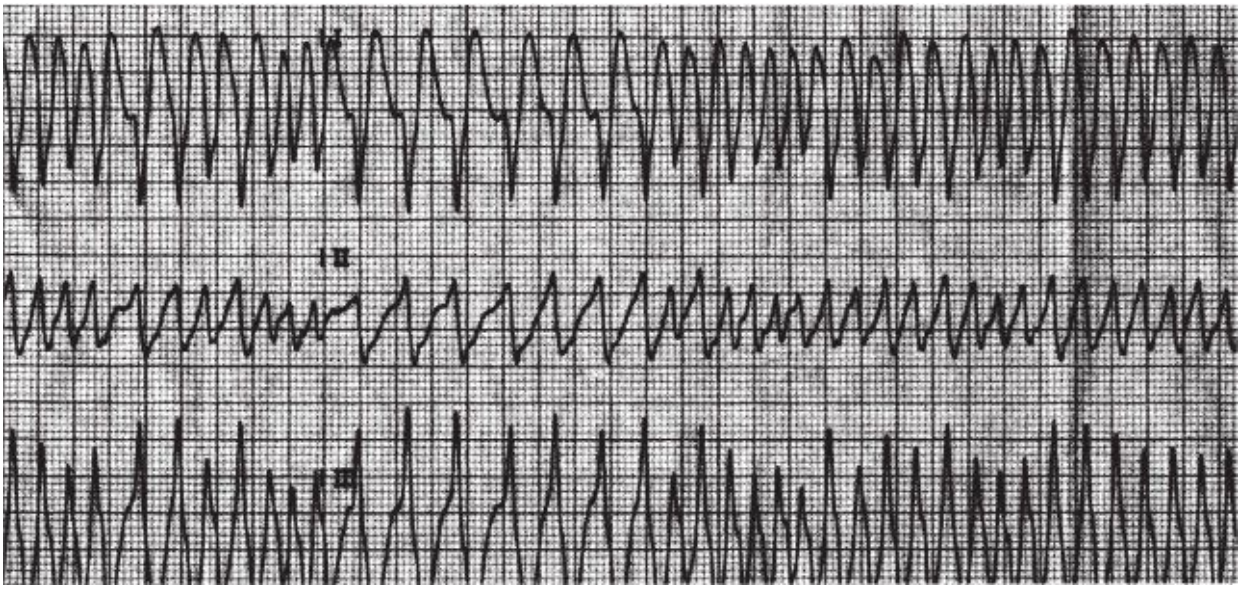

FIGURE 85.5 Atrial fibrillation in a patient with Wolff–Parkinson–White syndrome.

Patients with rate-related bundle-branch block often demonstrate both wide complexes (in beats that follow short RR intervals) and narrow complexes (in beats that follow longer RR intervals), but patients with AF and the WPW syndrome may also have both wide and narrow QRS complexes, depending on the conduction path followed by each depolarization. It is critical to recognize this latter entity, because agents that slow conduction through the AV node are absolutely contraindicated.

In WPW, the presence of rapidly conducting accessory pathways predisposes to a number of dysrhythmias, of which AF is the most dangerous. AF generates atrial impulses at 300 to 600 per minute. The accessory pathways of WPW syndrome, which bypass the AV node and its protective slowing, conduct impulses to the ventricle at rates exceeding 250 beats/min. The ventricle will fail or undergo fibrillation if these excessively rapid atrial impulses are conducted for more than a short period. Many patients are aware that they have WPW syndrome. Among patients who give no history of WPW

syndrome, the possibility should be considered when the irregular rhythm is wide and very fast and the QRS complexes are variable and bizarre.

Drugs such as adenosine, diltiazem, β-blockers, and digitalis are contraindicated in WPW syndrome with wide-complex AF, because they can actually increase the speed of conduction through the bypass tract. More importantly, relative blockade of the AV node causes preferential conduction through the bypass tract, thereby resulting in much higher ventricular response rates that can deteriorate into VF. Although amiodarone and procainamide are unlikely to be harmful in WPW syndrome-related AF, neither may be particularly effective in the acute setting. Therefore, even in the absence of acute hemodynamic deterioration, patients with WPW syndrome-related AF are best treated with electrical cardioversion.

Torsade de Pointes

Torsade de Pointes (TdP) is an unusual form of polymorphic VT characterized by the peculiar spiral pattern it produces on the surface ECG (Fig. 85.6). Drug-induced long-QT syndrome is the principle predisposing factor, with antiarrhythmic agents (e.g., ibutilide, procainamide, and sotalol) the most common inducing agents. Other drugs (most prominently, the phenothiazines and methadone), drug interactions, and many other conditions (especially hypocalcemia and hypokalemia) are also associated with TdP.

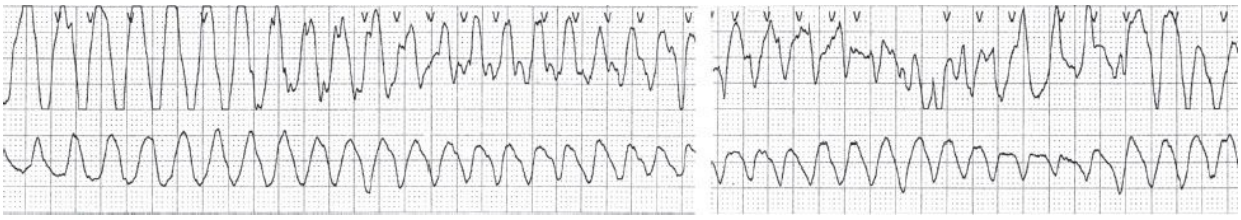

FIGURE 85.6 Torsade de Pointes.

Although most episodes of TdP are self-limited, they are nevertheless life-threatening, because any episode can precipitate VF. Because TdP usually converts spontaneously to sinus rhythm but

then recurs, treatment is directed at preventing recurrences rather than terminating a given episode. In the long term, this treatment often requires only withdrawal of the offending agent. In the ED, however, antiarrhythmic therapy is mandatory.

Magnesium, given as an IV infusion of 2 to 4 g over 5 to 10 minutes, is highly effective and is the treatment of choice for TdP (15). A normal serum potassium should be maintained. Alternately, overdrive electrical pacing can be used to speed the heart rate and thereby decrease the corrected QT interval and dispersion of refractoriness that is the underlying basis for this dysrhythmia. Infusions of isoproterenol have also been used with the same goal, although the prodysrhythmic effect of isoproterenol is worrisome.

Patients with polymorphic VT that is not TdP are almost invariably unstable and should be treated as VF with high-energy unsynchronized shocks. Patients with TdP may also have sustained episodes, may become severely unstable, and may require emergent unsynchronized electrical cardioversion. Since recurrence of TdP is so common, this treatment should be considered a temporizing measure, and magnesium should be promptly administered. Amiodarone and other antiarrhythmics that prolong the QT interval are contraindicated following cardioversion if TdP is suspected.

Ventricular Fibrillation

VF is the chaotic firing of the ventricle from multiple foci and never results in effective myocardial contraction. The only therapy shown to improve the outcome of patients with VF is electrical defibrillation (unsynchronized shocks), and delay in defibrillation is known to decrease survival. Accordingly, it has long been taught that when a defibrillator is available, no other activity should take precedence. Specifically, chest compressions (“cardiopulmonary resuscitation” or CPR) should be initiated only until the defibrillator is ready and charged, according to the 2010 AHAACLS guidelines for witnessed VF cardiac arrest (13). In unwitnessed VF cardiac arrest, the previous 2005 guidelines required 2 minutes of CPR before shocking. This strategy has been reversed in the 2010 guidelines based on two studies showing no benefit of intentionally delaying defibrillation to

perform CPR. Based on currently available evidence, defibrillation should be performed as soon as possible with CPR performed until the defibrillator is charged. This applies to both witnessed and unwitnessed VF, and pulseless VT arrest.

The previous practice of administering a single shock rather than three shocks at escalating energies has also been upheld in the 2010 ACLS Guidelines. The rationale for this change in strategy is the mounting evidence that reducing interruptions of CPR improves outcome, rather than convincing evidence that one or three shocks is more effective at terminating VF.

The optimal waveform and energy level for defibrillation of VF remain controversial. Biphasic waveform defibrillators have largely supplanted monophasic waveform defibrillators based on data demonstrating that biphasic defibrillation is more effective at terminating VF than monophasic defibrillation. Unfortunately, biphasic defibrillation has not been associated with any improvement in return of spontaneous circulation (ROSC) or survival to hospital discharge as compared to monophasic defibrillation (13). Although there is insufficient evidence to definitively determine an optimal energy for defibrillation using either waveform, the available evidence supports the following:

1. Biphasic defibrillation is effective at energy levels of 100 to 200 J. Biphasic defibrillators have differing waveforms and optimal energy levels for defibrillation. The specific energy level used should be based on manufacturer recommendation. Defibrillation with escalating higher energy levels was more effective than a fixed lower-energy protocol in a published randomized controlled trial (16). The 2010 ACLS guidelines recommend equal or greater energy levels be used for subsequent shocks (13).
2. Monophasic defibrillation is effective at 200 to 360 J. To date there is no evidence demonstrating superiority of the exclusive use of 360 J. On the contrary, defibrillation at 200 J may provide the greatest likelihood of success, and increasing the energy level may be detrimental (17).

Several adjunctive drugs are widely used when initial defibrillation is not successful. Although these drugs are considered standard therapy in this situation, it is important to remember that none of them has been definitively shown to increase the success of defibrillation or to improve long-term outcomes in humans with cardiac arrest. Thus, administration of these agents should never interfere with the rapid use of electrical defibrillation.

Specifically, no study has confirmed a positive effect of epinephrine use at either standard or high doses. Vasopressin has not been shown to be superior to epinephrine but remains on the ACLS protocol as an adjunct or alternative to epinephrine (18). Similarly, there is little evidence that amiodarone or lidocaine significantly improves outcomes in refractory VF. Amiodarone has supplanted lidocaine as the drug of choice, based on evidence suggesting that it is marginally more effective in achieving ROSC and survival to hospital admission (13,19).

IV amiodarone, procainamide, or lidocaine is used to help prevent recurrence of VF after successful defibrillation. Amiodarone is possibly more effective than lidocaine for this indication.

CRITICAL INTERVENTIONS

- Have a defibrillator and advanced airway equipment at bedside
- Perform immediate defibrillation for patients in VF
- Perform electrical cardioversion for unstable patients with a very rapid tachydysrhythmia except sinus tachycardia and MFAT
- Use a systematic approach to tachydysrhythmia identification

DISPOSITION

In most cases, the disposition of patients with tachydysrhythmia is apparent. The patient resuscitated from cardiac arrest resulting from VF obviously must be admitted to the intensive care unit. Similarly, there should be little controversy about discharging a healthy young patient with a brief, minimally symptomatic episode of PSVT that readily converted to sinus rhythm. In the few patients with a problematic disposition, the physician should remember that ED care

involves only initial therapy and not definitive management of the tachydysrhythmia. Several categories of patients should be admitted:

- Patients who are symptomatic after acute onset of tachycardia and who have failed appropriate therapy or responded only transiently.
- Patients who were clinically unstable as a result of a tachycardia, including all patients who require cardioversion because of end-organ hypoperfusion.
- Patients who were treated successfully before the development of serious symptoms but who have the potential for decompensation if the tachydysrhythmia recurs.

The basis of the dysrhythmia also plays a role in disposition decisions: Any patient with a realistic likelihood of a dangerous etiology (e.g., possible acute coronary syndrome) should be admitted, even if the dysrhythmia itself was benign. Finally, it may be appropriate to admit a stable patient for continuous ECG monitoring during initiation of chronic drug therapy.

Common Pitfalls

- Being overly concerned with definitive diagnosis. One should concentrate more on the hemodynamic effects of the rhythm than on its origin.
- Reliance on ECG and clinical findings to identify the likely anatomic source of a dysrhythmia. ECG and clinical findings are suggestive but not infallible guides.
- The use of a calcium channel blocker to treat a wide-complex tachycardia. Calcium channel blockers are appropriate for many narrow-complex tachycardias but can precipitate VF in wide-complex tachycardias, including those other than VT.
- Treatment of symptoms rather than the tachydysrhythmia precipitating those symptoms. In patients having symptoms related to a very rapid tachycardia, controlling the ventricular rate usually ameliorates the symptoms.
- Failure to seek and, if possible, correct the factors that precipitated a tachydysrhythmia. Examples include hypoxemia,

infectious or inflammatory processes, intoxications, and noncompliance with antidysrhythmic medications.

- Failure to consider myocardial ischemia in all patients. An acute coronary syndrome must be ruled out whenever it seems a reasonably likely cause of the dysrhythmia or when the dysrhythmia has itself produced a substantial period of ischemia as suggested by ECG changes or symptoms.
- Delays or errors in CPR and defibrillation during cardiac arrest. High-quality CPR and defibrillation are the only interventions shown to improve outcomes in cardiac arrest patients.

CHAPTER 86

Pacemakers and Implantable Cardioverter–Defibrillators

Robert M. Rodriguez

PACEMAKERS

The first permanent cardiac pacemakers were implanted in the late 1950s; since that time, advances in microprocessor technology have led to the production of compact pacemakers that readily adapt to changes in patient physiology (14). Current dual-chamber pacemakers are rate-responsive to increased patient activity with batteries that may last longer than 10 years (16). Beyond simple treatment for bradycardia syndromes, the therapeutic utility of pacemakers has grown over the years. Recent trials have demonstrated the efficacy of pacemakers in the prevention and treatment of atrial fibrillation and as adjunctive therapy for patients with congestive heart failure and ventricular dyssynchrony (1,5,8).

Given that more than 1 million Americans currently have pacemakers and the rate of implantation is steadily increasing (14,19), the emergency department (ED) physician will undoubtedly care for many patients with these devices. Although detailed knowledge of the myriad complexities of pacemaker programming and operation is unnecessary, the emergency physician must understand the basics of pacemaker terminology and function and must be familiar with the presentation, evaluation, and treatment of common pacemaker-related problems.

Central to the understanding of basic pacemaker function are the five-letter codes used by the North American Society of Pacing and Electrophysiology–British Pacing and Electrophysiology Group (NASPE/BPEG) to characterize the modes of operation of current pacemakers (Table 86.1). In everyday practice, description of the mode of pacing is limited to the use of the first three code letters: position I, chamber(s) paced; position II, chamber(s) sensed; and position III, pacemaker response to sensing. A VVI pacemaker thus paces the ventricle only, senses only ventricular depolarizations, and inhibits pacemaker output in response to a sensed ventricular depolarization. The vast majority of currently implanted devices are DDD pacemakers (14), which pace the atria, the ventricles, or both; sense atrial depolarizations, ventricular depolarizations, or both; and either inhibit or trigger pacemaker output to the atria and ventricles in response to sensed depolarizations. Intrinsic ventricular depolarizations will inhibit both atrial and ventricular output; intrinsic atrial depolarizations will inhibit atrial pacemaker output and will trigger ventricular output if the ventricle itself does not respond after a programmed time interval.

TABLE 86.1
North American Society of Pacing and Electrophysiology–British Pacing and Electrophysiology Group (NASPE/BPEG) Defibrillator (NBG) Codes

First Position Indicates the Chamber Paced

V = ventricle
A = atrium
D = dual
O = no pacing

Second Position Indicates the Chamber Sensed

V = ventricle
A = atrium
D = dual
O = no sensing

Third Position Indicates the Response to a Sensed Event

I = inhibited
T = triggered/tracking
D = dual
O = no response

Fourth Position Indicates Programmability and Rate Response

O = not programmable
P = simple programming (three functions or less)
M = multiprogrammable (more than three functions)
C = communicating (M + telemetry capabilities)
R = rate responsive

Fifth Position Indicates Antitachydysrhythmia Functions

O = none
P = pacing
S = shock
D = dual (shock and pacing)

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Syndromes of pacemaker malfunction can generally be divided into those that cause underpacing, with associated bradycardia, hypotension, light-headedness, and syncope and those that produce overpacing, manifested by tachycardia and palpitations with or without ischemia or hypotension symptoms.

The differential diagnosis of these nonspecific presenting complaints is broad, and the clinician should consider other disorders, including intrinsic dysrhythmias, vasovagal phenomena, anemia, hypovolemia, and nonrate-related syndromes of low cardiac output. Before attributing these nonspecific presenting symptoms to the uncommon entity of pacemaker failure, the physician must first determine whether the device is truly malfunctioning. Patient history, electrocardiographic (ECG) analysis, and identification of the current programming and specifications of the pacemaker are the keys to making this determination.

ED EVALUATION

In addition to elucidating standard history about the symptoms, time course, and precipitants related to the presenting complaint(s), the physician should also seek the following information regarding the pacemaker: pacemaker model, current programming, date of implantation, indication for implantation, history of pacemaker malfunction, and dates of last interrogation and battery check. Some of this vital information may be obtained from the pacemaker identification card, which the patient should carry at all times. If this card is unavailable, a chest radiograph may reveal the pacemaker's identifying serial number or code (15). For technical support or to find out other information about the pacemaker, the physician may call the pacemaker manufacturer's assistance department.

The emergency physician should also ask about exposure to potential sources of environmental electromagnetic interference with pacemaker function. Although most of the everyday appliances and devices pose virtually no risk to current pacemakers, electric toothbrushes, cellular telephones, induction ovens, and stove plates can markedly alter their operation. Most of the modern airport security gates pose minimal risk, but antitheft systems in stores emit signals of variable intensity, with unpredictable effects on pacemaker function (11).

Because pacemakers typically produce left bundle-branch block (LBBB) and other altered patterns of depolarization, the ECG diagnosis of myocardial ischemia or acute myocardial infarction (AMI) may be difficult, and patients with pacemakers have been shown to be less likely to receive reperfusion therapy and aspirin (27). In the absence of ischemia, discordant T waves after paced beats are the norm and minor ST-segment evaluations inferiorly and anteriorly (leads V_1 to V_3) and ST-segment depression (leads 1, V_1, V_5, and V_6) also occur commonly (4). Even after the patient's native, spontaneous rhythm emerges, transient ST-segment and T-wave abnormalities may be seen (4).

Despite these difficulties in AMI pattern recognition, the clinician should nonetheless look for ST-segment and T-wave changes in comparison to the patients' old ECG-paced rhythms. In the absence of such old ECGs, the physician may still diagnose MI in the patient with a pacemaker by applying the criteria used in the evaluation of patients with intrinsic LBBB (4). Concordant ST-segment elevations, ST-segment depression in leads V_1, V_2, and V_3, and markedly elevated (>5 mm) discordant ST segments are highly indicative of MI, especially when the T waves associated with these segments are of opposite polarity (4,23). A qR pattern after the pacemaker spike in leads I, V_1, and V_5 has low sensitivity but very high specificity for anteroseptal MI (4). In a meta-analysis of the diagnostic utility of the ECG algorithm of these patterns for the detection of MI in patients with intrinsic LBBB, investigators found that the algorithm had poor sensitivity (20%) but high specificity (98%) and a summary positive likelihood ratio of 7.9 for the prediction of MI (25). The few case series directly examining MI in patients with pacemakers have demonstrated similarly high specificity and low sensitivity of these Sgarbossa patterns (28,29). The emergency physician should therefore look for these patterns of MI, but, given their low sensitivity, their absence does not rule out ischemia or infarction.

Malfunction Associated with Bradycardia

Pacemaker malfunction leading to a slow pulse arises from noncapture, pacemaker output failure, or pacemaker oversensing. Noncapture refers to an absence of ventricular or atrial depolarization after a pacemaker spike (Fig. 86.1). The most common cause of this condition is pacemaker lead dislodgement, which typically occurs within a few weeks of implantation (11). Other mechanical causes include insulation breaks, lead fracture, and inflammatory reaction at the lead tip (11). Reversible metabolic abnormalities, such as hyperkalemia, and drug effects should also be considered. Of note, if a pacemaker spike occurs within 300 milliseconds of a prior ventricular depolarization, the ventricle may be in its refractory period and lack of capture is expected (11). In this case, the pacemaker may be firing early because of undersensing the prior depolarization, but it is not truly malfunctioning with regard to pacing (Fig. 86.2).

FIGURE 86.1 Noncaptured pacemaker spike between two captured spikes.

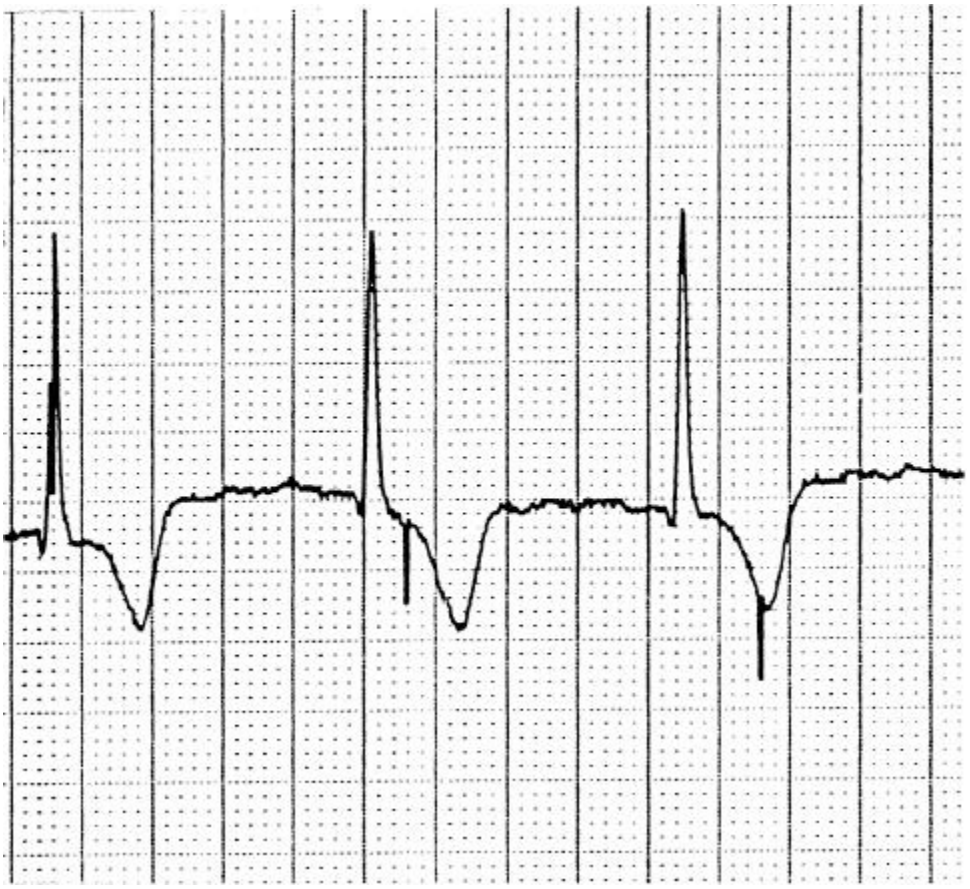

FIGURE 86.2 Pacemaker undersensing.

Absent or inappropriately delayed ventricular pacemaker spikes on the ECG of a patient with bradycardia indicate primary pacemaker output failure, battery depletion, or output failure secondary to oversensing (reading other signals as true ventricular depolarizations) (11). Causes of primary output failure include lead fracture or disconnection and various pulse generator component failures. Oversensed signals may be of cardiac (P and T waves) or extracardiac (myopotential) origin and lead to inappropriate inhibition of pacemaker ventricular output (11).

These causes of absent or delayed pacemaker spikes may be distinguished by performing a magnet test of the pacemaker.

Application of a ring magnet over a normally functioning pacemaker disables sensing and induces asynchronous pacing at model-specific rates, which may be determined by checking the patient's records or calling the pacemaker manufacturer (11,15). If the problem is oversensing, the magnet will induce asynchronous pacing at that model's characteristic rate. If battery depletion is the cause, asynchronous pacing will occur at a different, generally slower rate (11). If the malfunction is a result of lead displacement or some other circuit disruption, no pacing response to the magnet will be seen.

Malfunction Associated with Tachycardia

Pacemakers may produce inappropriate tachycardia by several mechanisms. When a pacemaker fails to sense intrinsic ventricular depolarizations, it will fail to inhibit pacemaker output, potentially causing a pacemaker-driven tachycardia, that is, "undersensing leads to overpacing" (15). In dual-chamber systems, the pacemaker circuit may act like an accessory pathway similar to those seen in Wolff–Parkinson–White syndrome, thereby propagating a re-entrant tachycardia known as pacemaker-mediated tachycardia or "endless-loop tachycardia" (15). This dysrhythmia may be terminated by vagal maneuvers, external magnet induction of asynchronous pacing, intravenous adenosine, or transthoracic cardiac pacing with 10 to 20 mA of output (9,15).

A final pacemaker-related tachycardia that occurs only rarely with current pulse generators is "runaway pacemaker," a potentially lethal disorder in which battery depletion or other component failure causes extremely rapid pacing, with rates restricted only by the pacemaker's upper rate limit (13). This disorder may not respond to traditional therapies to decrease the rate, including medications and cardioversion/defibrillation, and, in the setting of hemodynamic instability, the emergency physician should attempt to disable the runaway pacemaker by incising over the pacemaker pocket and disconnecting the pulse generator leads (13).

Pacemaker syndrome, a classic example of a pacemaker operating correctly according to its programming yet still causing bothersome symptoms, results from the loss of atrioventricular synchrony (15). Fatigue, light-headedness, syncope caused by decreased cardiac output (loss of atrial kick), and disturbing neck pulsations related to regurgitant cannon A waves (atria contracting against closed atrioventricular valves) are the predominant symptoms. Although this disorder is largely limited to patients with VVI pacemakers and is usually ameliorated with a change to synchronized dual-chamber pacing, it can occasionally occur in patients who have DDD pacemakers (11).

Infectious and Mechanical Complications of Pacemakers

In addition to rhythm and hemodynamic problems associated with pacemakers, foreign-body-related complications also occur. With *Staphylococcus* species being the most common pathogens, the incidence of pacemaker or implantable cardioverter defibrillator (ICD) infection is 1.9 per 1,000 device-years (26). In the patient presenting with fever and redness and tenderness over the pulse generator pocket, the diagnosis of pacemaker infection is obvious. Subtler presentations, however, are common, and the emergency physician should consider pacemaker-related infection as a potential cause of unexplained fever in any patient with a pacemaker. Notably, without superimposed endocarditis, embolic phenomena and murmurs are generally absent. Nuclear medicine scans may provide ancillary evidence of infected pacemaker hardware. Confirmed pacemaker infection mandates a course of parenteral antibiotics, and most authorities agree that removal of the device is indicated (19).

Pacemaker-associated thrombosis of the upper extremity vessels is uncommon, but it should be considered in the patient with unilateral arm swelling, erythema, or pain (7). Ultrasound or venography may be used to distinguish this entity from similar-appearing arm cellulitis. Anticoagulation without pacemaker removal has been reported to successfully treat the thrombosis (7).

ED MANAGEMENT

As with other ED problems, patient stability determines the urgency of intervention in the patient with a pacemaker. The cardiac arrest patient should receive standard advanced cardiac life support (ACLS)-guided resuscitation. During defibrillation or cardioversion, the physician should avoid placing pads or paddles directly over the pulse generator (9). Pacemakers of resuscitation survivors should be evaluated for damage or reprogramming arising from countershocks. In nonsurvivors, the pacemaker may continue to produce ECG spikes without associated ventricular capture, which represents isolated pacemaker activity and not true pulseless electrical activity.

The pacemaker patient with hypotensive bradycardia should receive the usual therapeutic measures (chronotropic support with medications, external pacing, or transvenous pacing). The physician may attempt to temporarily asynchronously pace the patient's rate with higher current by placing a ring magnet over the pacemaker, as described earlier in this chapter (11). This maneuver may be helpful if the pacemaker is oversensing, thereby suppressing output (absent or inappropriately slow rate of pacemaker spikes on ECG) or if low pacemaker current is leading to noncapture.

In the ED management of pacemaker patients, the physician must recognize that magnetic resonance imaging (MRI) and electrocautery may interfere with pacemaker function. Given that MRI may induce complete block of pacemaker output, severe pacemaker-driven tachycardias, and other potentially disastrous pacemaker malfunction, MRI is contraindicated for patients with pacemakers (11). If MRI is absolutely essential to patient management, some authorities have suggested switching the pacemaker to its "off" mode, turning pacemaker output down so that it will not capture, or surgically removing the device (3), all of which must be undertaken with the help of an electrophysiologist. Electrocautery may also induce a number of hazardous abnormalities in pacemaker function; precautions and steps to

minimize risk during surgical procedures are described elsewhere (3).

DISPOSITION

Disposition of the patient with a pacemaker-related problem largely depends on the severity of signs and symptoms and should be determined collaboratively with the patient's electrophysiologist. Patients with pacing malfunction, such as failure to capture or battery depletion, should be admitted to monitored settings. Patients requiring a higher level of care may need interhospital transfer. In these cases ACLS ambulance units should be used, and the patient's rhythm and hemodynamics must be stabilized prior to transfer; backup pacing modalities (transthoracic or transvenous) should be in place during transit.

IMPLANTABLE CARDIOVERTER&NDASH;DEFIBRILLATORS

The first ICD was placed in 1980, and, as with pacemakers, technologic improvements have produced smaller, "smarter" defibrillators that are more easily implanted (6). Early models were nonprogrammable shock or no-shock devices that required open thoracotomy for epicardial patch placement. Current programmable devices have defibrillator leads that are inserted transvenously and utilize improved rhythm-analysis algorithms to deliver sequential, tiered therapy. For example, slow ventricular tachycardia (VT) may be first treated with overdrive pacing; if this fails to convert the VT, low-energy shocks are delivered. If these shocks also fail, higher energy shocks are given (15). Many ICDs also incorporate pacing functions that may be activated if cardioversion or defibrillation produces a bradycardic or asystolic rhythm.

As with pacemakers, the indications for ICD implantation have also expanded. Major trials examining the treatment of patients with frequent ventricular dysrhythmias have demonstrated increased mortality with pharmacologic dysrhythmic therapy but markedly decreased mortality with ICDs (6). Prophylactic placement of an ICD

has also been demonstrated to increase survival in patients who have post-MI low ejection fractions even without electrophysiologic evidence of sustained dysrhythmias (20). In 2002, nearly 100,000 ICDs were placed in the United States (19).

NASPE/BPEG descriptive codes also characterize the types and functions of ICDs (15): position I, chamber(s) shocked; position II, chamber(s) for antitachycardia pacing; position III, method of tachycardia detection; and position IV, chamber(s) for bradycardia pacing (Table 86.2). In everyday practice, these codes are less commonly used than are pacemaker codes.

TABLE 86.2
North American Society of Pacing and Electrophysiology–British Pacing and Electrophysiology Group (NASPE/BPEG) Codes for ICDs

First Position Indicates the Chamber Shocked

V = ventricle

A = atrium

D = dual

O = no shock therapy

Second Position Indicates the Chamber for Antitachycardia Pacing

V = ventricle

A = atrium

D = dual

O = no antitachycardia pacing

Third Position Indicates the Method of Tachycardia Detection

E = electrogram

H = hemodynamic

Fourth Position Indicates Chambers for Bradycardia Pacing[a]

V = ventricle

A = atrium

D = dual

O = no bradycardia pacing

[a]Alternatively the three- or four-letter NBG pacing code may be used following the first three letters of the NBD code (e.g., VVE-VVIR, indicating ventricular shock, ventricular ATP, electrogram detection, and VVIR pacing capability).

From Love C, ed. *Handbook of Cardiac Pacing*. Georgetown, TX: Landes Bioscience; 1998, with permission.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The rate of ICD malfunction is approximately 20-fold higher than that of pacemaker malfunction (18). Patients with ICD malfunction generally present with either defibrillation–cardioversion failure or inappropriate ICD discharge. Defibrillation–cardioversion failure may result from failure to deliver a shock, analogous to pacemaker output failure, or from failure of delivered shock(s) to convert the dysrhythmia, analogous to pacemaker noncapture. In recent studies, 7.4% to 7.9% of patients with an ICD experienced a discharge per year. Of these, less than half (approximately 45%) of shocks were deemed appropriate (10). Although the potential lethality of inappropriate ICD discharge is less than that of ICD failure to discharge, repeated shocks may cause myocardial injury, temporary

ventricular dysfunction, and rapid battery depletion (21). Furthermore, shocks may be very painful and anxiety-provoking. Because all ICDs use ventricular rate as the primary criterion for ICD activation, the most common causes of recurrent discharges are supraventricular dysrhythmias, sinus tachycardia, and nonsustained VT (13).

ED EVALUATION AND MANAGEMENT

In a study of the mechanisms of sudden death of patients with ICDs, the most common causes were (i) electromechanical dissociation (EMD) after ICD conversion of ventricular fibrillation (VF) or VT (29%); (ii) shock failure defined as VT or VF that was not terminated by the full complement of four to six ICD shocks (26%); (iii) primary EMD not involving VT or VF (16%); and (iv) VT/VF that was successfully converted but recurred again and again (13%) (18). Considering these primary causes, when treating the ICD patient in cardiac arrest, the physician should focus on treating potentially reversible causes of EMD and on further attempts to convert persistent or recurrent VT/VF. Resuscitation should generally follow the standard ACLS protocols for cardiac arrest (21). Most ICDs analyze and shock VF or VT within 30 seconds; therefore, if a patient presents in these rhythms, the physician should assume that ICD defibrillation–cardioversion has been unsuccessful and should immediately proceed with external countershocks (10). However, to prevent ICD absorption of current, defibrillator pads or paddles should not be placed directly over the device and, when feasible, should be positioned anteroposteriorly (10). Chest compressions should be given in the standard fashion. Without gloves, the rescuer may feel a slight, harmless shock if an ICD discharges during compressions (10).

After successful resuscitation, the emergency physician should investigate the events surrounding the arrest, focusing on the few causes of ICD failure (electrolyte imbalance, myocardial ischemia or MI, and drug effects) that may be treated without ICD reprogramming or surgery. The physician should ask the patient if

he or she recalls chest pain, palpitations, or ICD discharges. As with the pacemaker patient, the emergency physician should use direct history, the patient's ICD card, medical records, and telephone calls to the ICD manufacturer to gather information about the ICD, including recent ICD interrogation and prior ICD malfunction. Repetitive shocks occurring seconds apart during intense exercise are more likely to represent an inappropriate response to sinus tachycardia, and conversely shocks to the resting patient are likely to be appropriately treating ventricular dysrhythmias (10). The emergency physician should ask about exposures to the sources of environmental electromagnetic interference described earlier in the section on pacemakers. The many etiologies of ICD malfunction may be explored later by an electrophysiologist through interrogation. In addition, referral to an electrophysiologist is essential to evaluate the ICD for lead fracture or displacement caused by chest compressions and for pulse generator damage or reprogramming arising from external countershocks (21).

When rapid atrial fibrillation triggers frequent ICD discharge, the physician should attempt to slow the ventricular rate with the usual pharmacologic agents (21). If, after a period of close monitoring, it is determined that frequent ICD discharges are inappropriate or if frequent ineffective ICD discharges are interfering with resuscitation, the physician may disable the ICD by applying a ring magnet to the chest wall over the device (21). Occasionally, two magnets, stacked one on top of the other, are required to deactivate the ICD in markedly obese patients (21). Although the magnet suspends all antitachycardia functions (the ICD will not deliver a shock for VT), backup pacing functions of the ICD may persist.

If the ICD is delivering multiple appropriate shocks for ventricular dysrhythmias, the physician should consider administration of antiarrhythmic medications, such as amiodarone (10). Attention to hemodynamics, close monitoring, and sedation or analgesia for the anxious patient are other keys to ED management of frequent ICD discharges. The emergency physician must understand that although a ring magnet generally causes changes in pacemaker function only during application of the magnet (i.e., the pacemaker resumes its

normal function after removal of the magnet), a magnet may reset some ICD models to the "off " mode indefinitely (21). Therefore, if a magnet is either intentionally or inadvertently applied to an ICD, the physician should assume the device has been deactivated and should arrange for ICD interrogation and reprogramming.

The rate of ICD infections is higher than that of pacemakers (26). The presentation and management of infectious and thrombotic complications of ICDs parallel those of pacemakers, except that ICD infections may be more serious and difficult to treat (19). Hospital admission for administration of parenteral antibiotics and hardware removal is recommended for all infected ICDs (19). If the patient has an older model with epicardial patches, computed tomographic imaging of the heart and mediastinum is warranted to determine the extent of mediastinal involvement.

CRITICAL INTERVENTIONS

- Distinguish between causes of absent or delayed pacemaker spikes by performing a magnet test of the pacemaker, which, in a normally functioning pacemaker, disables sensing and induces asynchronous pacing at model-specific rates.
- Avoid placing pads or paddles directly over the pulse generator during defibrillation or cardioversion.
- Disable the ICD by applying a ring magnet to the chest wall over the device if frequent, inappropriate ICD discharges are causing substantial patient discomfort or are interfering with resuscitation. However, this action may reset the ICD to "off," even after removal of the magnet, so the ICD must subsequently be interrogated or reprogrammed.

DISPOSITION

Given the potentially catastrophic consequences of ICD failure, urgent referral to an electrophysiologist is recommended for essentially all types of ICD malfunction. ICD patients should be observed in or admitted to monitored settings until specialist evaluations are completed. If specialist evaluation or higher level of

care issues mandate transfer to another facility, ACLS units should be used and transthoracic (anteroposterior) defibrillation/pacing pads should be applied to the patient prior to transit. Patients who experience an ICD discharge, especially with associated lightheadedness or impairment of consciousness, should be instructed not to drive until they are cleared by their electrophysiologist (10).

Common Pitfalls

- Misdiagnosing pacemaker or ICD malfunction because of inadequate information about the current programming and operation of the device. The physician should gather as much information about the pacemakers or ICDs as possible from patient history, device identification cards, pacemaker or ICD registration departments, and patients' cardiologists or electrophysiologists.
- When evaluating the pacemaker patient for MI, failing to understand both the utility and the limits of 12-lead ECG interpretation. Several ECG patterns have high specificity and are reliable indicators of ischemia or infarction during RV pacing, but a normal LBBB pattern of pacing does not rule out infarction or ischemia.
- In a patient with cardiac arrest, allowing the presence of a pacemaker or ICD to change resuscitation procedures. Other than anteroposterior positioning of paddles and avoiding shocks over the devices, resuscitation should generally follow the usual ACLS protocols.
- Assuming that—after magnet application over an ICD or after cardioversion or resuscitation of a patient with an ICD or a pacemaker—the device has reverted to its normal programming and operation. The ICD or pacemaker must be re-evaluated after these procedures.
- Failing to make disposition decisions for most pacemaker problems and for essentially all cases of ICD malfunction in collaboration with an electrophysiologist.

CHAPTER 87

Valvular Heart Disease

Joseph P. Ornato

A wide variety of diseases and conditions can affect the heart valves (Table 87.1). In the 1950s, virtually all patients with clinically significant valvular disease had complications of acute rheumatic fever or syphilis, or congenital heart disease. Since then, the pattern of disease responsible for valvular dysfunction in adults has changed dramatically in highly industrialized countries such as the United States. The major reasons for this shift are a marked decline in the incidence and better early treatment of acute rheumatic fever and syphilis; the wide availability of invasive and noninvasive testing to detect valvular heart disease; the development and perfection of surgical techniques for the repair or replacement of diseased valves; the increased longevity of the general population, allowing even normal valves to be subjected to more years of wear and tear; and sociocultural changes in our society (e.g., intravenous drug abuse).

TABLE 87.1
The Most Common Causes of Valvular Heart Disease in Adults

Cause	Specific Disease	Valves Affected	Murmur
Congenital	Bicuspid value	A	S, R
Rheumatic	Rheumatic fever	M > A > T > P	S, R
Infectious	Endocarditis	A, M (rheumatic) A, M, T, P (i.v. drugs)	R
Myxomatous degeneration	Prolapse	M:T	R
	Aortic root dilatation	A	R
Degenerative aging	Sclerosis	A	S

A, aortic; M, mitral; P, pulmonic; T, tricuspid; S, stenotic; R, regurgitant; i.v., intravenous.

Regardless of the cause, significant acute or chronic valvular dysfunction has predictable hemodynamic consequences. Regurgitant lesions (e.g., mitral or aortic regurgitation) cause volume overload of the affected atrium or ventricle. Although massive acute regurgitation can lead to shock and pulmonary edema rapidly, mild-to-moderate volume overload is usually tolerated well until after months or years, when the ventricle will often dilate and fail, leading to signs and symptoms of heart failure. Stenotic lesions above, at, or below the valve can cause pressure overload of the affected atrium or ventricle. Pressure overload is metabolically more costly to the myocardium than volume overload and leads to myocardial hypertrophy and eventual heart failure.

The combined hemodynamic effect of multiple valvular lesions is often complex. Some compound lesions (e.g., combined aortic regurgitation and stenosis) impose a tremendous burden on the myocardium by producing both volume and pressure overload of a single chamber (in this example, the left ventricle). Other combination lesions may be “protective” of a given chamber (e.g., in aortic stenosis combined with mitral stenosis, the volume of blood reaching the left ventricle is decreased, thereby “protecting” it to some extent from manifesting heart failure). However, the net effect may be to decrease forward, and thus net, cardiac output.

Some valvular lesions produce a rapidly downhill course. For example, acute, severe mitral, or aortic regurgitation can lead rapidly to pulmonary edema, shock, or both, which can usually be remedied only by immediate valve replacement. Other lesions, such as chronic

mitral or aortic regurgitation, can be tolerated well for decades. A structurally abnormal valve puts the patient at increased risk of developing infective endocarditis, which can further impair valvular function. Other concomitant diseases (e.g., coronary atherosclerosis, myocarditis), dysrhythmias (e.g., atrial fibrillation), or valvular calcification can also unfavorably influence the patient's symptoms and length of survival.

CLINICAL PRESENTATION

Patients with valvular heart disease may present to the emergency department (ED) with a complication of previously known disease, or they may challenge the emergency physician to evaluate a previously undetected and undiagnosed heart murmur (1). If complex congenital heart diseases, such as Tetralogy of Fallot, are excluded, complications of adult valvular heart disease are most often the result of left heart lesions (Table 87.2).

TABLE 87.2
Common Complications of Left Heart Valvular Disease in Adults

Valvular Lesion	Common Complications(s)
Mitral stenosis	Pulmonary edema, atrial fibrillation, systemic embolism
Mitral regurgitation	Heart failure, endocarditis
Aortic stenosis	Angina, syncope, heart failure, dysrhythmias, sudden death, endocarditis
Aortic regurgitation	Heart failure, endocarditis

When a patient with a heart murmur presents to the ED with symptoms that could be caused by valvular heart disease, an immediate question is whether the heart murmur is *causing, unrelated to,* or *caused by* the symptom complex. For example, if a 70-year-old man with dyspnea and moderate pulmonary edema on chest X-ray has a grade 3/6 systolic ejection murmur at the left upper sternal border and cardiac apex, the murmur may be caused by aortic stenosis or mitral regurgitation, either of which could cause heart failure. The patient's heart failure could also be caused by an

unrelated problem, such as ischemic heart disease, cardiomyopathy, myocarditis, or a congenital shunt lesion (e.g., atrial septal defect). Finally, left ventricular (LV) failure and dilatation could be causing a "functional" murmur owing to dilatation of the mitral valve and its supporting structures (papillary muscle dysfunction).

Myocardial ischemia (e.g., during angina) can also increase the murmur of papillary muscle dysfunction. "Functional" tricuspid regurgitation can be caused by right ventricular dilatation secondary to left heart failure. In practice, it is sometimes impossible to determine the relationship between the murmur and the patient's symptoms without further diagnostic evaluation, such as echocardiography or cardiac catheterization.

Common conditions affecting the heart valves in adults presenting to the ED are (i) mitral valve prolapse (MVP); (ii) aortic valve sclerosis in the elderly, with or (more typically) without significant stenosis; (iii) valvular aortic stenosis resulting from congenital bicuspid aortic valve; (iv) mitral regurgitation caused by papillary muscle dysfunction, rheumatic heart disease, infectious endocarditis, or ruptured chordae tendineae; (v) aortic regurgitation caused by rheumatic fever, infectious endocarditis, bicuspid aortic valve, or aortic root disease; and (vi) mitral stenosis resulting from rheumatic fever.

ED EVALUATION

A careful cardiovascular physical examination, beginning with the pulse and blood pressure, often identifies the cause of a heart murmur (2). A wide pulse pressure accompanied by a brisk (often bifid) carotid upstroke and a bounding ("water-hammer") peripheral pulse is common in moderate-to-severe aortic regurgitation; a narrow pulse pressure with a slow, delayed carotid upstroke ("pulsus parvus et tardus") is found in severe aortic stenosis. When a harsh systolic murmur suggesting valvular aortic stenosis is accompanied by a brisk carotid upstroke (and *no* aortic regurgitation), idiopathic hypertrophic subaortic stenosis (IHSS) should be suspected. In a young person (especially male), hypertension in the upper extremities and a *lower* arterial pressure in the legs with a weak

femoral pulse and a basal systolic murmur suggests coarctation of the aorta (which is associated with congenital bicuspid aortic valve in 40% to 80% of cases).

All normal and abnormal heart sounds should be noted carefully. A loud first heart sound (S_1) at the apex and/or an opening snap after the second heart sound halfway between the left sternal border and the apex are clues to the presence of mitral stenosis with a mobile valve. Paradoxical splitting of the second heart sound (S_2) (i.e., widening of the split on *expiration*) is seen in moderate-to-severe aortic stenosis. A widely ("fixed") split S_2 that fails to close fully during normal expiration in the upright position suggests atrial septal defect.

A high-pitched, early systolic click that is heard best along the left sternal border and that is followed by a systolic murmur usually signifies valvular pulmonic or aortic stenosis with a pliable, noncalcified valve. Systolic clicks heard later than the carotid upstroke or multiple systolic ("machine gun") clicks suggest MVP.

A third heart sound (S_3) is often heard in healthy children, adolescents, and young adults without heart or valvular disease. When the heart rate is rapid, the third heart sound is usually termed an S_3 gallop. In a person with heart disease, it usually indicates LV failure. Chronic or acute mitral regurgitation is often accompanied by an S_3, but its presence in this condition does *not necessarily* indicate heart failure, because its presence may indicate only the torrential inflow of blood from the left atrium into the left ventricle in early diastole.

A fourth heart sound (S_4) is abnormal in a young person; it can occur with hypertension or aortic stenosis. A loud S_4 accompanying mitral regurgitation indicates that the lesion is acute and substantial, the sound being caused by the valiant attempt of the left atrium to cope with overwhelming volume overload. With time, the left atrium dilates and the S_4 disappears.

Both an S_3 and S_4 can occur simultaneously, causing a quadruple cadence. Patients with severe, particularly acute, heart failure can have a mild sinus tachycardia (typically in the range of 110 to 120

beats/min) that shortens diastole, allowing an S_3 and S_4 gallop to superimpose into a loud "summation" gallop. Always suspect a summation gallop when a loud triple cadence is heard in the presence of a mild tachycardia. A few seconds of gentle carotid sinus massage during auscultation will usually slow the heart rate slightly, allowing the superimposed S_3 and S_4 sounds to separate into a quadruple cadence, thereby confirming the presence of a summation gallop.

The timing of heart murmurs should be studied carefully and characterized as systolic, diastolic, or continuous (Table 87.3). Innocent murmurs are virtually *never* accompanied by a thrill. In an older individual, a harsh, musical, vibratory murmur with a thrill at the base is usually caused by valvular aortic stenosis. A similar murmur with the thrill at the apex can be heard with mitral regurgitation. A new-onset musical "cooing-dove" murmur at the apex is almost always caused by rupture of the mitral valve chordae tendineae owing to underlying MVP, Marfan syndrome, or trauma. It is interesting that, although MVP occurs slightly more often in young women than in men, most complications (infective endocarditis, mitral regurgitation, and ruptured chordae) although unusual occur disproportionately more often in men.

TABLE 87.3
Classification of Common Murmurs by Timing

Systolic Murmurs
Aortic stenosis (valvular, supravalvular, and subvalvular)
Mitral regurgitation, including MVP
Tricuspid regurgitation
Pulmonic stenosis
IHSS
Coarctation of the aorta
Ventricular septal defect
Atrial septal defect
Innocent systolic murmur

Diastolic Murmurs
Mitral stenosis
Tricuspid stenosis
Aortic regurgitation
Pulmonic regurgitation

Continuous Murmurs (Extending Through S_2 Without Relationship to Aortic or Pulmonic Valve Closure)
Patent ductus arteriosus
Mammary souffle
Ruptured sinus of Valsalva aneurysm

IHSS, idiopathic hypertrophic subaortic stenosis; MVP, mitral valve prolapse.

The response of murmurs to "provocative" maneuvers, spontaneously occurring extrasystoles, changes in body position, brief exercise, and pharmacologic intervention can help emergency physicians to differentiate among causative entities. Virtually all systolic murmurs—except that caused by IHSS—get softer or disappear during the strain phase of the Valsalva maneuver (Table 87.4). After the Valsalva strain is released, right-sided systolic heart murmurs (such as pulmonic stenosis and many innocent murmurs) usually return during the next 1 to 4 beats as blood rushes back into the right side of the heart. Left-sided systolic heart murmurs (mitral regurgitation, valvular aortic stenosis) are usually not heard well for 8 to 10 heartbeats, until the right heart and pulmonary circulation have refilled.

TABLE 87.4
Differentiation of Common Heart Murmurs in Adults

Valve Lesion	Timing	Pattern	Pitch	Location	Valsalva Strain	Other
AS	Systolic	CD	High	Base, neck	Decr	Slow carotid
IHSS	Systolic	CD	High	Base	Incr	Bifid carotid with rapid upstroke
AR	Diastolic	D	High	LSB	Decr	Water hammer pulse
MS	Diastolic	Rumble	Low	Apex	Decr	OS
MR, rheumatic	Systolic	CD or Pan	High	Apex, axilla	Decr	Increase
MR, MV prolapse	Systolic	CD or Pan	High	Apex, axilla	Decr	Systolic click(s)
PS	Systolic	CD	Med or high	Pulmonic area	Decr	May have systolic ejection click
PR	Diastolic	D	High	Base, LSB	Decr	Slight delay from S_2 to murmur
TS	Diastolic	Rumble	Low	LSB or RSB	Decr	Increase on inspiration
TR	Systolic	CD or Pan	High	LSB	Decr	Systolic pulsation of jugular pulse

A, aortic; M, mitral; T, tricuspid; P, pulmonic; V, valve; S, stenosis; R, regurgitation; Med, medium; C, crescendo; D, decreascendo; Pan, pansystolic; Decr, decrease; Incr, increase; LSB, left sternal border; RSB, right sternal border; OS, opening snap; IHSS, idiopathic hypertrophic subaortic stenosis.

The isometric handgrip (squeezing two of the examiner's fingers tightly for 30 to 60 seconds) increases the systemic vascular resistance and typically increases the intensity and duration of mitral or aortic regurgitation. If the patient has extrasystoles or an irregular rhythm, as in atrial fibrillation, the murmur of valvular aortic stenosis usually becomes much louder in the beat following a long pause because of increased LV stroke volume and flow across the valve. In contrast, the murmur of mitral insufficiency generally does not change in intensity with the change in cardiac cycle length.

Listening to murmurs with the patient in different body positions may also be helpful. For example, most innocent systolic murmurs decrease or disappear in the sitting or standing position. These murmurs are often soft and blowing in quality, are heard best along the left sternal border without radiation, and are unaccompanied by any other abnormal clinical findings or symptoms. The diastolic rumble of mitral stenosis is heard best in the left lateral decubitus position with the bell of the stethoscope placed lightly over the apex (see Table 87.4). The high-pitched, early diastolic decrescendo murmur of aortic insufficiency is heard best along the left sternal border with the patient leaning forward and holding a maximal expiration. This murmur is almost always louder to the left of the sternum when aortic regurgitation is caused by rheumatic heart disease or a bicuspid valve. If the murmur is louder to the right of the sternum, one should suspect that aortic regurgitation results from aortic root dilatation caused by aortic dissection, hypertension, syphilis, ruptured sinus of Valsalva aneurysm, or Marfan syndrome.

Percutaneous catheter balloon valvuloplasty (3–5) can be performed to palliate or treat pulmonary, mitral, and aortic valve stenosis. Following a successful procedure, it is common to have a persistent stenotic murmur or a new murmur owing to valve regurgitation. Complications of this procedure include valve regurgitation, inadequate opening of the stenosis, endocarditis, arrhythmias, embolization, or atrial septal defect (mitral valvuloplasty only).

Prosthetic Valves

Surgically implanted or percutaneously inserted prosthetic valves present special diagnostic problems in the ED. Echocardiography and fluoroscopy are useful tools for assessing prosthetic valve dysfunction (6). Patients with such devices are at risk for (i) endocarditis (which may present with fever, chills, or peripheral embolic complications, including stroke); (ii) embolization resulting fro m clot formation (which may present as a new stroke, transient ischemic attack, or occluded peripheral artery); and (iii) prosthetic valve dysfunction caused by dehiscence of suture lines, thrombosis of the valve, valve degeneration (porcine heterografts or human homografts), hemolysis, or structural failure (disc devices). Patients with prosthetic valve dysfunction may develop heart failure or fatigue gradually, or may present suddenly with syncope or pulmonary edema.

The sounds and murmurs that should be heard after valve replacement vary from device to device. Mechanical disc valves should produce clicking or metallic opening and/or closing sounds. Most implanted mechanical valves are relatively stenotic compared with native valves, so it is common and permissible to have a short systolic murmur with a prosthetic aortic valve or a short diastolic rumble with a prosthetic mitral valve. Short whiffs of aortic regurgitation, common after aortic valve replacement, are often caused by a small periprosthetic leak at the suture line. Prominent mitral regurgitant murmurs are usually not present following mitral valve replacement unless there is a mechanical problem with the valve.

Because severe mitral or aortic regurgitation resulting from prosthetic valve dysfunction occasionally produces no audible murmur, the development of heart failure or the appearance of other potential indicators of valve failure always warrants immediate investigation as to the valve's integrity, even in the absence of a murmur. Surgical thrombectomy and fibrinolysis are the two treatment options for prosthetic valve thrombosis, with recent clinical series showing better hemodynamic results and fewer complications with surgery (7,8).

KEY TESTING

- Careful physical examination
- CXR
- Electrocardiogram (ECG)
- Echocardiogram

ED MANAGEMENT

All patients with a previously undiagnosed heart murmur should, of course, receive a thorough cardiovascular physical assessment, as described previously. A high-quality posteroanterior and lateral chest X-ray and an ECG complement the physical examination. Specific chamber enlargement (e.g., LV dilatation owing to aortic or mitral regurgitation, or left atrial enlargement resulting from mitral stenosis, regurgitation, or both) or poststenotic dilatation of the aorta or pulmonary artery on X-ray, or chamber hypertrophy on ECG (LV hypertrophy in aortic stenosis, left atrial enlargement in mitral stenosis, right ventricular hypertrophy in pulmonic stenosis) can help to disclose the cause of a murmur. Cardiomegaly, pulmonary vascular congestion, pulmonary edema, or pleural effusions on chest X-ray can detect or confirm heart failure.

Two-dimensional (2D) echocardiography with Doppler is a sensitive and precise means of detecting and evaluating the severity of valvular lesions noninvasively. It is particularly helpful in the patient who presents to the ED with cardiogenic shock and/or acute heart failure/pulmonary edema (9–11). It should be performed in the

ED or ordered electively for any patient who is being referred to a cardiologist for follow-up evaluation of a murmur that is suspected to result from valvular disease. This technique can often detect vegetations or intracardiac thrombi in patients with suspected endocarditis or evidence of systemic embolization and can be used to evaluate prosthetic valve motion and function. If transthoracic echocardiography cannot provide sufficient resolution to adequately define the anatomy, transesophageal echocardiography can be performed. The latter technique can produce spectacular images of the heart and great vessels.

Specific complications of valvular heart disease, such as heart failure, cardiogenic shock, embolization, or dysrhythmias, should be managed in the normal fashion. Severe heart failure, hypotension, and shock resulting from massive acute aortic or mitral regurgitation may be refractory to medical therapy. In such cases, it is often preferable to use dobutamine or low-to-medium doses (5 to 15 μg/kg/minute) of dopamine, or both, rather than potent alpha vasoconstrictors (e.g., high-dose dopamine or norepinephrine), because increases in afterload will only worsen valvular regurgitation. Intra-aortic balloon counterpulsation or other LV mechanical assist devices may be required for stabilization prior to cardiac catheterization or surgery.

Consensus guidelines for antibiotic prophylaxis against infective endocarditis in patients with valvular heart disease and/or prosthetic valves have changed dramatically in the last decade (12,13) (see Chapter 88, “Infective Endocarditis for specific recommendations”). Consultation with a cardiologist may be warranted for patients with significant valvular heart disease.

CRITICAL INTERVENTIONS

- Investigate for prosthetic valve dysfunction when heart failure develops even in the absence of a murmur because severe mitral or aortic regurgitation due to prosthetic valve dysfunction occasionally produces no audible murmur.
- In patients with significant valvular disease or prosthetic valves if they are undergoing a procedure that might result in bacteremia,

discuss with a cardiologist whether antibiotic prophylaxis against infective endocarditis is indicated.
- Listen to murmurs with the patient in different body positions to detect and distinguish the etiology of murmurs.

DISPOSITION

Indications for ED consultation with a cardiologist include (i) known or suspected valvular lesions that are accompanied by hemodynamic instability (heart failure or shock), fever, dysrhythmia, or embolization; and (ii) new onset or progression of these symptoms; (iii) significant hemolysis following valve surgery or valvuloplasty; and (iv) consideration of antibiotic prophylaxis for infectious endocarditis. Admission to the intensive care unit is usually indicated for significant dysrhythmia (particularly in new-onset cases or those causing hemodynamic compromise), pulmonary edema, hypotension, or when there are other concomitant life-threatening medical problems. Immediate cardiac catheterization and surgical intervention are indicated for new-onset severe valvular regurgitation, prosthetic valve malfunction, systemic embolization in the face of adequate anticoagulation, valve ring abscess, intractable heart failure, or shock.

If transfer to another facility is required, an emergency physician should consult by telephone with the receiving cardiologist to discuss the initial treatment and stabilization and the appropriate means of transportation. If available, an advanced cardiac life-support team with monitoring and resuscitation equipment should always accompany the patient. Air transport by helicopter or pressurized fixed-wing aircraft may be indicated if the patient is in need of urgent cardiac catheterization and operative intervention.

Most asymptomatic patients in whom a previously undetected heart murmur is found incidentally should be referred electively to a cardiologist for further evaluation. Pregnant patients with newly detected murmurs or abnormal heart sounds should also be referred for further cardiac evaluation if there is any question of the finding not being physiologic during pregnancy or if there is the slightest possibility that the patient may have structural heart disease.

Common Pitfalls

- Underestimating the severity of valvular disease during periods of severe heart failure, shock, or tachycardia, since decreased cardiac output results in decreased intensity of heart murmurs.
- Overestimating the value of physical findings in the elderly patient with valvular heart disease. The presence of concomitant atherosclerosis with rigid vessels may either mask or amplify pulse or blood pressure changes resulting from valvular disease. In addition, the location and radiation of murmurs are notoriously unreliable diagnostic indicators in older patients.
- Mistaking a normal heart sound or an innocent murmur in a young person for the presence of structural heart disease. Children or young adults may have a cervical venous hum, heard best in the upright position, at the base of the neck, and occasionally in the upper chest. The murmur is continuous, extending throughout the second heart sound, and can mimic a patent ductus arteriosus murmur. It can be correctly diagnosed by showing that it can be eliminated by having the patient lie down, by applying pressure at the base of the neck with the stethoscope while listening, and by turning the patient's head away from the examiner.
- The evaluation of murmurs is challenging during pregnancy (14). Murmurs may come and go as the cardiac output, blood volume, and vascular resistance change during the course of the pregnancy and in the postpartum period. A continuous, innocent "mammary souffle" murmur can often be heard along the right or left chest during late pregnancy or during lactation following delivery; it is caused by the increased flow of blood through the mammary arteries owing to hypertrophied breast tissue. It can often be eliminated by direct chest wall pressure or with changes in body position.
- Overlooking the fact that physical examination is often unreliable in detecting heart failure. For example, almost 60% of chronic heart failure patients with an elevated pulmonary capillary wedge pressure will not have jugular venous distension, rales, or

peripheral edema on physical examination. In such cases, a chest X-ray or brain natriuretic peptide level may be helpful.

- Failure to consider the possibility of infectious endocarditis in patients with known or suspected valve disease who present with suspicious signs or symptoms (e.g., unexplained fever, anemia, heart failure, hypotension, or signs of systemic embolization). When in doubt, consider infectious endocarditis to be present until proven otherwise.

CHAPTER 88

Infective Endocarditis

Benjamin S. Heavrin, Ian D. Jones, and Corey M. Slovis

Infective endocarditis (IE) is an infection of the endothelial lining of the heart usually involving the heart valves. The first reported autopsy evidence of the disease dates to 1647. In 1885, Sir William Osler further reported on the autopsy and clinical findings of the disease in a series of classic papers published in the *British Medical Journal.*

Traditionally, IE has been divided into two forms: (i) a relatively insidious, chronic disease, subacute bacterial endocarditis (SBE), and (ii) a more abrupt-onset, fulminant form, acute bacterial endocarditis (ABE).

Although there is broad geographic variation in cases of IE, the overall incidence and mortality of IE had remained unchanged for the last 30 years (1). Despite the unchanged number of overall cases of IE, the proportion of cases involving increasing patient age, prosthetic valve infection, and nosocomial infection is increasing (2–4). As the incidence of these cases has increased, the incidence of IE from rheumatic heart disease has decreased and is now relatively uncommon (5). Additionally, the incidence of endocarditis due to *Staphylococcus aureus,* once primarily associated with intravenous (IV) drug abuse, is now the leading cause of IE in many parts of the world (6).

The incidence of IE is highly variable depending on predisposing anatomic risk factors, including prosthetic valves, anatomic valve abnormalities, degenerative valvular disease, and the presence of mechanical intracardiac devices such as pacemakers and implanted defibrillators (4). An increase in risk is also seen in patients with

prolonged exposure to indwelling IV catheters, hemodialysis patients, and intravenous drug users (IVDUs) (Table 88.1). Reviews of multiple studies have shown that IE remains uncommon in patients with healthy valves and no identifiable risk factors. Despite considerable advances in detection and therapy, IE remains a challenge to diagnose, and mortality continues to be high.

TABLE 88.1
Emergency Department Patients at Highest Risk for Endocarditis

Patients with valvular or structural heart disease
Intravenous drug users
Patients with prosthetic heart valves
Patients with repetitive indwelling catheters devices, especially hemodialysis shunts
Elderly patients who have recently undergone an invasive procedure
Patients with implantable cardiac devices including pacemakers and implantable defibrillators

The organisms most commonly causing IE have also changed. As IE has evolved, the frequency of *Streptococcus viridans* as a causative agent has decreased, whereas the incidence of *Staphylococcus* species has risen. *S. aureus* is now the most common cause of all types of IE and the incidence of methicillin-resistant *S. aureus* (MRSA) in these isolates has risen dramatically (3,6,7). *S. aureus* endocarditis also confers a higher risk of embolism, neurologic involvement, persistent bacteremia, and overall mortality than does infection caused by other organisms (6,7). In addition to the changing spectrum of infection, methods for elucidating the causative organism in endocarditis have been improved, including better culture techniques, serologic testing, and the use of polymerase chain reaction (PCR).

There are four steps in the development of SBE: (i) a hemodynamically defective valve produces turbulent blood flow and endothelial disruption; (ii) a sterile platelet–fibrin thrombus forms on the damaged valve lining; (iii) transient bacteremia infects the

thrombus; and (iv) high titers of antibodies to the infecting organism are produced. Furthermore, the infecting organism must have the capability to adhere to injured endothelium. Bacterial endocarditis may also develop on previously normal native and prosthetic heart valves. In these cases, the only necessary measure is an inoculum of a highly invasive organism.

Once endocarditis develops on a valve, the clinical manifestations are attributable to the following series of events: (i) local destruction and malfunction of the cardiac valve; (ii) invasive infection of contiguous structures of the heart; (iii) continuous bacteremia, leading to distant infections; (iv) embolization of vegetations that break off from the valve; and (v) an antigen–antibody response, leading to immune-mediated complications.

CLINICAL SUBGROUPS

IE is often classified into one of four distinct patient-centered clinical groups: (i) patients with a damaged native valve; (ii) patients with prosthetic valves (further classified as either early or late infection); (iii) IVDUs; and (iv) patients with nosocomial IE (3). A fifth category has also recently been described: health care-related endocarditis related to implantable intracardiac devices, invasive procedures, and chronic hemodialysis (8). IE in hemodialysis patients is becoming increasingly more common. It has been reported that patients on hemodialysis make up 30% of all cases of hospital-acquired IE and have a 50 to 60 times higher incidence of IE than the rate in the general population (9).

DAMAGED NATIVE VALVE

Any condition causing an alteration in the normal structure of the cardiac valves (e.g., rheumatic, degenerative, and congenital cardiac abnormalities) can predispose a patient to IE. Patients with native-valve IE are most likely to develop a syndrome similar to the classic SBE, a relatively chronic infection with only left-sided cardiac involvement, often with a streptococcal organism. The mitral valve is the most common valve to be infected in the native-valve group.

Isolated mitral involvement occurs in 35% to 45% of cases, isolated aortic valve involvement in 15% to 35%, and involvement of both valves in 15% to 30% (10). Mitral valve prolapse by itself is not a risk factor for IE unless accompanied by regurgitation (3). Tricuspid valve and pulmonic involvement is relatively rare in native-valve IE.

Staphylococcus species have now surpassed *Streptococcus* species as the most common organism causing native-valve IE, being responsible for 44% of native-valve IE, whereas *Streptococcus* and *Enterococcus* species account for 31% and 10% of cases, respectively (3). *S. aureus* and coagulase-negative *Staphylococcus* are probably introduced via the skin and are most likely to cause infection in patients on hemodialysis and those who have diabetes, implantable cardiac devices, chronic illness, and the elderly or otherwise debilitated (6,7). *S. aureus* is now the predominant pathogen in all types of IE (3,6). There has also been a significant rise in the percentage of these cases caused by MRSA. Though overall mortality is not statistically different, there is evidence that MRSA endocarditis may actually confer a lower risk for embolism but a higher risk for persistent bacteremia (6).

S. viridans is by far the most common *Streptococcus* species causing IE. *S. viridans* bacteremia and subsequent valvular seeding traditionally have been attributed to bacterial seeding during dental procedures in patients with pre-existing valvular or structural heart disease. This presumed cause-and-effect relationship has been increasingly questioned and, to date, there is no compelling evidence that dental procedures are the cause of a significant number of cases of IE. Additional organisms causing native-valve IE include *Streptococci bovis* and *Enterococcus faecalis* (3). These infections are more commonly introduced by bowel and urologic infections or procedures, especially in the elderly. Gram-negative organisms, fungi, polymicrobial infections, and diphtheroids are seldom contributors to native-valve IE (3,7).

INTRAVENOUS DRUG USERS

IVDUs are one of the leading groups at high risk for developing IE. Between 5% and 8% of hospital admissions in IVDUs are due to endocarditis (11). Because IV cocaine users inject themselves so frequently relative to other IVDU groups, they appear to have the highest risk of developing IE. Their increased relative risk may also be a result of factors such as lack of heating the drug before injection, needle sharing, immunosuppression from the drug, or direct valvular damage caused by cocaine (12). There are conflicting data in the literature regarding the predominance of right-sided versus left-sided endocarditis in IVDUs. Although left-sided endocarditis is seen in all patient populations, right-sided endocarditis is rarely seen outside of the IVDU population. Thirty-two percent of IE caused by IVDU involves the mitral valve, 19% the aortic valve, and almost all of the remaining cases involve the tricuspid valve (11). In right-sided endocarditis, pulmonic valve involvement is rare and is seen in $<1\%$ of patients (11).

Patients who inject illicit drugs often are infected with organisms that are normal skin flora. *S. aureus* is the most common causative agent in this group of patients, accounting for approximately 69% to 80% of cases *Streptococcus* species are the next most common. Interestingly, coagulase-negative staphylococci are rarely isolated from this patient population (3,11). Fungal infection and large (>2 cm) valve vegetations both portend a significantly worse prognosis in this patient population and may make these patients candidates for early surgery.

PROSTHETIC VALVE INFECTIVE ENDOCARDITIS

As the number of prosthetic valve surgeries increases, the number of cases of prosthetic valve infective endocarditis (PVIE) continues to rise. Once making up only 1% to 5% of the total number of cases of IE, PVIE now accounts for 20% of all cases of IE (13). Individuals with PVIE tend to be significantly older, have a lower likelihood of using injectable drugs, and have a higher likelihood of health care–associated infection and a higher mortality than patients with native valve infective endocarditis (13).

Early-Onset Prosthetic Valve Infective Endocarditis

Patients with early-onset PVIE either are contaminated intraoperatively or develop infection in the perioperative period, which is defined as 60 days after surgery (13,14). The rate of infection is highest in the first 3 months after surgery and diminishes to between 0.3% to 0.6% per year thereafter (14). Early prosthetic valve infections are predominantly nosocomial in etiology. The most common pathogens encountered in the first 2 months after surgery are *Staphylococcus* species (*S. aureus,* 36%, and coagulase-negative staphylococci, 15%) (13). *S. aureus* is now the most frequent organism associated with early-onset PVE with more than 50% of these isolates being methicillin-resistant (13). Though the overall number of cases of early-onset PVIE seems to be falling in comparison to late-onset PVIE, mortality remains very high, with cases due to *S. aureus* conferring a significantly higher mortality than infection from other organisms (13). Other organisms encountered less frequently include *S. viridans, Enterococcus* species, gram-negative organisms, and fungi.

Late-Onset Prosthetic Valve Infective Endocarditis

The predominant organisms responsible for late-onset PVIE continue to be *Staphylococcus* species. Coagulase-negative staphylococci (20%) and *S. aureus* (18%) were the predominant causative organisms in a recent large-scale observational study (13). In this same population, MRSA made up $<$20% of the staphylococcal isolates whereas *Enterococcus* species (12%), *Viridans streptococci* (10%), and *S. bovis* (7%) also caused a significant number of infections.

Mechanical valves and tissue valves have an approximately equal incidence of infection (overall incidence, 2.2% to 4.4%), but mechanical valves are more likely to develop early-onset PVIE. Mechanical valves tend to develop perivalvular abscesses, myocardial abscesses with conduction delays, pericarditis, and regurgitation caused by perivalvular leaks. An acute regurgitant murmur caused by partial dehiscence of the valve is a surgical

emergency because severe heart failure can develop rapidly or the valve can undergo total dehiscence. Tissue valves, however, are more likely to develop leaflet tears, also resulting in new regurgitant murmurs and heart failure. Valvular stenosis is also a potential complication with tissue valves.

CLINICAL PRESENTATION

Patients with IE may present acutely with fulminant heart failure and sepsis; with a chronic, indolent, nonspecific disease process; or with a syndrome intermediate between the two extremes. Because of the overlap, the artificial separation of ABE and SBE is usually not clinically helpful. Table 88.2 lists the historical and physical findings seen most often in IE.

TABLE 88.2
Historical and Physical Findings Suggestive of Endocarditis

	History	Physical Examination
General	Fever, chills, malaise, weakness, anorexia, weight loss, back pain, myalgia, arthralgia	Acute or chronically ill appearance, fever, diaphoresis pallor, splenomegaly, arthritis
Cardiopulmonary	Chest pain, dyspnea, edema	Murmurs, especially valvular insufficiency; signs of congestive heart failure
Neurologic	Headache, stiff neck, mental status changes, focal neurologic complaints, extremity pain or paresthesia	Meningismus, abnormal mental status, focal deficits
Other	Hematuria, abdominal pain	Skin: petechiae, Osler nodes, Janeway lesions, splinter hemorrhages
Risk factors	Intravenous drug abuse; heart disease; recent gastrointestinal, genitourinary, or dental procedure; poor dental hygiene	Embolic: mycotic aneurysm, visceral or extremity infarct, or ischemia Other: pneumonia, skin abscess, urinary tract infection

Complications

Cardiac

Cardiac complications of IE may involve any of the three layers of the heart. Endocardial damage of the valve may result in valvular destruction and variable degrees of congestive heart failure (CHF). CHF is the most common cause of death in patients with IE (15). Severe failure is usually a result of acute aortic insufficiency and, if not promptly amenable to medical intervention, is an indication for emergent valve replacement surgery (15). Myocarditis or perivalvular abscess results when the infecting organism invades the contiguous myocardium.

Electrocardiographic (ECG) abnormalities in cases of IE are much more likely to be seen with perivalvular spread of infection and confer a significant increase in mortality (16). The majority of ECG abnormalities are conduction abnormalities. The infection involving the conduction system results in conduction delays, bundle-branch block, or complete heart block. Mortality is significantly higher if there is a presence of infranodal block (15). Intracranial catastrophes may occur if thrombolytics are used in cases in which complications of IE cause ECG changes that mimic those of acute ischemia resulting from coronary artery disease.

Additional complications include aortocardiac fistula, perforated valves, or perforation of the myocardium (15). A perforated myocardial abscess may result in a purulent pericarditis. Large emboli to the coronary arteries can cause acute myocardial infarction or sudden death (17).

Central Nervous System

Central nervous system complications occur not only in 20% to 40% of patients with IE but may be the presenting complaints in a significant number of cases (7). Mortality is significantly higher in patients with IE and neurologic manifestations. Embolic cerebral infarction or stroke is the most common event and usually involves the middle cerebral artery or its branches (18). Intracerebral hemorrhage, isolated seizures, and transient ischemic attacks are also reported complications (18). Cerebral mycotic aneurysms

resulting from septic emboli eroding the vessel wall may remain asymptomatic or may enlarge, leak, or rupture and present as subarachnoid hemorrhage, cerebral abscess, or classic bacterial meningitis (19). A syndrome consisting of lethargy, delirium, hallucinations, and psychosis (i.e., toxic encephalopathy) may occur (17). When these findings are accompanied by a stiff neck and cerebrospinal fluid consistent with aseptic meningitis, the patient has meningoencephalitis. The cause is not clear, but multiple microinfarcts or microabscesses may be responsible. The likelihood of an embolic event decreases markedly after the initiation of antibiotics (18).

Emboli and Immunologic Responses

Peripheral embolization can occur anywhere in the body and is seen in up to one-third of patients with IE (19). In addition to the brain (50% of all events) and heart, other important areas of embolization are the splenic, renal, mesenteric, and extremity vasculature. The emboli result in endarteritis, mycotic aneurysm, local abscess formation, and distal infarction. Studies have shown that patients with large valve vegetations have a worse prognosis most likely because of a higher likelihood of embolic sequelae (17). It is not clear how many of the signs and complications of IE are immune complex–mediated, although it is thought that glomerulonephritis, aseptic arthritis, and most of the classic skin manifestations are immune-related. Prosthetic joint infections and vertebral osteomyelitis may, if seen, be likely a result of bacteremia during the acute phase of the infection (15).

ED EVALUATION

A definitive diagnosis of endocarditis relies on a combination of histologic, microbiologic, clinical, and echocardiographic findings. The Duke criteria, first proposed in 1994, have been well validated, and the modified Duke Criteria remain the gold standard for diagnosing IE. Because culture data are unavailable and most emergency departments (EDs) have limited access to

transesophageal echocardiography (TEE), a definitive diagnosis of IE is often impossible to obtain at the time of initial presentation. Therefore, the Duke criteria are of limited use in ED patients, and the clinician must rely on history, physical findings, and other rapidly available tests that will support a presumptive diagnosis of IE and the initiation of additional directed diagnostic testing and empiric antibiotic therapy.

Patients with IE often have numerous vague and nonspecific complaints. The classic patient presenting with persistent fever of unknown origin represents only a fraction of endocarditis cases (15). Most patients have nonspecific extracardiac complaints including fever, malaise, anorexia, and weakness. Approximately one-half of patients report headache, weight loss, night sweats, arthralgias, and myalgias (7). A history of back pain, rash, or dyspnea or a spectrum of neuropsychiatric symptoms is not uncommon in IE (7). Clinicians, however, seldom initially attribute these less-common symptoms to IE. Physicians should also be aware of patients at higher risk for IE such as patients with diabetes, immunocompromised patients, valvular cardiac disease patients, IVDUs, patients with indwelling cardiac devices (pacemakers and implanted defibrillators), and patients receiving chronic hemodialysis (1,3,7,9). Patients should be asked about recent dental, gastrointestinal, and urologic procedures. Elderly patients, in particular, may not volunteer or may forget to relate these high-risk procedures. Young patients who are being evaluated “for the flu” or other febrile illnesses seldom provide information about IV drug use unless specifically questioned.

Physical findings suggestive of endocarditis are listed in Table 88.2. Patients with IE may appear acutely or chronically ill. Nearly all nonimmunocompromised patients have fever. The presence of unexplained fever for more than 1 week should raise the clinician’s suspicion for endocarditis (17). Other abnormal vital signs, especially tachycardia, are relatively common. It is important for the clinician to be vigilant because many of the symptoms of endocarditis are nonspecific and many of the classic findings of endocarditis are not commonly seen.

A careful cardiac examination is critical in patients suspected of having IE. The majority of patients with IE will have a murmur and many of these will be pre-existing (7). Patients most likely to lack murmurs are those with acute IE. Therefore, lack of a murmur in an IVDU should never decrease the suspicion for IE. On the other hand, a new aortic or mitral regurgitant murmur in a febrile patient is very strong evidence for the disease (17). The cardiac examination should also seek any findings suggestive of heart failure. Findings of new-onset heart failure, especially in younger patients without a history of cardiac disease, should prompt a high index of suspicion for endocarditis. Rarely, a large (usually fungal) vegetation may block the outflow tract, resulting in a new stenotic murmur.

A variety of skin lesions are considered classic for IE, but these are relatively uncommon. Petechial lesions may be found in different locations. Splinter hemorrhages are tiny red, purple, brown, or black splinter-like lesions that appear under the fingernails. They are seen in up to 20% of patients with IE, but they are also found in approximately 8% of all hospitalized patients. Osler nodes are small, painful, tender erythematous nodules that are most commonly seen in the distal finger pads; they occur in 5% to 20% of patients. Janeway lesions are small, flat, nontender red spots on the palms and soles; they occur in only about 10% of patients with IE. Conjunctival petechiae may occur in approximately 10% of patients. Roth spots are retinal petechial hemorrhages with central pallor, which may be seen in 10% to 25% of patients with IE. The remainder of the physical examination may reveal abnormal abdominal or neurologic findings. Splenomegaly is a common finding, and a tender, enlarged liver is often noted. The presence of a splenic abscess should raise a high suspicion for IE (19). Neurologic examination may reveal signs consistent with meningitis, encephalitis, embolic stroke, or a leaking aneurysm. Some patients present with subtle mental status changes or behavioral symptoms that appear to be psychiatric in nature (17).

There are numerous nonspecific laboratory findings in IE (Table 88.3). Normochromic, normocytic anemia occurs in up to 75% of patients and microscopic hematuria occurs in nearly 50%.

Leukocytosis is seen in about 50% of cases and, thus, its absence should not be used to rule out the diagnosis. Studies differ in regard to the value of the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in patients ultimately diagnosed with IE. Both tests lack specificity and neither test has perfect sensitivity to rule-out a diagnosis of IE.

TABLE 88.3
Laboratory and Diagnostic Findings in Endocarditis

Blood	**Echocardiogram**
Positive blood cultures	Vegetations
Anemia	Valve dysfunction
Microscopic or gross hematuria	Perivalvular abscess
Leukocytosis	Aortic Root aneurysm
Uremia	Chamber enlargement
Elevated ESR or CRP	Pericardial effusion
Chest Radiograph	**V/Q Scan**
Cardiomegaly	Multiple pulmonary infarcts
Congestive heart failure	**Cerebrospinal Fluid**
Pulmonary infiltrates	Purulent meningitis
Pulmonary infarcts	Aseptic meningitis
Pulmonary effusions	Bloody leaking aneurysm
Chamber enlargement	**Computed Tomography**
Abnormal movement of prosthetic valve	Lung abscess
Stimson sign	Cerebral abscess
Electrocardiogram	Splenic Abscess
Conduction defect	Subarachnoid hemorrhage
Acute myocardial infarction	Pulmonary Emboli
Pericarditis	Mycotic aneurysm

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; V/Q, ventilation/perfusion.

The most important part of the laboratory evaluation is the blood culture, as precise identification of the organism is critical in tailoring appropriate antibiotic therapy. Approximately 20 mL of blood (not 5 to 10 mL) should be drawn for each set of blood cultures and sent for aerobic and anaerobic cultures. The diagnosis

of possible endocarditis should appear on the specimen label so that the laboratory will hold the specimen for at least 3 weeks to ensure detection of slow-growing organisms. Whenever possible, a minimum of three blood cultures should be performed from three separate sites and should be drawn over a period of approximately 1 hour.

Blood cultures may be positive in the majority of patients with IE. Even in cases wherein the blood cultures are negative, other tests can be obtained that may aid in a definitive diagnosis. If the cultures are sterile in cases of proven endocarditis, *Coxiella, Bartonella,* and *Chlamydia* species may be identified by the use of serology, immunohistochemical staining, and PCR (7). To maximize the chances of a positive culture and to minimize the confusion caused by contaminant, multiple cultures are recommended as described above in the IE work-up. Recent antibiotic use by the patient and infection with fastidious or slow-growing organisms are the two major reasons for negative cultures in the context of IE. The patients who most commonly have negative cultures are drug users, patients with prosthetic valves, and those who have recently received antibiotics.

Although usually normal, the ECG should always be carefully examined for evidence of pericarditis, ischemia, infarction, conduction delay, or any degree of heart block. These changes may be indirect evidence for the coexistence of myocarditis, myocardial abscess, pericarditis, or coronary artery embolism (16).

The chest radiograph of patients with IE is usually normal. Signs of CHF, including cardiomegaly, isolated chamber enlargement, and abnormal vascular patterns, provide valuable information regarding abnormal valvular or cardiac function. The chest radiograph may also reveal pneumonia, especially in patients who are IVDUs. Multiple pulmonary infarcts or nodular infiltrates suggest right-sided disease, usually tricuspid valve endocarditis. In PVIE, a double shadow of a mechanical valve, known as Stimson sign, indicates movement of a valve that has undergone partial dehiscence.

Echocardiograms are almost always performed in patients who are suspected of having IE. The finding of vegetation is a very strong

evidence for the diagnosis of IE. However, a negative echocardiogram should never be used as the definitive test to rule out IE, as up to one-third of patients with IE have nondiagnostic echocardiograms (20). Although it is probably more appropriate to begin with transthoracic echocardiography (TTE), TEE should be performed in all patients in whom there is strong suspicion for IE (20). The greater value of TEE lies in its ability to provide greater spatial resolution of cardiac anatomy and the fact that by placing the probe in the esophagus, limitations from overlying structures and chest wall structures are eliminated (20). Various studies have shown sensitivities for TTE in diagnosing IE at between 18% and 63%. This compares to 48% to 100% sensitivity for TEE in diagnosing IE. Furthermore, TEE is far more sensitive in diagnosing accompanying pathology such as perivalvular abscess. Because of their anterior location, aortic root abscesses may be better visualized with TTE (20). Echocardiographic detection of valve malfunction, chamber enlargement, or an associated pericardial effusion may also be helpful in the clinical management of IE. Mechanical valves are too echo-dense for TTE to be of significant value, and valvular function should instead be evaluated by either TEE or cinefluoroscopy (20,21).

KEY TESTING

- Obtain at least three sets of high-volume blood cultures from separate sites over a period of 1 hour in stable patients suspected of having endocarditis.
- Obtain a transthoracic echocardiogram (TTE) to evaluate for vegetations and valvular insufficiency, followed by a TEE in conjunction with cardiology consultation based on the TTE results.
- Obtain an ECG and chest X-ray to evaluate for conduction disease and signs of heart failure or secondary infectious processes such as pneumonia.
- Laboratory studies such as ESR, CRP, and white count may influence the probability of a diagnosis but are never sufficient

to rule-in or rule-out a diagnosis of IE.

ED MANAGEMENT

Definitive therapy for IE is guided by the infecting organism's sensitivity to specific antimicrobial agents. If a stable patient presents to the ED with the possibility of IE, it is best to obtain at least three sets of blood cultures from three separate sites over a period of 1 hour. Administration of antibiotics reduces the positive blood culture rate by as much as 40% (21). The patient should be admitted to an inpatient area, and subsequent care and additional culturing should be provided at the direction of the patient's physician or infectious diseases consultant. Antibiotics should, however, be started in the ED if the patient appears septic, is elderly, is debilitated, is immunocompromised, has concomitant pneumonia, is in heart failure, or is hemodynamically unstable. Once blood culture and sensitivity data are available, optimal therapy should follow the most recent AHA guidelines (21). The choice of optimal empiric therapy for presumed IE in a specific patient type is guided by the most commonly suspected organism and the organism's antibiotic sensitivities.

Empiric Antibiotic Coverage

There is no universal agreement on optimal empiric antibiotic therapy. However, ED physicians can begin therapy by choosing an antibiotic regimen that provides broad-spectrum bactericidal coverage for the most common organisms causing IE. The authors' specific recommendations for empiric therapy for use in the ED appear in Table 88.4.

TABLE 88.4
Empiric Emergency Department Therapy for Presumed Endocarditis Prior to Culture Results

Patients with Native Valves (Including Intravenous Drug Users)		Patients with Prosthetic Valves	
Nafcillin[a]	2 g IV q4h	Rifampin	300 mg PO q8h
and		and	
Gentamicin[b]	3 mg/kg IV q24h	Gentamicin[b]	3 mg/kg IV q24h
and		and	
Vancomycin	1 g IV q12h (or 30 mg/kg per 24 hrs in equally divided doses)	Vancomycin	1 g IV q12h (or 30 mg/kg per 24 hrs in equally divided doses)

[a]Consider ceftriaxone 2 g IV in penicillin-allergic patients.
[b]Use q8h dosing and not single daily dosing in infective endocarditis.

The recommendations attempt to provide broad coverage divided into two regimens: one for presumed IE in a seriously ill patient with native valves and a second for presumed IE in a patient with one or more prosthetic valves. The regimens are designed to be easily remembered and do not address whether the patient may have developed IE in association with IV drug abuse or how long ago the prosthetic valve was implanted. In addition, with the increasing frequency of all types of IE from *S. aureus* and the increasing frequency of MRSA, empiric therapy must cover MRSA until culture data prove otherwise. Consequently, patients with the possibility of IE should receive nafcillin, gentamicin, and vancomycin. Patients with prosthetic valves who require that therapy be initiated on an emergent basis should receive rifampin, gentamicin, and vancomycin. The regimen should be adjusted after the patient is admitted to the hospital, on the basis of inpatient physician preference and culture and sensitivity data. Consultation with an infectious disease physician should be accomplished at the earliest possible time.

Antibiotics Based on Known Organism

The rapid changes in the epidemiology and antibiotic susceptibilities in all of the major bacterial organisms causing IE make specific recommendations for precise therapy beyond the scope of this

chapter. The most recent AHA guidelines give precise details on appropriate antibiotic therapy once organism and antibiotic susceptibilities are known (21). The clinician should be aware of these guidelines as well as the possibilities that empiric therapy will need to be altered, as increasing cases of high level resistance to vancomycin are being reported in both *S. aureus* and enterococci (21).

Anticoagulants

Anticoagulation is contraindicated in patients with native-valve IE because of the greatly increased risk of intracranial bleeding that occurs in patients with IE who have cerebral emboli. Anticoagulants confer no protection against cerebral or peripheral embolization in native-valve IE, although many experts recommend their continued use. The exception is the patient who develops massive life-threatening pulmonary emboli. Patients with PVIE who are already maintained on anticoagulation should probably continue the medication and be closely monitored for complications related to the prosthetic valve unless there has been a recent central nervous system embolic event (21).

Surgery

Valve replacement has become much more widely accepted as a therapy for complicated IE (22). Surgery is required in 25% to 50% of all cases of acute endocarditis (23). Although there is agreement on the indications for surgery, the timing and specific details are being debated. The following are general indications for valve replacement: heart failure as a result of new valve malfunction, acute valvular insufficiency, major embolic complications, continued bacteremia despite administration of appropriate antibiotics, dysrhythmia or new conduction defect, or a fungal cause (2,21–23). Indications for emergent surgical intervention include acute aortic regurgitation with early closure of the mitral valve, rupture of the pericardium, and rupture of a sinus of Valsalva aneurysm into the right heart chamber (16,23). Furthermore,

certain infections such as those caused by *Brucella* species, *Coxiella burnetii, Pseudomonas aeruginosa, Staphylococcus lugdunensis,* and Candida species are difficult to manage medically and are best managed by surgery (7).

Traditionally, surgical management has been considered superior to medical management alone with regard to the treatment of PVIE. This continues to be true in the case of patients with hemodynamic instability, heart failure, or perivalvular abscess. Persistent infection, advanced age, and the development of renal failure are associated with an increased postsurgical mortality (21,22). There is emerging evidence that in a subset of stable patients medical management with antibiotics alone may suffice (21). It is not clear to what extent the size of the vegetations seen on the echocardiogram determines the prognosis and need for valve replacement.

CRITICAL INTERVENTIONS

- Obtain at least three sets of high-volume blood cultures from separate sites over a period of 1 hour in stable patients suspected of having endocarditis.
- Initiate antibiotics if the patient appears septic, is elderly, is debilitated, is immunocompromised, has concomitant pneumonia, is in heart failure, or is unstable.
- Administer prophylactic antibiotics to at-risk patients undergoing dental procedures, upper-respiratory tract procedures, or procedures involving infected skin or musculoskeletal tissue.

DISPOSITION

Because of the frequency of serious complications and the need for parenteral antibiotic therapy, all patients who are strongly suspected of having IE should be admitted to the hospital. Patients with overwhelming sepsis, serious embolic complications, or any degree of heart failure or conduction block require admission to an intensive care setting. In addition, intensive care unit admission is mandatory for PVIE patients with any evidence of perivalvular leak.

Blood cultures (20 mL of blood for each set) should be obtained in patients suspected of having IE but in whom the diagnosis is thought to be unlikely. Outpatient follow-up for these patients is appropriate if the patient is reliable and can be readily contacted and if the patient's private physician agrees.

When IE is strongly suspected, a cardiologist should be consulted for possible echocardiographic examination. TEE must be done as soon as possible in any patient with a prosthetic valve in whom the possibility of IE is considered. Patients with PVIE or those who may need valve replacement should have a cardiac surgeon involved early to ensure that the timing of surgery is optimal. For patients with possible brain abscess or aneurysm, appropriate imaging studies should be performed, and a neurosurgeon should be consulted promptly.

ANTIBIOTIC PROPHYLAXIS AGAINST INFECTIVE ENDOCARDITIS

The aim of antibiotic prophylaxis is to prevent bacteremia from occurring during procedures in patients who have conditions that may predispose them to IE. Prophylactic antibiotics may, in fact, not confer any significant protection from IE and there is no good evidence that prophylactic antibiotics prevent IE caused by dental, GI, or GU procedures (2,24,25). As a result, the AHA has implemented major revisions in its 2007 guidelines that eliminate the antibiotic prophylaxis recommendations for GI and GU procedures and significantly alter the recommendations for dental procedures, respiratory procedures, and those involving infected skin and musculoskeletal structures (Table 88.5). According to current recommendations, only those at the highest risk for IE should receive prophylaxis (24). These include patients with prosthetic heart valves, previous endocarditis or certain types of congenital heart disease, and cardiac transplant recipients with cardiac valvular disease (2,24). Specific antibiotic recommendations and dosages are listed in Table 88.6.

TABLE 88.5
Cardiac Conditions Warranting Antibiotic Prophylaxis for Dental Procedures,[a] Respiratory Procedures, or Procedures Involving Infected Skin or Musculoskeletal Tissue

Prosthetic cardiac valve

Previous endocarditis

Congenital heart disease only in the following categories:

- Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
- Completely repaired congenital heart disease with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 mos after the procedure[b]
- Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients with cardiac valvular disease

[a]All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth, or perforation of the oral mucosa.

[b]Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

Common Pitfalls

- Not asking about risk factors in patients who present with nonspecific symptoms consistent with IE.
- Missing the diagnosis in the elderly by attributing a cardiac murmur to chronic heart disease.
- Not asking specifically about IV drug use in patients who present with nonspecific symptoms consistent with endocarditis.
- Failing to consider the embolic and immune-mediated complications of IE as the underlying cause of stroke, meningitis, myocardial infarction, septic arthritis, or renal failure.

- Not asking about risk factors for IE in patients about to undergo a procedure prone to cause bacteremia.

CHAPTER 89

Acute Pericarditis and Cardiac Tamponade

Richard Byyny and Howard A. Bessen

Pericarditis is present in approximately 5% of chest pain patients presenting to the ED without myocardial infarction (MI) (1) and can complicate nearly any class of disease, including infectious, neoplastic, rheumatologic, and metabolic diseases, as well as trauma. In the majority of cases the cause remains unclear despite testing (i.e., idiopathic pericarditis) (2,3). Many of these cases are thought to be viral in origin.

However, pericarditis may also occur as a complication of a systemic or intrathoracic infection. It is the most prominent cardiac complication of neoplastic disease, and nontraumatic pericardial tamponade is usually of metastatic origin (4,5). In addition, patients receiving radiation treatment as therapy for their cancer may develop postirradiation pericarditis. Pericarditis may occur as a complication of chronic renal failure or of connective tissue diseases such as systemic lupus erythematosus, scleroderma, or rheumatoid arthritis. Medications may also be implicated.

Pericarditis frequently occurs during the first few days after acute MI (6,7) and may also present as late-onset postinfarction pericarditis (Dressler syndrome). Aortic dissection, cardiac trauma, invasive procedures that involve the great vessels and the heart (central venous catheter insertion and cardiac catheterization), and thoracic surgery may also cause pericarditis and pericardial tamponade within hours to weeks. The common causes of acute pericarditis are listed in Table 89.1.

TABLE 89.1
Causes of Acute Pericarditis

Idiopathic	Systemic lupus erythematosus
Infectious	Scleroderma
Viral	Drug-related
Bacterial	Anticoagulants
Tuberculosis	Procainamide
Fungal	Hydralazine
Parasitic	Methyldopa
Malignancy	Cardiac Injury
Metastatic disease	Postmyocardial infarction
Radiation-induced	Postsurgical
Uremia	Postinstrumentation
Connective Tissue Disease	Cardiac trauma
Rheumatoid arthritis	Aortic dissection

From Khandaker MH, Espinosa RE, Nishimura RA, et al. Pericardial disease: Diagnosis and management, Mayo Clinic proceedings. *Mayo Clinic*. 2010;85(6):572–593.

Acute pericarditis is a diagnostic challenge because its presentation is similar to that of several other disorders and because it may have life-threatening complications. Management ranges from symptomatic treatment to lifesaving invasive procedures.

CLINICAL PRESENTATION

There are no predefined diagnostic criteria for pericarditis. However, presence of two of the following four criteria is highly suggestive: (1) characteristic chest pain, (2) pericardial friction rub, (3) suggestive ECG changes, and (4) new or worsening pericardial effusion (1,8–10). The prevalence of symptoms is presented in Table 89.2.

TABLE 89.2
Symptom Prevalence with Acute Pericarditis

Symptom	%
Chest pain	95.5
Character of chest pain	
Pleuritic pain	66.5
Retrosternal pain	59.2
Sharp	50.0
Dull or other	50.0
Postural change in pain	46.4
Radiation	
Left shoulder	45.3
No radiation	23.5
Multiple regions	14.5
Neck/jaw/throat	8.4
Back	6.7
Arm	4.5
Abdomen	1.7
Across chest	1.1
Associated Symptoms	
Shortness of Breath	33.5
Recent infection	27.4
Nausea/vomiting	11.7
Light-headedness	7.8
Dysphagia	1.1

Hooper AJ, Celenza A. A descriptive analysis of patients with an emergency department diagnosis of acute pericarditis. *Emerg Med J*. 2013;30(12):1003–1008.

Chest pain is the most common presenting complaint with acute pericarditis. The pain is usually sharp, substernal, and often pleuritic, but it may also be dull, constrictive, or aching. Pain may radiate to any part of the chest and back as well as to the ridge of the trapezius (11). Typically, the chest discomfort is described as being positional with the pain being eased by sitting up and leaning forward and increased with recumbency. The pain may be associated with shortness of breath, which may be caused by coexisting pleuritis or by cardiac tamponade. Patients may also present with hypotension and other signs and symptoms of tamponade.

The classic diagnostic physical finding is the pericardial friction rub, which may consist of one, two, or three components (1). An audio file can be found in the work by Carlson et al. (12). It is

important to recognize that the rub is often transient and may not be heard at all times. However, it is present at some point in up to 85% of patients. The rub is often described as being high-pitched like leather squeaking or scratching. It is typically heard best along the left sternal border and is increased by having the patient sit or lean forward. The rub may be confused with a heart murmur or a pleural friction rub. However, having the patient hold their breath helps distinguish a pleural friction rub from a pericardial rub.

The major complications of acute pericarditis are pericardial effusion (potentially leading to cardiac tamponade), recurrent pericarditis, and chronic constrictive pericarditis. Dysrhythmias are unusual in pericarditis but may occur in patients with associated myocarditis or other underlying heart disease.

Cardiac tamponade is an acute life-threatening complication resulting from the accumulation of fluid within the pericardial space. The pericardium is poorly distensible; therefore, the fluid can cause an impairment of cardiac filling and thus a decrease in cardiac output. Beck's triad (jugular venous distension [JVD], hypotension, and distant heart sounds) has been taught as the classic presentation, but the sensitivity of these findings is poor (Table 89.3). The presentation may be subtle, potentially leading to a delayed or missed diagnosis and a poor outcome. Close attention to physical findings is essential to make the diagnosis. Clinical decompensation can be rapid. Tamponade is often mistaken for congestive heart failure (CHF) because patients present with dyspnea, orthopnea, JVD, and hepatic enlargement.

TABLE 89.3
Sensitivity of Presenting Signs and Symptoms of Cardiac Tamponade

Sign or Symptom	Sensitivity (%) (95% CI)
Tachycardia	77 (69–85%)
Hypotension	26 (16–36%)
Diminished heart sounds	28 (21–35%)
Jugular venous distension	76 (62–90%)

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other conditions that cause chest pain and dyspnea, such as acute MI, CHF, pulmonary embolism, pneumonia, pneumothorax, pneumomediastinum, pleuritis, and aortic dissection. Cardiac tamponade may be confused with CHF, cardiogenic shock, or massive pulmonary embolism.

Acute pericarditis has many overlapping features with acute MI. Both cause chest pain, cause electrocardiographic abnormalities, and can cause elevations of cardiac markers (13). In contrast to patients with MI, patients with pericarditis may describe a viral prodrome, may present with fever, and typically have sharper pain that increases with body motion and varies with position. ECG findings may be useful in distinguishing MI from pericarditis (see section "ED Evaluation"). Patients with pericarditis (even with tamponade) have clear lung fields, unlike patients with CHF with pulmonary edema or those with pneumonia.

ED EVALUATION

Initial assessment and therapy consists of measures appropriate for any patient who presents with shortness of breath and chest pain: supplemental oxygen administration, intravenous access placement, cardiac monitoring, and a 12-lead ECG.

The ECG can be diagnostic. The most common ECG finding is concave-upward ST-segment elevation seen in most of the leads; PR-segment depression may also be seen (Fig. 89.1). Although the ECG is usually abnormal, diagnostic changes may be absent in patients with clinically evident pericarditis, particularly in patients with post-MI pericarditis.

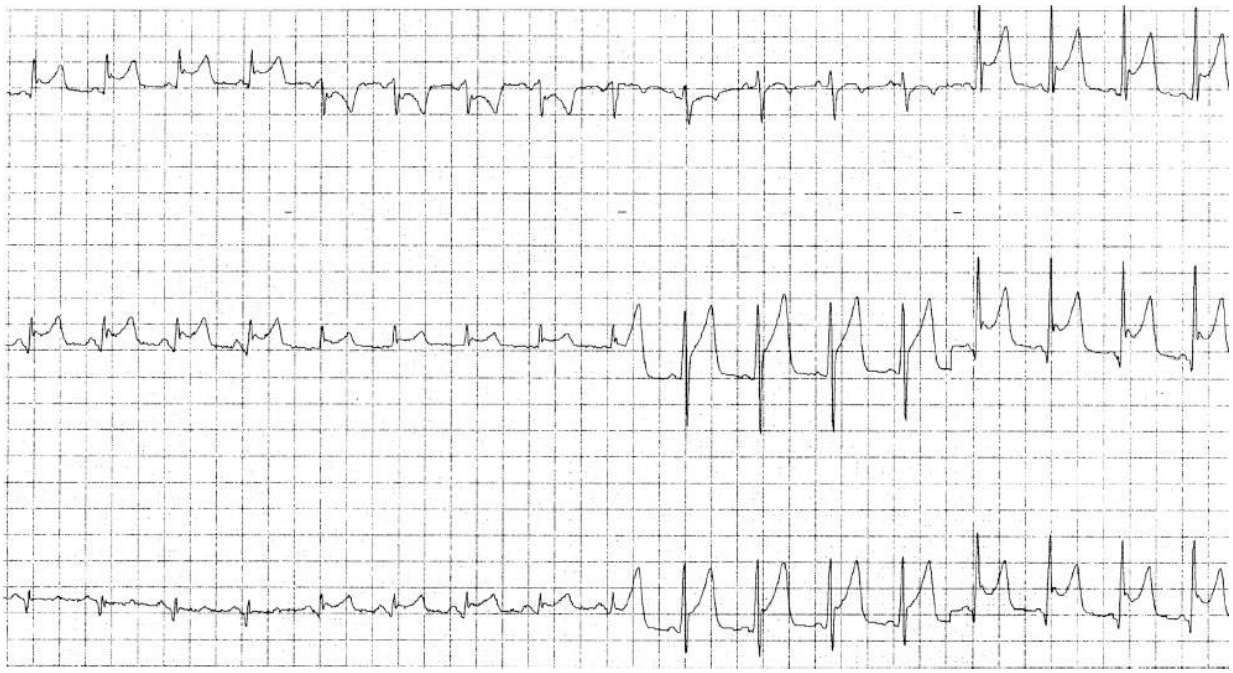

FIGURE 89.1 Electrocardiogram of a 35-year-old man with acute (stage 1) pericarditis. Note the diffuse, concave upward ST-segment elevation.

Early repolarization, a normal electrocardiographic variant characterized by ST-segment elevation, can be difficult to distinguish from pericarditis (1,14–16). If the clinical presentation suggests pericarditis, serial ECGs may be required to differentiate pericarditis from the benign early repolarization variant. On a single ECG, an ST/T ratio (the amount of ST-segment elevation divided by the height of the T wave) of 0.25 or more in lead V_6 is suggestive of pericarditis.

MI and pericarditis may be difficult to differentiate. In pericarditis, ST-segment elevation is more diffuse, usually is upward sloping and is without reciprocal ST depression (16), and the Q waves that evolve in acute infarction do not develop. Pericarditis is also more likely to have associated PR depression. Having PR depression in both limb and precordial leads has a positive predictive value of 96.7% and a negative predictive value of 90% (17). Additionally ST-segment elevation in patients with acute MI is typically focal (in the distribution of a coronary artery), usually is convex or downward

sloping and may be associated with ST-segment depression in reciprocal leads.

The chest radiograph is often normal. The cardiac silhouette may be enlarged secondary to a pericardial effusion, but the heart size may be normal even if an effusion is present (18).

The white blood cell count can range from normal to markedly elevated and is usually not helpful in making or excluding the diagnosis. Similarly, the erythrocyte sedimentation rate is usually elevated, but this is a nonspecific finding. Cardiac marker levels may be significantly elevated because of associated myocarditis (13,19,20).

Echocardiography can provide useful information in suspected pericarditis. In the absence of significant associated myocarditis, most patients with pericarditis have normal cardiac wall motion. In contrast, patients with chest pain caused by cardiac ischemia often have focal wall motion abnormalities. Echocardiography is also the best method for detecting and monitoring pericardial effusions (discussion follows).

Cardiac Tamponade

The classic findings of cardiac tamponade are muffled heart sounds, diminished arterial pressure, and JVD. However, these findings are seen only with fully developed tamponade and are much more likely to occur when pericardial fluid accumulates quickly, precluding pericardial distension (5,21). The most common presenting signs and symptoms associated with tamponade are summarized in Table 89.3 (22).

An important clue to the diagnosis is the presence of pulsus paradoxus, an inspiratory decrease in systolic blood pressure of >10 mm Hg (23). Other clinical entities associated with pulsus paradoxus include emphysema, asthma, obesity, pulmonary embolism, cardiogenic shock, right ventricular infarction, and restrictive cardiomyopathy. Patients with acute traumatic tamponade may not have a pulsus paradoxus.

Patients with tamponade may have relatively normal ECGs. With large effusions, reduction of the QRS amplitude or electrical alternans

(alternating beat-to-beat variation in QRS amplitude) may be seen. Central venous pressure measurements reveal an elevation of right-sided pressures and can help confirm the diagnosis, although this may also be present in patients with pulmonary embolism or CHF.

A definitive diagnosis can be made with cardiac ultrasound. Echocardiography can detect small amounts of pericardial fluid; in cardiac tamponade, it may demonstrate diffuse hypokinesis, right atrial collapse, and right ventricular diastolic collapse (21,24). If possible, echocardiography should be performed emergently in any patient with suspected tamponade, because delays in evaluating the presence and size of a pericardial effusion can be disastrous (4).

The diagnosis of tamponade can also be definitively established by measuring pressures in the cardiac chambers. Right atrial, right ventricular diastolic, pulmonary artery diastolic, and pulmonary capillary wedge pressures are equalized in this condition.

Recurrent Pericarditis

After recovering from acute pericarditis, patients may have one or several episodes of recurrent pericarditis, weeks to months after the initial episode (25–28). Evaluation and management of recurrences are, for the most part, the same as for a first presentation of acute pericarditis. Choice of initial therapy may affect the frequency of recurrence (see the ED management section of this chapter).

Constrictive Pericarditis

Constrictive pericarditis, an uncommon complication of acute pericarditis, results when healing of acute pericarditis leads to encasement of the heart in fibrous tissue, impeding ventricular filling (1,9). Patients often present with dyspnea on exertion, ascites, peripheral edema, and hepatic enlargement. The lung fields are clear in these patients, in contrast to patients with CHF. The presence of distended neck veins in constrictive pericarditis helps to separate these patients from those with severe liver disease, who may appear clinically similar. Pericardial calcification on the chest radiograph and pericardial thickening on echocardiography may also provide

clues to this diagnosis. The definitive treatment is resection of the pericardium.

KEY TESTING

Test	Indication	Supports Pericarditis	Does Not Support Pericarditis
EKG	Chest Pain	Diffuse ST elevation	Focal ST elevation
	Auscultated rub	Diffuse PR depression	Reciprocal ST depression
		ST-segment elevation to T-wave height ratio >0.25 in V6	
Troponin	Suspected coexisting myocarditis Suspected myocardial infarction	Troponin may be positive or negative in simple pericarditis but is usually only mildly elevated or indeterminate	Very high troponin implies either coexisting myocarditis or myocardial infarction
Bedside ultrasound	Suspected pericarditis Suspected tamponade	Pericardial effusion	Absence of pericardial effusion does not rule out pericarditis
	Suspected myocardial infarction		Regional wall motion abnormality
Consultative ultrasound	Suspected tamponade Large effusion on bedside ultrasound	Pericardial effusion	Absence of pericardial effusion does not rule out pericarditis
	Suspected coexisting myocarditis Suspected myocardial infarction		Regional wall motion abnormality

ED MANAGEMENT

The treatment of uncomplicated pericarditis is largely symptomatic, but specific therapy is available for a few causes of pericarditis. Most studies have evaluated either aspirin at moderate to high doses or other nonsteroidal anti-inflammatory drugs in particular ibuprofen (29). There is no standard duration of therapy but many studies suggest a course of several weeks with a gradually tapering dose during that time period. Because of the high doses recommended, physicians should consider giving a proton pump inhibitor as prophylaxis against gastrointestinal discomfort or hemorrhage. In patients with suspected coronary artery disease indomethacin should be avoided because it can decrease coronary blood flow (1,30). In patients with post-MI pericarditis nonsteroidal anti-inflammatory drugs in general should be avoided because they impair myocardial remodeling and it is recommended that patients should be on aspirin therapy at baseline (31).

Colchicine can also be used to treat patients with idiopathic, viral, or autoimmune pericarditis. In a randomized trial of aspirin alone versus aspirin plus colchicine, patients who received both drugs had both a faster resolution of symptoms (36.7% of patients in the aspirin group were still symptomatic at 72 hours versus only 11.7% in the

combination group) and a lower rate of recurrence (32.3% in the aspirin only group versus 10.7% in the combination group) (9). The most common reason for discontinuation of colchicine is diarrhea. Colchicine is generally safe but should be avoided in severe liver or kidney disease.

Bacterial pericarditis must be treated with drainage and appropriate antimicrobial therapy. Uremic pericarditis is usually an indication for dialysis. Corticosteroids should be avoided in most patients, because steroids have been associated with an increased rate of recurrence of pericarditis (28). The exception to this contraindication are patients in whom pericarditis is secondary to rheumatologic causes, where treating the underlying rheumatologic etiology with steroids may be indicated.

The definitive treatment for pericardial tamponade is pericardiocentesis. However, to “buy time” until pericardiocentesis can be performed, volume infusion is the treatment of choice. Ideally, pericardiocentesis should be done with echocardiographic or fluoroscopic guidance (often in the cardiac catheterization laboratory), but emergent “blind” pericardiocentesis may be necessary for hypotensive patients who do not respond to volume infusion.

The pericardium may be accessed by a left parasternal or subxiphoid puncture. In the parasternal approach, the needle is inserted perpendicular to the skin in the fifth intercostal space, just lateral to the sternum. In the subxiphoid approach, the puncture is made about 2 cm below and 1 cm to the left of the xiphoid process; the needle enters the skin at a 30° to 45° angle and is aimed toward the sternal notch or the left shoulder. The needle is advanced with constant syringe aspiration. As much fluid is aspirated as is needed to improve the clinical condition or to obtain specimens for diagnostic use.

After completing the procedure, a chest radiograph should be obtained to look for complications such as pneumothorax or pleural effusion secondary to laceration of the lung or myocardium. Serial physical examinations and central venous pressure monitoring are critical to detect reaccumulation of fluid. The admitting consultant

may choose to observe the patient for fluid reaccumulation, may place a soft catheter in the pericardial space for continued drainage, or may perform surgical drainage in the operating room.

CRITICAL INTERVENTIONS

- Perform pericardiocentesis (with echocardiographic or fluoroscopic guidance if possible) to treat pericardial tamponade.
- Obtain an echocardiogram to exclude pericardial effusion before discharging patients with pericarditis.

DISPOSITION

Many patients with pericarditis can be successfully treated on an outpatient basis. Patients should be considered for admission if they exhibit any high-risk features (Table 89.4) (32,33). Before making a decision for outpatient therapy, it is prudent to obtain an echocardiogram to rule out a large effusion, tamponade, or myocarditis. Patients without high-risk clinical features on history, physical examination, or echocardiogram can be treated as outpatients if close follow-up can be assured; otherwise, they should be admitted with a cardiology consultation.

TABLE 89.4
High-Risk Features of Pericarditis

Fever >38°C
Subacute onset
Anticoagulated
Immunocompromised
Trauma
Tamponade
Severe pericardial effusion (an echo-free space >20 mm)

Common Pitfalls

- Failing to consider pericarditis in the differential diagnosis of chest pain.

- Mistakenly diagnosing pericarditis in patients with other causes of chest pain, such as MI, pulmonary embolism, or aortic dissection.
- Misdiagnosing acute pericarditis as acute MI, potentially leading to the inappropriate administration of thrombolytics or activation of the catheterization laboratory.
- Failing to consider the etiology of pericarditis. Many of the causes require specific therapy.
- Failing to consider cardiac tamponade in the differential diagnosis of hypotension, especially in patients with cancer.

CHAPTER 90

Hypertension

Philip Shayne and Edward Stettner

When does an elevated blood pressure become an emergency? The World Health Organization has established that hypertension contributes to one in every eight deaths worldwide. One-quarter of all Americans have hypertension, yet only one-half of those individuals receive treatment, and less than one-third of cases are adequately controlled (6). National treatment guidelines exist based on large studies involving tens of thousands of patients (3); however, there is a dearth of evidence available to guide the acute management of severely elevated blood pressure (1–4,8,14,18,19,21,22). As many as one-third of all patients in the emergency department (ED) with markedly elevated blood pressure have been referred there for blood pressure evaluation from some other clinical setting, making the emergency physician the recognized expert. Yet few of these patients are in crisis or require immediate intervention. In most cases, this requires the emergency physician to determine what to do with the incidental finding of an elevated blood pressure in the patient with no symptoms or with nonspecific complaints. The broad spectrum of disease, from the asymptomatic to the critically ill patient, creates the dilemma for the emergency physician in deciding how and when in the process to intervene.

A hypertensive emergency involves rapid and progressive decompensation or damage of vital-organ function resulting from severely elevated blood pressure. These patients need careful evaluation and monitoring; many, but not all, need immediate parenteral blood pressure control. There is no evidence to suggest

that the severe, but asymptomatic, hypertensive patient requires any emergent care. Each patient does require a careful and specific evaluation for signs of critical organ compromise. A rational approach to the elevated blood pressure should be formulated on the basis of the patient's history and presentation.

CLINICAL PRESENTATION

The presence or risk of target-organ deterioration determines the urgency with which a patient with elevated blood pressure must be treated. A hypertensive emergency is defined as the acute and progressive decompensation or damage of vital organ function caused by an elevated blood pressure. The major organs affected by hypertension are primarily the brain, kidney, heart, and vascular system. Patients determined to have a hypertensive emergency need to be carefully evaluated, be monitored, and usually need to have their blood pressure controlled. The treatment should be dictated by the clinical situation, not the severity of blood pressure elevation. No degree of hypertension by itself defines an emergency.

Many patients present with an elevated blood pressure and with nonspecific symptoms. The emergency physician needs to make a decision as to the etiology of the symptoms to determine how the blood pressure must be managed. If a hypertensive patient's chest pain is possibly angina, immediate parenteral control might be necessary. However, if that pain is determined not to be cardiovascular in origin, the same patient might need no immediate treatment for the blood pressure. The assessment of the patient determines the need to treat.

The concept of the hypertensive urgency, usually referring to markedly elevated, asymptomatic blood pressures requiring rapid intervention, is no longer widely used. Most patients without acute and progressive target-organ disease can have their severely elevated blood pressure managed on an outpatient basis (19). This approach de-emphasizes the degree to which the blood pressure is elevated. However, the clinician should be aware that certain patients are at higher risk of near-term complications from their uncontrolled

hypertension, especially those patients with a history of previous end-organ disease. These patients do require increased vigilance.

Hypertensive Encephalopathy

The triad of severe hypertension, altered mental status, and, often, papilledema characterizes hypertensive encephalopathy. This encephalopathy may be accompanied by the acute or subacute onset of lethargy, confusion, headache, visual disturbances, and seizures. Retinopathy may or may not be present. The diagnosis is confirmed if cerebral function improves with lowering of the blood pressure. The mechanism is cerebral overperfusion; in effect, the pressure overwhelms the brain's ability to autoregulate cerebral blood flow (CBF). Overperfusion results in vasodilation and increased permeability of cerebral blood vessels, leading in turn to the development of cerebral edema. If not adequately treated, hypertensive encephalopathy can progress to cerebral hemorrhage, coma, and death (1).

Hypertensive encephalopathy is most likely to occur in previously normotensive individuals who experience a rapid rise in blood pressure, such as children with acute glomerulonephritis and young women with preeclampsia or eclampsia. Patients with chronic hypertension usually experience a more gradual rise in blood pressure and therefore develop a right shift in their pressure perfusion autoregulation curve that makes cerebral decompensation less likely. Hypertensive encephalopathy produces characteristic findings on computed tomography (CT), a posterior leukoencephalopathy that predominantly affects the white matter of the parieto-occipital regions bilaterally (17). CT is useful in excluding other causes of altered mental status such as intracranial bleeding.

Accelerated Malignant Hypertension

Accelerated malignant hypertension occurs most commonly in young African American men with underlying renal parenchymal disease or renovascular disease. When endothelial-vasodilator responses are

overwhelmed, endothelial decompensation causes further hypertension and endothelial damage, resulting in an inflammatory vasculopathy (22). The diagnosis is based on marked elevation of blood pressure and characteristic eye-ground findings. Flame-shaped hemorrhages occur around the optic disk because of high intravascular pressures, and "soft" exudates are caused by ischemic infarction of the nerve fibers secondary to occlusion of supplying arterioles. Papilledema is considered by many to be the sine qua non of "malignant hypertension." For this reason, the term "accelerated hypertension" has been used to describe the same condition (hemorrhages and exudates) without papilledema. Because absence of papilledema does not connote different clinical features or a better prognosis, the term "accelerated malignant hypertension" is now recommended (9).

Common symptoms include headache (85%), visual blurring (55%), nocturia (38%), and weakness (30%). Laboratory evidence includes azotemia, proteinuria, hematuria, hypokalemia, and metabolic alkalosis. Accelerated malignant hypertension is most commonly found in patients with long-standing hypertension and usually occurs without encephalopathy. Since the 1950s, the long-term prognosis of accelerated malignant hypertension has improved from a 1-year survival rate of 10% to a 5-year survival rate of >75% (10).

Cerebrovascular Crisis

Hypertension frequently complicates the presentation of cerebrovascular ischemia and hemorrhage (7). An understanding of cerebrovascular physiology is helpful in determining the best treatment strategy (1,9). CBF is a function of the cerebral perfusion pressure (CPP), which is equal to the mean arterial pressure (MAP) minus the intracranial pressure (ICP): CPP = MAP – ICP. CBF is maintained by vasoconstriction and vasodilation of the cerebral vasculature. However, cerebral autoregulation fails at about 25% more or less than the MAP. In addition, changes in ICP or brain injury can result in loss of the brain's ability to autoregulate blood flow. Increased ICP, commonly seen with hemorrhage or edema,

decreases the CPP, making the brain more vulnerable to changes in MAP.

Cardiovascular Crisis

Hypertensive emergencies involving the heart and great vessels include congestive heart failure (CHF), acute coronary syndromes, and dissecting aortic aneurysm. Blood pressure is frequently elevated in patients with acute pulmonary edema, particularly when a high output state is the cause, as in volume-overloaded patients with renal failure, patients with thyrotoxicosis, or those with severe anemia. Acute pulmonary edema with hypertension and CHF may be caused by transient diastolic dysfunction, which may or may not be a direct result of the elevated blood pressure.

Acute coronary syndromes are also frequently accompanied by hypertension. The reduction of myocardial work by lowering the blood pressure and heart rate has been demonstrated to reduce infarct size in patients not receiving thrombolytic therapy. However, Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study trial demonstrated an increased incidence of cardiogenic shock with the administration of intravenous metoprolol in patients with suspected myocardial infarction. This effect was greatest in patients >70 years of age, with systolic blood pressure (SBP) <120 mm Hg, a heart rate >110 beats/min, or with evidence of CHF (Killip class greater than one). American Heart Association (AHA) guidelines for the treatment of acute coronary syndrome recommend the administration of oral β-blockers within 24 hours for patients without signs of heart failure, evidence of a low-output state, or other relative contraindications to β-blockers (13). Nitroglycerin remains the agent of choice in patients with ST-elevation myocardial infarction; intravenous β-blockers should be considered only in those patients who are not at risk of developing CHF or hypotension.

Acute aortic dissection is thought to occur via aortic dilatation or high blood pressures superimposed on a structural weakness of the arterial wall. The result is a tear of the intimal layer of the aorta. Pulsatile pressure extends the dissection by separating the layers of

the arterial wall. Historical series report a mortality of 1% to 2% per hour. The stresses that extend the dissection are related as much to the pulse pressure (d*p*/d*t* or difference between SBP and diastolic blood pressure [DBP] throughout time) as it is to MAP. Factors that contribute to increased pulse pressure include the heart rate, myocardial contractility, and the MAP (15).

Renovascular Crisis

The kidney is unique in being both a target organ as well as the cause of many hypertensive emergencies. Chronic hypertension causes 30% of cases of end-stage renal disease, making it the second most common cause after diabetes. Chronic hypertensive patients may develop nephrosclerosis after 10 to 15 years, which is manifested by damage to the medial layer of capillaries, reduced kidney size, and nonnephrotic levels of proteinuria without hematuria. In contrast, malignant hypertension damages the intimal layer of the renal capillary bed and may result in enlarged kidneys, a cellular urinary sediment, hematuria, and severe proteinuria.

Severe hypertension in a young patient should raise the possibility of intrinsic acute renal disease, such as glomerulonephritis. Immunoglobulin (Ig) A nephropathy has surpassed poststreptococcal glomerulonephritis in frequency, and Henoch–Schönlein purpura is the most likely cause of acute glomerular disease among children.

Stenosis of the renal arteries is present in only 1% of unselected patients with hypertension, but it is present in 4% of blacks and 32% of whites who have severe hypertension (DBP >125 with retinopathy). It is also more common among patients who have a rapidly progressive course. Most patients have atherosclerosis, but a minority of these patients are young women with medial fibroplasia of the renal arteries. An abdominal bruit is present in 46% of patients, and these patients are more likely to have the onset of hypertension after age 50.

Occasionally, a rare but devastating acute renal failure may occur because of intrarenal vasculitis. This disorder is common in the setting of scleroderma and may be responsive to angiotensin-converting enzyme inhibitors (ACEIs).

Catecholamine Excess

The most familiar drugs that cause hypertension in EDs today are sympathomimetic drugs such as phenylephrine, cocaine, and methamphetamine. Tyramine can induce a hypertensive crisis in patients who are taking a monoamine oxidase inhibitor drug, and hypertension can complicate withdrawal syndromes from alcohol, clonidine, and, less frequently, β-blockers.

Pheochromocytomas can cause intermittent hypertensive crises, usually accompanied by headache. Patients with pheochromocytoma can secrete a bewildering variety of catecholamines and even peptide hormones in either a constant or wildly intermittent pattern. Patients can produce many clinical findings other than hypertension, such as headache, sweating, palpitations, pallor, nausea, and, rarely, seizures. Some patients with pheochromocytomas have paroxysms of low blood pressure rather than high blood pressure.

Hypertension in Pregnancy

Hypertension in pregnancy is addressed separately in Chapter 140. Emergencies include eclampsia and preeclampsia. Pregnant women between 20 weeks of gestation and 2 weeks postpartum who have any degree of hypertension ($\geq$140/90 mm Hg) or an increase of more than 30/15 mm Hg above their baseline, accompanied by peripheral edema and proteinuria, should be considered to have preeclampsia. Hypertension is important mainly as a symptom of the underlying disorder rather than a cause. Preeclampsia is important to recognize, because it can progress suddenly to eclampsia, which is defined by the occurrence of convulsions and can rapidly progress to coma or death. Magnesium infusion is more effective than other anticonvulsants in this setting (11). Definitive treatment consists of delivery of the fetus, so the emergency physician usually collaborates with an obstetrician early in the patient's progress through the department.

Asymptomatic Hypertension

Many ED patients are found to have incidentally elevated blood pressure without active symptoms of target-organ injury. Many of these patients will have a spontaneous decrease in their blood pressure without intervention, though some will remain persistently hypertensive. These patients present a diagnostic and therapeutic challenge to the clinician as there is a dearth of evidence concerning how best to manage them acutely. In general, workup for these patients should be focused on their presenting complaints and symptoms, with therapy directed toward any identified active medical emergencies. There is little evidence to support routine testing in patients with asymptomatic hypertension.

DIFFERENTIAL DIAGNOSIS

Blood pressure elevation may be primary or secondary to underlying causes (pain, anxiety, drugs). A hypertensive emergency exists if the elevated blood pressure is causing progressive target-organ damage. Two of the entities described above are specific complications of uncontrolled hypertension: hypertensive encephalopathy and malignant accelerated hypertension (9). The other hypertensive emergencies are primary crises of the brain, heart, kidneys, or vasculature that are precipitated or exacerbated by the stress of an elevated blood pressure (Table 90.1). For example, a myocardial infarction may occur in a normotensive as well as hypertensive patient. If the blood pressure is elevated in the setting of an infarct, then it must be managed, but the therapy must be decided primarily in the context of treating the coronary ischemia.

TABLE 90.1
Hypertensive Emergencies

- Primary
  - Hypertensive encephalopathy
  - Accelerated malignant hypertension
- Secondary
  - Cerebrovascular accidents
    - Thromboembolic stroke
    - Hemorrhagic stroke
    - Subarachnoid hemorrhage
  - Cardiovascular crises
    - Myocardial infarction
    - Acute coronary syndromes
    - Cardiogenic pulmonary edema
    - Aortic dissection
    - Uncontrollable arterial bleeding
  - Renal crises
    - Acute renal failure
    - Glomerular nephritis
    - Severe hypertension after kidney transplant
  - Other emergencies
    - Preeclampsia/eclampsia
    - Perioperative hypertension
    - Catecholamine excess

ED EVALUATION

The clinical evaluation should determine the nature, severity, and management of patients in hypertensive crisis. When a patient with markedly elevated blood pressure presents to the ED, attention should first be given to assessing the patient's airway, breathing, and circulation. This includes accurate measurement of blood pressure. Initially, elevated ED blood pressures frequently decrease spontaneously by the time a second reading is obtained (14). For this reason alone, interventions should be based on the composite of several, separate blood pressure determinations in the ED. To obtain an accurate measurement, the patient should be seated with the arm at the level of the heart and the cuff bladder should cover at least 80% of the arm circumference. Blood pressure should be evaluated in both arms. Blood pressure measurement with an automated cuff is inaccurate in patients with atrial fibrillation and other heart rhythm

irregularities, especially tachydysrhythmias. Appropriate pain management and relief of underlying causes (e.g., hypoxia, bladder distention) may resolve hypertension (3). Other medications, over-the-counter preparations, or illicit drugs may exacerbate or mitigate blood pressure (Table 90.2).

TABLE 90.2
Drugs that Can Elevate Blood Pressure or Interfere with the Effectiveness of Antihypertensive Agents

Oral contraceptives
Steroids
NSAIDs
Nasal decongestants
Cold remedies
Appetite suppressants
Tricyclic antidepressants
Monoamine oxidase inhibitors

NSAIDs, nonsteroidal anti-inflammatory drugs.

If the patient's blood pressure is persistently elevated, the history should start with an assessment of symptoms that might be consistent with target-organ compromise. Physicians should ask about specific symptoms such as dyspnea, chest pain, neurologic complaints, and visual changes. Additional important historical details include the duration and severity of pre-existing hypertension, the degree of previous success with blood pressure control, and the presence of target-organ disease (cardiovascular, cerebrovascular, renovascular, and great vessel). The physical examination should be directed toward identifying signs of target-organ damage. A fundoscopic examination demonstrating retinal hemorrhage or papilledema is sufficient to diagnose accelerated malignant hypertension. The cardiovascular examination should focus on identifying signs of heart failure (e.g., increased jugular venous pressure, pulmonary rales, and an S_3) and asymmetric pulses. The neurologic examination should assess the level of consciousness, visual fields, and the presence of focal motor and sensory deficits.

Diagnostic studies should be based primarily on the patient's symptoms. A chest radiograph is indicated for patients with dyspnea and a head CT scan for abnormal neurologic findings. Few studies have assessed the prognostic value of abnormal laboratory findings in patients with severe asymptomatic hypertension (17). If a patient's blood pressure remains persistently >180/110 mm Hg after treatment of any aggravating symptoms, practitioners should consider a brief assessment of target-organ function. According to the 2013 American College of Emergency Physicians clinical policy, there is no definite role for screening for end-organ damage in adults with markedly elevated blood pressure, though high-risk populations may benefit from a limited evaluation (23). Because renal failure is silent, the measurement of the serum creatinine and/or a urinalysis is used to detect evidence of renal failure or glomerular disease. An ECG is useful in assessing the baseline level of left ventricular hypertrophy, which carries a poor prognosis and should prompt more vigilant follow-up. When renovascular disease or hypercortisolism are suspected causes of hypertension, a serum tube for plasma renin activity and aldosterone should be drawn before medications are administered. A urine screen for cocaine and amphetamines may help confirm common causes of hypertension. The incremental value of obtaining a chest radiograph or complete blood count in the ED patient without relevant symptoms is generally likely to be low.

KEY TESTING

- Base diagnostic evaluation on individual patient presentation and symptoms.
- Consider urinalysis and chemistry panel to assess renal function in patients with markedly elevated blood pressure.
- Patients with suspected cerebrovascular crisis or hypertensive encephalopathy should receive immediate CT of the head.
- Patients with suspected cardiovascular crisis should receive immediate ECG, cardiac enzyme, and chest radiography.

ED MANAGEMENT

The goal of therapy in a hypertensive crisis is a reduction in the mean MAP by 20% to 25% in 1 to 2 hours. Although not well evidence based, this therapeutic guideline is supported by shared practice experience in patients who have done poorly with more aggressive blood pressure reduction. The ideal drug for treating hypertensive emergencies has a rapid onset, rapid maximal effect, and rapid offset for easy titration of blood pressure. These characteristics are found only in parenteral agents. The most common drugs of this group are summarized in Table 90.3 from the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VII) (8).

TABLE 90.3
Parenteral Drugs for Treatment of Hypertensive Emergencies

Drug	Dose[a]	Onset of Action	Duration of Action	Adverse Effects[b]	Special Indications
Vasodilators					
Sodium nitroprusside	0.25–10 µg/kg/min as IV infusion (maximal dose for 10 min only)	Immediate	1–2 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure or azotemia
Nicardipine hydrochloride	5–15 mg/hr IV	5–10 min	1–4 hrs	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Fenoldopam mesylate	0.1–0.3 µg/kg/min IV infusion	<5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	5–100 µg/min as IV infusion[c]	2–5 min	3–5 min	Headache, vomiting methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Enalaprilat	1.25–5 mg q6 h IV	15–30 min	6 hrs	Precipitous fall in pressure in high-renin states; response variable	Acute left-ventricular failure; avoid in acute myocardial infarction
Hydralazine hydrochloride	10–20 mg IV 10–50 mg IM	10–20 min 20–30 min	3–8 hrs	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Diazoxide	50–100 mg IV bolus repeated or 15–30 mg/min infusion	2–4 min	6–12 hrs	Nausea, flushing, tachycardia, chest pain	Now obsolete; when no intensive monitoring available
Adrenergic Inhibitors					
Labetalol hydrochloride	20–80 mg IV bolus every 10 min 0.5–2 mg/min IV infusion	5–10 min	3–6 hrs	Vomiting, scalp tingling, burning in throat, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250–500 µg/kg/min IV for 1 min, then 50–100 µg/kg/min for 4 min; may repeat sequence	1–2 min	10–20 min	Hypotension, nausea	Aortic dissection, perioperative
Phentolamine	5–15 mg IV	1–2 min	3–10 min	Tachycardia, flushing, headache	Catecholamine excess

These doses may vary from those in the *Physicians' Desk Reference* (51st edition).
[a]IV, intravenous; IM, intramuscular.
[b]Hypotension may occur with all agents.
[c]Requires special delivery system.
From the National High Blood Pressure Education Program (JNC-VII) (8).

Nitroprusside remains the classic treatment for patients with hypertensive emergencies (8). Nitroprusside is a direct arteriovenous vasodilator that decreases both preload and afterload without significant reflex tachycardia. It is quick in onset of action, and its effect lasts for only 2 to 5 minutes after the drug is discontinued. Nitroprusside should be given with close hemodynamic monitoring to prevent inadvertent hypotension. Thiocyanate toxicity may occur if the drug is used for a period of days, particularly in patients with renal failure. Although not strictly contraindicated in pregnancy, nitroprusside does cross the placental barrier and causes elevated fetal cyanide levels. Because there is no oral form, the patient must be switched to another antihypertensive once control is achieved. Despite the many benefits of nitroprusside, there are often agents better suited for individual hypertensive crises.

Nicardipine is a rapid-acting parenteral calcium channel blocker. Nicardipine has a predictable and smooth onset of action but is relatively long acting. Esmolol is a β-blocking agent that is both rapid in onset and of short duration, making it easy to titrate. Labetalol is a combined α- and β-blocker that is more potent than esmolol and is perhaps better at maintaining a consistent CPP. Unlike esmolol, labetalol has a long half-life, making it possible to administer in miniboluses rather than a constant perfusion, but it is more difficult to titrate down. β-Blockers should not be used in patients with asthma, chronic obstructive pulmonary disease, acute CHF, cocaine abuse, or other contraindications to β-blockade. Fenoldopam is a parenteral dopaminergic receptor-blocking agent with an excellent efficacy and safety profile. Fenoldopam holds some promise as being equivalent to nitroprusside in efficacy, without the rare side effects associated with the nitroprusside cyanide moiety and perhaps with less overshoot hypotension. Enalaprilat is a parenteral ACEI, and phentolamine is a pure α-blocking agent.

Cerebrovascular Crisis

Blood pressure control in cerebrovascular hypertensive emergencies should be undertaken with parenteral drugs that have a short half-life and that are easily titrated with minimal effect on cerebral

vasculature. Because labetalol does not dilate cerebral capacitance vessels, it is theoretically attractive for use in intracerebral disorders. Direct vasodilators, such as nitroprusside, should be used with caution in the setting of focal brain injury, as they can extend the area of ischemia. Nitroprusside has also been implicated in raising ICP and should be avoided in patients with suspected elevated ICP. Some calcium channel blockers have been linked to this rise as well and therefore are not favored in patients with brain injury, although nicardipine is safe and widely used (20).

The treatment of elevated blood pressure in the setting of ischemic cerebrovascular accidents is controversial. When systemic blood pressure is reduced, cerebral autoregulation may fail, thereby producing an ischemic penumbra surrounding the infarct, leading to stroke extension (7). Alternatively, infarction can lead to edema, which will elevate ICP and reduce CBF further. The current AHA guidelines recommend lowering the blood pressure with stroke only when the DBP is >120 mm Hg or the SBP is >220 mm Hg (12). The guidelines further suggest that for patients deemed to be eligible for thrombolytic therapy, blood pressure should be controlled to a systolic <185 mm Hg and diastolic <110 mm Hg. Recommended agents include intravenous labetalol, intravenous nicardipine, or transdermal nitroglycerin paste. Although no study has examined the use of thrombolytics after acutely lowering arterial hypertension, failure to achieve this level of control is considered an absolute contraindication to the administration of systemic thrombolytic therapy. The AHA guidelines are based on consensus opinion, as there is currently no definitive data that establish the clinical benefit of rapidly lowering blood pressure in patients with ischemic stroke. When the decision is made to lower arterial hypertension, the current guidelines recommend a drop of 15% to 25% in the first 24 hours (12).

The role of antihypertensive therapy in hemorrhagic cerebrovascular accidents and subarachnoid hemorrhage is similarly unclear. Theoretically, treatment for elevated blood pressure in intracranial hemorrhage should be more aggressive than for patients with ischemic stroke. The rationale is to decrease the risk of ongoing

bleeding from ruptured small arteries and arterioles; however, the relationship between rebleeding and systemic blood pressure is unproven. As with an ischemic cardiovascular accident, overly aggressive treatment of hypertension may worsen brain injury by decreasing CPP, especially when ICP is increased. There is some evidence to suggest that the tissue immediately surrounding the hemorrhage may be particularly sensitive to changes in the CPP and aggressive lowering of blood pressure may cause tissue ischemia. The most recent AHA guidelines for blood pressure control with hemorrhagic stroke advocate a three-tiered approach. For an SBP >200 mm Hg or MAP >150 mm Hg, it is recommended that clinicians consider aggressive parenteral blood pressure control. The guidelines further suggest that when the SBP is >180 mm Hg or the MAP is >130 mm Hg and there is the possibility of elevated ICP, clinicians should consider using antihypertensive therapy in conjunction with ICP monitoring to maintain a CPP between 60 and 80 mm Hg. Finally, in patients with an SBP >180 mm Hg or a MAP >130 mm Hg and in which elevated ICP is not a concern, the guidelines suggest a modest reduction in blood pressure to a MAP of 110 mm Hg or a blood pressure of 160/90 (12). Nimodipine may be given to decrease the incidence of vasospasm and rebleeding after subarachnoid hemorrhage, but the drug is not recommended for blood pressure control (20).

Cardiovascular Crisis

Nitroglycerin is favored in the treatment of severe hypertension complicating cardiac ischemia. *Nitroglycerin* is a direct vasodilator that affects the venous vasculature more than the arterial. Nitroglycerin dilates the coronary arteries and, in contrast to nitroprusside, promotes a favorable redistribution of blood flow to ischemic areas. As previously discussed, the role of β-blockers in acute coronary syndromes has changed, and intravenous β-blockers are no longer considered first-line therapy in the ED. Oral β-blockers should be given within 24 hours to patients with acute coronary syndrome who are not at high risk for developing heart failure. The goal of treatment for patients with acute coronary syndromes is

reduction of blood pressure to normal or even lower if evidence of ischemia persists. However, this reduction should occur carefully with the patient monitored intensively. Overly vigorous blood pressure lowering may worsen ischemia, because coronary perfusion depends on DBP.

Most critical cases of CHF are treated with a combination of nitroglycerin, furosemide, and an ACEI. For patients with pulmonary edema and hypertension, initiate sublingual nitroglycerin while preparing intravenous nitroglycerin. An ACEI is helpful whenever there is pulmonary congestion and hypertension; captopril may be given orally or sublingually, or enalaprilat can be given intravenously if the patient cannot take oral medications. If systemic fluid overload is present, then administer intravenous furosemide. However, some patients with CHF will not have signs of right-sided heart failure (e.g., jugular venous congestion, peripheral edema, and hepatomegaly) and will in fact be volume depleted because of a pressure diuresis despite the presence of pulmonary edema. In these patients with "dry failure," diuresis may initially exacerbate the underlying pressure natriuresis and further stimulate the renin–angiotensin axis, leading to hypotension. The decision is based on a clinical judgment of whole-body fluid status. β-Blockers have been found to improve survival in patients with chronic CHF; however, this observation should not be extended to patients with acute pulmonary edema because the negative inotropic effects and bradycardia of β-blockade may precipitate immediate worsening.

In aortic dissection, unlike many presentations of hypertensive emergencies, immediate and aggressive blood pressure control is required. Most guidelines recommend targeting an SBP between 100 and 120 mm Hg, as long as tissue perfusion can be maintained (5). Additionally, it is important to control heart rates in patients with aortic dissection, as tachycardia can increase shearing forces on the damaged aorta, therefore increasing the size of the dissection. β-Blockers should be initiated before starting nitroprusside to avoid the potential adverse effects of reflex tachycardia. As an alternative, labetalol is a unique parenteral agent that achieves its maximal effect within minutes and then remains effective for several hours. This

quality allows titration with small boluses, thereby avoiding the constant monitoring required and increased cost incurred with use of nitroprusside (15). Labetalol can also be administered as a parenteral infusion rather than as individual boluses, but careful monitoring is required with this strategy.

Renovascular Crisis

Although malignant hypertension may precipitate acute renal failure by injuring the kidney's microvasculature, this causal chain is often reversed with hypertension being a manifestation, rather than a cause, of the renal failure. Because this distinction cannot be made in the ED, these patients should have their blood pressure lowered. Both nitroprusside and labetalol are excellent choices in this setting. ACEI drugs definitely improve prognosis among chronic hypertensive patients with mild proteinuria; however, they should be used cautiously in hyperkalemic patients with renal failure. Nitroprusside can cause thiocyanate poisoning in several days in patients with renal failure and should be used only briefly or if the patient is to have dialysis soon.

Treatment with an ACEI may reverse high blood pressure dramatically in patients with unilateral stenosis, but it may provoke acute renal failure and severe hyperkalemia in patients with bilateral stenosis, particularly if these patients are taking supplemental potassium or a potassium-sparing diuretic. This complication can be completely reversed by discontinuing the ACEI (16).

Catecholamine Excess

Patients with severe hypertension resulting from pheochromocytoma are commonly treated with the pure α-blocker phentolamine, given intravenously. This drug may be accompanied by a β-blocker if needed for tachycardia. Administration of β-blockers alone in the setting of any sympathomimetic (e.g., cocaine) may leave the α-receptors "open," with subsequent worsening of hypertension. Therefore, an attractive alternative to β-blockers is labetalol, a β-blocker with some α-antagonist properties. However, the α- and β-

blockade with labetalol may not be equally effective. Although several studies report reductions in blood pressure and heart rate when labetalol is given to patients with cocaine toxicity, case reports indicate that some individuals may get worse. The clinical importance of the "unopposed α" effect of labetalol increasing blood pressure requires further investigation.

Benzodiazepine therapy is considered by some to be the first-line treatment for hypertension caused by catecholamine excess, especially in the setting of sympathomimetic (e.g., cocaine or methamphetamine) toxicity. It is believed that the central nervous sedation may blunt the sympathomimetic effects caused by central stimulation, therefore lowering blood pressure. Regardless of which benzodiazepine is selected as the therapeutic agent, it is important to titrate the dose to clinical efficacy while carefully observing for respiratory depression.

Hypertension in Pregnancy

The mainstay of antihypertensive treatment for hypertensive crisis in pregnancy in many institutions is hydralazine administered intravenously in boluses of 5 to 10 mg every 20 to 30 minutes. This dose is in addition to magnesium therapy for seizure control. If treatment is refractory to hydralazine, second-line agents are diazoxide and β-blockers. Calcium channel blockers have been studied in chronic hypertension among pregnant patients, but they may not be effective with proteinuric hypertension.

Asymptomatic Hypertension

In patients with asymptomatic elevations in blood pressure and no evidence of target-organ damage, there is no role for immediate lowering of blood pressure. The 2013 American College of Emergency Physicians clinical policy states explicitly that routine intervention is not required, though clinicians can consider beginning therapy in selected high-risk populations, and all patients should be referred for follow-up (level C recommendation).

CRITICAL INTERVENTIONS

- Base clinical decisions on correctly measured and repeated blood pressure.
- Search for and correct underlying causes of an elevated blood pressure (e.g., pain, hypoxia, bladder distention, ingestion, or withdrawal).
- Investigate complaints carefully for evidence of target-organ disease.
- Treat the blood pressure according to specific indications (e.g., ischemia).
- Avoid relative hypotension or dropping blood pressure in the absence of an indication.

DISPOSITION

All hypertensive emergencies require admission to a monitored setting. These patients generally require emergent involvement of an appropriate specialist for management of a neurologic, cardiovascular, or renovascular crisis. Close blood pressure monitoring, preferably with an arterial line, is indicated. Patients with preeclampsia/eclampsia require emergent obstetric consultation.

Most patients presenting with elevated blood pressures are not in crisis. In patients with asymptomatic elevated blood pressure with no evidence of target-organ disease, the most important intervention is to ensure proper follow-up (3,18). The goal should be life-long control of the blood pressure. When the elevated blood pressure may be the artifact of a systemic process such as pain or infection, the best strategy is to refer the patient for reevaluation of the blood pressure once the primary problem has resolved. If the patient has discontinued their blood pressure medications, the regimen should be restarted, barriers to compliance evaluated, and a primary care physician contacted to ensure reevaluation in a week. The JNC-VII guidelines recommend a thiazide-type diuretic as an initial agent, usually in combination with drugs from other classes (3). The second agent may be from a number of categories and is best chosen in

relation to any compelling indications in the patient's history (Table 90.4).

TABLE 90.4
Compelling Indications for Individual Drug Classes for Hypertension Therapy

Compelling Indication[a]	*Recommended Drugs*[b]					
	Diuretic	BB	ACEI	ARB	CCB	Aldo ANT
Heart failure	X	X	X	X		X
Postmyocardial infarction		X	X			X
High coronary disease risk	X	X	X		X	
Diabetes	X	X	X	X	X	
Chronic kidney disease			X	X		
Recurrent stroke prevention	X		X			

[a]Compelling indications for antihypertensive drugs are based on benefits from outcomes, studies, or existing clinical guidelines; the compelling indication is managed in parallel with the blood pressure.
[b]Drug abbreviations: BB, β-blocker; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blockers; CCB, calcium channel blocker; Aldo ANT, aldosterone antagonist.
From the National High Blood Pressure Education Program (JNC-VII) (3).

In principle, if there has never been a previous measurement of elevated blood pressure, the blood pressure needs to be rechecked during another visit before the diagnosis of hypertension can be made. However, in individuals with readings persistently >180/110 mm Hg in the ED, the latest national guidelines recommend starting a combination therapy immediately (3). Ideally, the physician who will provide ongoing supervision should be the one to pick the initial agents with which they are comfortable. The best role of the emergency physician is to identify a primary physician for the patient, encourage that physician to select an initial antihypertensive agent, and provide a follow-up appointment within the week.

There is an intermediate group of patients with a severely elevated blood pressure and with known target-organ disease but without

active decompensation. Examples include a severely hypertensive patient with a previous history of myocardial infarction or stroke. The immediacy arises because the patient with known target-organ disease may be considered at higher risk for a hypertension-related adverse event in the short term. There is no good evidence basis for how these patients should best be managed. These patients should have a treatment strategy initiated from the ED although the blood pressure does not necessarily need to be lowered during the visit. These patients do require an increased level of vigilance. It may be reasonable to treat these patients as outpatients, although some may need to be held for short-term observation if there is question as to medication compliance or blood pressure monitoring. The decision depends on the clinical judgment of the physician.

Common Pitfalls

- Diagnosing a hypertensive emergency when one does not exist. Patients with hypertensive emergencies have evidence of acute end-organ dysfunction.
- Reducing the blood pressure too quickly or to too low a level. In patients with chronic hypertension whose autoregulation curve has been reset, this reduction can lead to cerebral or cardiac ischemia.
- Lowering a patient's blood pressure acutely without an urgent indication.
- Failing to diagnose hypertension or preeclampsia in pregnant patients with blood pressures >140/90 mm Hg or with an increase in blood pressure of more than 30/15 mm Hg.
- Neglecting to match the antihypertensive agent to the clinical scenario.

SECTION IX
Vascular Emergencies

Section Editor: GREGORY W. HENDEY

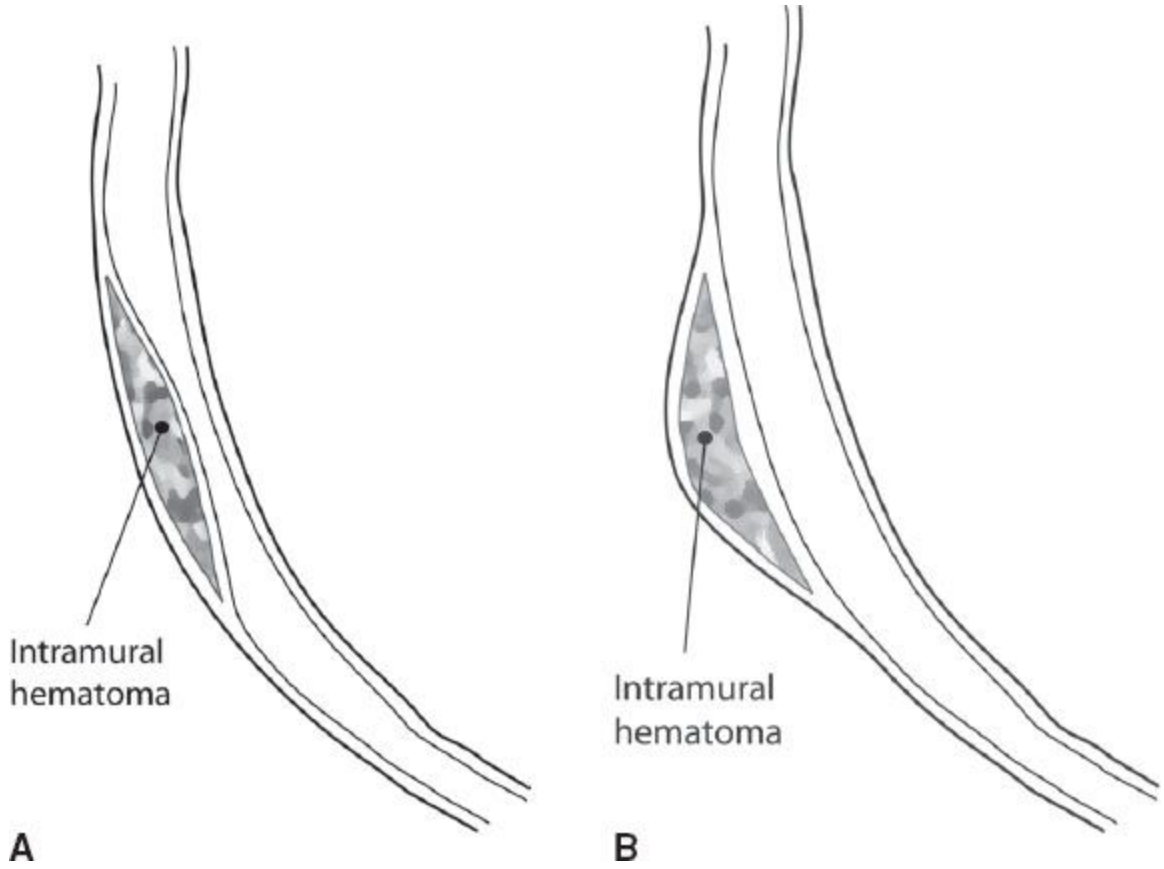
CHAPTER 91

Nontraumatic Carotid and Vertebral Artery Disorders

Brian Chinnock

PART 1: DISSECTION

Internal carotid artery (ICA) or vertebral artery (VA) dissection results from an intimal tear. Following the tear, blood under pressure enters the wall of the artery within the tunica media, forming an intramural hematoma. The hematoma, while contained within the tunica media, may press toward either the intima causing vessel stenosis (eFig. 91.1A), or toward the adventitia (eFig. 91.1B) causing aneurysmal dilation. Neurologic sequelae may result from either decreased blood flow, or more often from distal embolization of clots formed in this thrombogenic environment, causing CVA or TIA. In the intracranial portion of the artery, dissection may result in subarachnoid hemorrhage.



eFIGURE 91.1 A: Intramural hematoma producing vessel stenosis. B: Intramural hematoma causing aneurysmal dilation without vessel stenosis.

The extracranial ICA and VA are much more vulnerable to dissection than are the intracranial segments, probably due to increased mobility. Thus, the origin of the ICA dissection is typically just distal to the carotid bulb. VA dissection most commonly begins at its exit point from the transverse foramen between the first and second cervical vertebrae.

Together, ICA and VA dissections cause about 20% of strokes in patients younger than 45 years of age (1). ICA dissection is twice as common as VA dissection.

Spontaneous (atraumatic) dissections are thought to be the result of structural defects and connective tissue disorders, such as Ehlers–Danlos syndrome type IV, osteogenesis imperfecta, Marfan syndrome, and autosomal dominant polycystic kidney disease (2). Family history is important because 5% of patients with a spontaneous ICA or VA dissection will have a family member with an arterial dissection. Risk factors for the development of carotid and VA stenosis, such as hypertension, hypercholesterolemia, diabetes, or tobacco use, have not been found to be risk factors for dissection.

Spontaneous dissection of the ICA or VA is often associated with commonplace events that cause sudden neck movement or sustained positioning of the neck in a position that may predispose to vessel damage. Some of the reported events include forceful flexion–extension movements of the neck (coughing, sneezing, roller-coaster riding), prolonged neck extension (painting a ceiling or "beauty-parlor" syndrome where the neck is extended over the sink), or prolonged lateral bending (propping a phone between the neck and shoulder) (3–5). Chiropractic treatment is more commonly associated with VA than ICA dissection (6), probably because of the rapid rotation of C1 on C2 stretching the VA as it exits the foramen.

CLINICAL PRESENTATION

The median ages of patients presenting with extracranial ICA or VA dissection are 44 and 41 years, respectively (7). Intracranial dissection of either artery reportedly occurs in younger patients, 20

to 30 years of age (3). The clinical effects from arterial dissection generally result from the local effects of the dissection causing pain, and the distal embolization from the dissection site causing ischemic symptoms.

ICA Dissection

Table 91.1 illustrates the differences in the clinical presentation of ICA versus VA dissection. Headache is the most prominent initial complaint of the patient with ICA dissection. The headache is typically frontotemporal and unilateral. The onset is usually gradual, but "thunderclap" headaches have been described. Facial, eye, or ear pain, without headache, is described in 10% of patients (7). The unilateral neck pain is typically over the area of the carotid artery itself and has also been mistaken for a peritonsillar abscess. Oculosympathetic palsy (ipsilateral miosis and ptosis) is classically associated with ICA dissection, but only half of patients will have it. Oculosympathetic palsy can be differentiated from Horner syndrome in that there is no facial anhidrosis, because facial sweat glands are innervated by the sympathetic plexus surrounding the external, not internal, carotid artery. The focal cerebral and retinal ischemic symptoms of extracranial ICA dissection begin a median of four days after the onset of pain and are similar to those described for ICA-territory strokes (see Chapter 151) (7). In intracranial ICA dissection, the neurologic symptoms begin only a few hours after the onset of pain (8). The lower cranial nerves are commonly affected, particularly the hypoglossal nerve, and is thought to be caused by either compression or stretching of the nerve by the enlarged ICA or by interruption of nutrient vessels of the nerves (3–5).

TABLE 91.1
ICA Versus VA Dissection

Clinical Presentation (% Incidence of Finding)	
Carotid	**Vertebral**
Unilateral headache (67–90)	Occipital headache (66–83)
Unilateral facial/orbital pain (50)	Posterior neck pain (50)
Unilateral anterior neck pain (25)	Unilateral arm pain
Oculosympathetic palsy (50)	Isolated cervical cord ischemia
Pulsatile tinnitus (25)	Nausea, vomiting
Syncope	
Cerebral or retinal ischemic symptoms (50–95)	Vertebrobasilar ischemic symptoms (70–90)
Cranial nerve palsies (12)	Wallenberg syndrome
More likely to have preceding TIA	Less likely to have preceding TIA
Neurologic findings begin days after headache	Neurologic findings begin hours after headache

ICA, interval carotid artery; VA, vertebral artery; TIA, transient ischemic syndrome.

Vertebral Artery Dissection

As with ICA dissection, headache is the most common presenting complaint. The headache is almost always occipital, may involve the frontal area and may be intermittent. Neck pain is more commonly noted in VA dissection than in ICA dissection and is more commonly described as posterior. Unilateral arm pain may be noted when the dissection occurs within the cervical spine and compresses a cervical nerve root most commonly at the C5 to C6 level (4,9).

The focal ischemic neurologic symptoms are typically those of vertebrobasilar insufficiency, as described in Chapter 155. The classic finding is involvement of the posterolateral medulla and cerebellum, termed Wallenberg syndrome. The thalamus and cerebral hemispheres may also be affected, although less commonly than the cerebellum and brainstem. Importantly, neck pain has been described as beginning a median of about 2 weeks before the development of neurologic findings, but headache may precede neurologic symptoms by a matter of hours (10).

DIFFERENTIAL DIAGNOSIS

The main differential diagnoses for carotid and VA dissection before the development of focal neurologic symptoms are meningitis, subarachnoid hemorrhage, subdural or epidural hematoma, migraine or tension headache, and cervical strain, fracture, or radiculopathy. Once neurologic symptoms appear, the differential is similar to that of ischemic stroke. One of the main ways to differentiate ICA or VA dissection from these other disorders is the history of head or neck pain, followed hours to days later by ICA or VA-territory neurologic symptoms. The ideal situation is to diagnose and treat dissection before the development of neurologic symptoms. This is why it is important to consider ICA and VA dissection in the differential for headache and neck pain.

ED EVALUATION

When ICA or VA dissection is suspected by history and physical examination findings, the most important consideration is the imaging modality. The gold standard by which other radiologic tests are measured is four-vessel contrast digital subtraction angiography (DSA). The disadvantages of this procedure include its invasiveness and the need to have access to a specialist to perform the procedure. The most commonly used alternative radiologic tests are duplex ultrasound (DUS), magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), and computed tomography angiography (CTA).

Duplex Ultrasound

Extracranial DUS can identify intimal defects and aneurysmal dilation. In addition, color flow DUS is useful for identifying the true and false lumens seen in dissection. The true lumen typically has antegrade flow, and the false lumen has high-resistance flow that is forward, reversed, or bidirectional. DUS is limited by its inability to visualize intracranial dissection.

Two prospective studies have compared DUS to the gold standard of DSA or MRA in the evaluation of ICA dissection. The sensitivity of Doppler to detect flow abnormalities was 93% to 96%. Standard

DUS had a sensitivity of 72% to 79%, and color flow scanning had a sensitivity of 82% (11,12). The sensitivity of DUS has improved in the last decade owing to technologic improvements.

The use of DUS in the diagnosis of VA dissection is less clear because it is technically more difficult. Most VA dissections show abnormal flow patterns, but no finding is characteristic. Small case series have shown promise, but it is not currently the study of choice for suspected VA dissection.

Magnetic Resonance Imaging/Magnetic Resonance Angiography

MRI allows visualization of the intramural hematoma itself, as well as aneurysmal dilation. Contrast-enhanced MRA shows luminal irregularities and stenosis. The combination of MRI with MRA demonstrates a sensitivity of 84% to 100% and specificity of 95% to 100% when compared against DSA in small studies (13). One study that examined ICA dissection demonstrated a better sensitivity of the MRI/MRA combination than with DSA (14). DSA is unable to detect an abnormality if there is no luminal irregularity (eFig. 91.1B). MRI can also show cerebral parenchymal abnormalities in the affected vascular area, including acute ischemic lesions with diffusion-weighted MRI.

Computed Tomography Angiography

Multislice CTA gives excellent visualization of vessels because of the contrast difference between the enhanced lumen and surrounding structures. Postprocessing of the data in multiplanar formats can also provide three-dimensional images that closely approximate DSA but also show the surrounding soft tissues. Two studies examining CTA showed sensitivities near 100% for the diagnosis of ICA and VA dissection (15).

MRI/MRA VERSUS CT/CTA

Studies comparing MRI/MRA, CTA, and conventional angiography have shown similar high sensitivities and specificities (16). Small

studies have reported that CT/CTA has better ability to visualize specific anatomic features of the dissection, such as pseudoaneurysm, intimal flaps, and high-grade stenoses than MRI/MRA. However, MRI/MRA has the advantage of being able to detect ischemic lesions. The decision of which test is more appropriate should be guided by local protocol and resources. Whether CT or MRI is chosen, it is important to include both the standard and angiographic components.

KEY TESTING

- For suspected ICA or VA dissection, perform MRI/MRA or CT/CTA

ED MANAGEMENT

The treatment for an extracranial ICA or VA dissection is anticoagulation with heparin followed by coumadin. The goal is to reduce the risk of distal embolization, the most common cause of neurologic insult. Anticoagulation is contraindicated if there is intracranial dissection because of its theoretical risk of hemorrhagic transformation, or pseudoaneurysm. Despite the wide acceptance of anticoagulation, there is no controlled study comparing anticoagulation to placebo in the treatment of dissection. Antiplatelet agents such as aspirin, and, less commonly, ticlopidine and clopidogrel have been described as treatment options. There are no randomized trials comparing anticoagulant with antiplatelet drugs, and nonrandomized studies did not demonstrate any difference. Antiplatelet agents are often considered as first-line treatment in patients who are poor candidates for anticoagulation and in those patients who have a dissection with no ischemic symptoms. Thrombolytics have been used safely in one small study, but in 9 of 11 treated patients the vessel remained occluded (17). Blood pressure control to a normotensive level has a theoretical benefit in preventing extension of the dissection, but no studies have examined this treatment.

Surgery or endovascular treatment for ICA or VA dissection is used for those not responding to conservative measures. This includes patients with neurologic deterioration or ischemic insult despite adequate anticoagulation, or a persistent or worsening aneurysm after 6 months of anticoagulation. Intradural VA dissections are treated aggressively with endovascular therapy, as the rate of subarachnoid hemorrhage is high (15).

CRITICAL INTERVENTIONS

- Anticoagulation is the most common treatment option for extracranial ICA or VA dissection.

DISPOSITION

Patients with ICA or VA dissection should be admitted to the hospital to monitor for further progression of neurologic injury and to establish anticoagulation. Either neurology, neurosurgery, or vascular surgery should be consulted, depending on institutional arrangements.

The prognosis for neurologic recovery is good. Approximately 70% of extracranial ICA dissection patients have full neurologic recovery, 14% have a mild deficit, and 16% have a moderate to severe deficit or death (5). One long-term follow-up study of extracranial VA dissection patients showed 88% with good or excellent recovery and 12% with moderate or severe disability (18). Intracranial dissection patients and bilateral extracranial dissection patients have significantly higher morbidity and mortality rates.

Common Pitfalls

- Failure to consider the diagnosis in a patient with headache or neck pain associated with minor trauma, particularly if neurologic symptoms are present.
- Failure to consider the diagnosis in a relatively young patient with stroke symptoms.
- Failure to perform a CT or MRI in addition to the contrast angiography component of each of these examinations, as some

dissections will not be detectable on angiography

PART 2: STENOSIS

Stenosis or occlusion of the ICA or VA is most commonly caused by atherosclerosis. There is a 2% to 5% annual ipsilateral stroke risk for people with ICA stenosis of >50%. Although less is known about VA stenosis, symptomatic patients with >50% stenosis have a 1-year stroke risk of as high as 22% (19). ICA stenosis is responsible for approximately 30% of all anterior circulation strokes and transient ischemic attacks (TIAs). Cerebral ischemia may result directly from decreased blood flow, or more commonly, from distal embolization from the plaque.

The risk factors are those of atherosclerosis, and include hypertension, tobacco use, hypercholesterolemia, and obesity. Other less common causes of stenosis include fibromuscular dysplasia, radiation, and arteritis (i.e., Takayasu arteritis).

The most common location for extracranial ICA stenosis is at the carotid bulb, and for extracranial VA stenosis, at its origin from the aorta or brachiocephalic trunk.

ICA kinking and VA occlusion resulting from rotation (bow hunter syndrome) deserve special mention as they are causes of vessel occlusion without stenosis or dissection (20). ICA tortuosity with kinking is a common incidental finding on ultrasound or angiography. In some patients, the site of kinking can be caused by atherosclerosis and stenosis, and this is a source of potential embolization. It may also cause reversible cerebral ischemia during head or neck rotation.

The VA may also be occluded because of head or neck rotation. *Os odontoideum,* a condition in which the dens is hypoplastic, absent, or incompletely fused to the body of C2 with subsequent atlantoaxial instability and bony impingement on the VA during movement, is described as a cause. Other causes include impingement by nerve fibers of the stellate ganglion, or lateral cervical disk herniation.

CLINICAL PRESENTATION

The patient with symptomatic ICA or VA stenosis will usually present to the ED with symptoms related to stroke or TIA of the affected vascular area (see Chapter 155). Table 91.2 contrasts the neurologic findings associated with ICA versus VA stenosis, although there can be considerable overlap between the two.

TABLE 91.2
ICA- Versus VA-Territory Stroke or TIA

ICA Territory	VA Territory
Weakness and/or numbness contralateral face and extremities	Weakness and/or numbness ipsilateral face, contralateral extremities
Vision loss ipsilateral, monocular (amaurosis fugax)	Vision loss bilateral homonymous hemianopia
Aphasia	Ataxia
	Vertigo
	Diplopia

ICA, internal carotid artery; VA, vertebral artery; TIA, transient ischemic attack.

DIFFERENTIAL DIAGNOSIS

As noted previously, TIA and stroke are the most common events bringing the patient with ICA or VA stenosis to the ED.

ED EVALUATION

In addition to evaluating the patients for history and physical examination findings of stroke, imaging can be an important part of the evaluation for ICA or VA stenosis.

Internal Carotid Artery Stenosis

The degree of extracranial ICA stenosis can be used to predict which patients are at the highest risk for stroke and will get the most benefit from surgery. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) demonstrated that in patients with 70% to 99% stenosis demonstrated on DUS, carotid endarterectomy is superior to medical therapy in preventing stroke (21). A systematic review of trials done between 1994 and 2001 compared

imaging modalities to the gold standard of DSA in detecting 70% to 99% stenosis and gave the following pooled test characteristics: DUS, sensitivity 86% and specificity 87%; MRI/MRA, 95% and 90%, respectively; and the combination of MRA + DUS, 95% and 95%, respectively (22). More recently, CTA has shown good agreement with DSA, and may be especially helpful in evaluating the ICA in a patient with complete obstruction, as CTA can better show a small residual lumen, which may influence the decision of medical versus procedural management (23). DUS is highly operator dependent, and it is often used as the sole test in determining degree of stenosis at centers with expertise.

Vertebral Artery Stenosis

The degree of VA stenosis that is most clinically important is not well defined, although 50% to 99% is the range usually cited. A systematic literature review comparing DUS, MRI, MRA, and CTA to the reference standard of DSA demonstrated little high quality data directly comparing these modalities. However, using this data, MRA and CTA had the best sensitivity for detection of VA stenosis (24).

KEY TESTING

- Extracranial ICA stenosis is most commonly evaluated with DUS. MRA or CTA may be used if there is continued diagnostic uncertainty.
- Extracranial VA stenosis is evaluated with MRA or CTA.

ED MANAGEMENT

Acute treatment of stroke caused by ICA or VA stenosis is described in detail in Chapter 155 and includes prevention of hyperglycemia and hyperthermia and monitoring of volume status and blood pressure. An important intervention is to start the patient on antiplatelet therapy after ruling out hemorrhagic stroke with a CT scan. Aspirin, at a dose of 160 to 300 mg, has been shown to significantly decrease death and disability in acute ischemic stroke.

Clopidogrel and ticlopidine are alternatives for patients unable to take aspirin.

Patients with 70% to 99% symptomatic ICA stenosis as demonstrated on ultrasound are likely to benefit from carotid endarterectomy, but in patients with 50% to 69% stenosis, only certain subgroups, such as those with large hemispheric TIAs, may benefit from surgery (21). The CREST study compared carotid stenting to endarterectomy in an RCT of 2,502 patients and found no difference in combined stroke, MI, or death rate in a 2.5-year follow-up (25). Current practice is to stabilize the symptomatic patient medically prior to either procedure, but future studies may challenge this practice. Patients with 100% occlusion are treated medically.

The optimal treatment strategies for extracranial VA stenosis are more poorly understood. No RCT has shown an advantage of medical management, surgery, or endovascular stenting. Case series have demonstrated drug-eluting stent placement to have a low rate of periprocedural complications and restenosis rates comparable to non-drug-eluting stenting. Surgical options include endarterectomy or reconstruction (often done by transposing the VA to the common carotid artery). Surgery is recommended for patients with symptomatic ICA kinking. Correction of the process that causes extrinsic VA compression during neck rotation (i.e., atlantoaxial stability or cervical disk protrusion) is also necessary to prevent further cerebral ischemia.

CRITICAL INTERVENTIONS

- Aspirin (160 to 325 mg) is recommended for patients with symptomatic ICA or VA stenosis, or clopidogrel or ticlopidine for those patients who cannot take aspirin.
- Obtain imaging studies of patients with stroke or TIA to determine whether they may be candidates for carotid stenting or endarterectomy.

DISPOSITION

Stroke resulting from significant ICA or VA stenosis mandates admission to the hospital to monitor for deterioration, cerebral edema, or hemorrhagic transformation. Cardiac monitoring, swallowing studies, and aggressive rehabilitation are also commonly needed.

Patients with TIAs that are not crescendo or recurrent and are unlikely to have an embolic source may be candidates for outpatient care with urgent imaging and rapid follow-up. However, 5% of patients presenting to an ED with a TIA will have a stroke within 2 days after presentation. Consultation should involve the patient's primary care doctor and/or a neurologist. Patients who are found to have significant ICA or VA stenosis as an acute cause of TIA or stroke are candidates for inpatient evaluation for endarterectomy or angioplasty.

Common Pitfalls

- Failure to recognize the difference between ICA and VA territory neurologic symptoms. A normal carotid DUS study is irrelevant when the symptomatology suggests VA stenosis.
- Failure to consider ICA kinking or "bow hunter syndrome" in the patient with stroke or TIA symptoms with head or neck rotation.

CHAPTER 92

Thoracic Aortic Dissection and Aneurysm

Shawna J. Perry

THORACIC AORTIC DISSECTION

Aortic dissection is the most frequently occurring catastrophic event involving the aorta. First recognized postmortem by Morgagni in 1761, aortic dissection remains a diagnostic challenge to the emergency medicine physician because of its nonspecific presentation, diverse population at risk, and time pressure for diagnosis. Delays or misdiagnosis can have devastating consequences.

Dissection of the aorta begins with a tear in the innermost layer of the vessel, the intima. This tear occurs most commonly in the proximal ascending portion of the thoracic aorta. The tear may begin in the aortic root or between the origin of the left subclavian artery and the ligamentum arteriosum. These areas of the aorta are relatively fixed, and it is believed that a tear can be initiated when maximum stress is applied to these areas during systole. An intimal tear can then allow blood to penetrate into the media layer of the aorta (middle layer of a blood vessel), separating the intimal layer from the outermost layer of the vessel, the adventitia. The length of time required to dissect the entire aorta can be seconds, with the dissection continuing either distally or proximally. Reentry tears occur distal to the initial site, creating a false lumen which provides an alternate path for aortic blood flow. An intramural hematoma can develop within this false lumen, minimizing flow and occasionally causing dilation. The dissection may dilate as the flow of blood increases through the false lumen or as an intramural hematoma organizes. The term *dissecting aneurysm* is frequently used because of this pathologic finding of dilation, but the term is inaccurate, because this is not a true aneurysm. Spontaneous rupture is common, occurring most often into the pericardium. A small number of patients develop an intramural hematoma within the dissection with no evidence of a reentry tear. A dissection that begins with a tear high in the aorta that is associated with an open false lumen, has a very poor prognosis.

The exact causes of the intimal tear and other structural defects of the aortic wall remain unclear. The classic pathologic model is based on histologic changes found in patients with Marfan syndrome that demonstrate recurrent injury and repair to the aorta associated with cystic medial necrosis. This model is expanding to include a variety of molecular derangements that result in collagen and elastin degradation within the aorta (1). The result is a weakening of the aortic wall that may then make it more susceptible to injury from another insult, such as chronic hypertension.

Hypertension is the most common predisposing factor to dissection. It is not yet known why one hypertensive person undergoes dissection and another does not. Aortic dissection is likely a multifactorial disease, with hypertension as the principal risk factor. Marfan syndrome is a widely recognized risk factor that carries a mortality rate over 90% in the event of acute dissection or rupture. Connective tissue diseases such as Ehlers–Danlos syndrome, systemic lupus erythematous, and Turner syndrome, have all been associated with aortic dissection. Cigarette smoking and dyslipidemia may be contributing factors, although aortic dissection does not occur secondary to atherosclerotic disease. Congenital abnormalities of the aorta, such as bicuspid valve and coarctation, are also risk factors. Dissection has also been reported in the third trimester of pregnancy, during the postpartum period and in association with cocaine and methamphetamine use, blunt trauma, and weightlifting. Most of these patients have evidence of systemic hypertension or connective tissue abnormalities similar to those of Marfan syndrome (2,3). Iatrogenic aortic dissection can result from invasive vascular procedures (i.e., cardiac catheterization) or nonaortic cardiac surgery such as a valve replacement or coronary artery bypass graft (CABG) (4).

CLASSIFICATION

DeBakey originally classified aortic dissection into three categories according to the origin of the dissection: Type I, involving the entire length of the aorta; Type II, beginning in the ascending aorta (the aortic root to the left subclavian); and Type III, originating from the

area distal to the left subclavian (5). The Stanford classification, a simpler and more widely used nomenclature, divides dissections into type A, involving the ascending aorta, and type B, beginning after the left subclavian artery and confined to the descending aorta (Fig. 92.1).

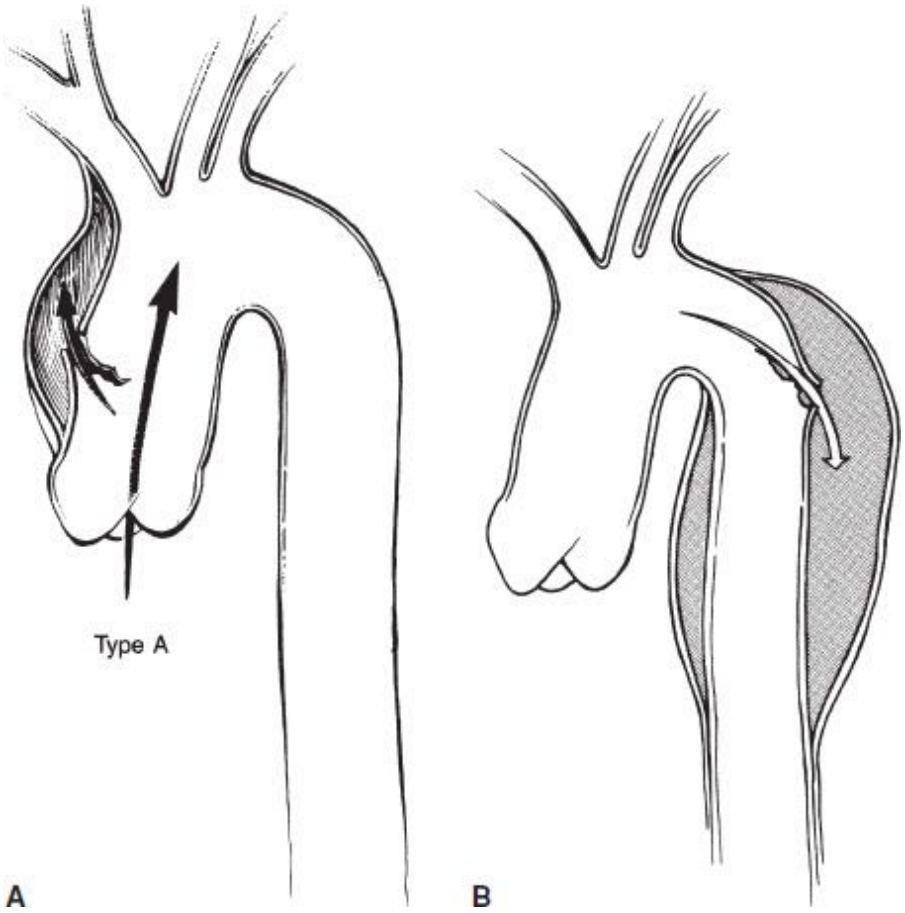

FIGURE 92.1 Classification of aortic dissections. **A:** Dissection of ascending aorta. **B:** Dissection of descending aorta.

Type A dissections are the most common (80%) and considered surgical emergencies. Potential complications include aortic rupture, cardiac tamponade, aortic valve insufficiency, shock, stroke, and involvement of coronary arteries resulting in acute cardiac ischemia and arrhythmias (e.g., atrial fibrillation from direct compression of atrium) (6). Type B dissections are predominantly managed medically, but up to one-fourth of patients require urgent operation because of hemorrhage, limb or organ ischemia, intractable pain,

progression of dissection, expansion, or impending rupture. Women tend to present with dissection at a later than men (over 70 vs. 61 years of age).

The most common cause of death for untreated type A dissections is rupture of the aortic wall into the pericardial sac. This rupture usually occurs along the right lateral wall of the aorta where the adventitia is thinnest. Rupture may also occur into the mediastinum, pleural space, abdomen depending upon how far the dissection extends. Death may result from associated pericardial tamponade, myocardial infarction, hemorrhagic shock, acute congestive heart failure, or cerebrovascular accident. Patients with painless acute aortic dissection have a very high mortality rate, especially when it is type B, and are more likely to have associated congestive heart failure, syncope, and a history of previous cardiovascular surgery (7).

The mortality rate for patients with untreated or medically managed type A dissection ranges from 52% to 75%. Risk factors for death include age over 70 years, hypertension, preoperative cardiopulmonary resuscitation or shock, lack of cerebral perfusion, syncope with residual neurologic dysfunction, cardiac tamponade, migrating pain, pulse deficit, or ECG findings of myocardial ischemia (8). Of note, women with Type A dissections tend to be diagnosed 24 hours later than men, and are more likely to present with gradual onset, altered mental status, and complications (myocardial infarction, pericardial effusion) (9). The in-hospital postsurgical mortality for all patients with type A dissection averages 26%, but is higher for women (32%) (9,10). Because mortality rates for uncomplicated type-B dissections are the same with either medical or surgical treatment, medical therapy is preferred. The use of β-blockers and afterload-reducing medications appears to decrease the risk of extension or dilation of the dissection. Medical treatment does not stop the progression of the disease indefinitely, and aortic replacement is eventually needed. With aggressive medical management the early mortality rate of uncomplicated acute type B dissection is 8% to 10%, and with continued pharmacologic therapy 1-year and 4-year mortality of 72% and 81%, respectively (11,12). Emergent surgery is indicated in type B dissections that are

complicated by rupture, leak, ischemia, intractable pain, uncontrollable hypertension, or aneurysm, but with generally poor results (11). Death is almost certain in the presence of mesenteric, renal, or peripheral vascular ischemia. Newer treatment options include percutaneous stent-graft placement, also known as thoracic endovascular aortic repair (TEVAR), which may provide better results than open surgical repair of Type B dissections (10,13).

CLINICAL PRESENTATION

To make the diagnosis of aortic dissection, the emergency medicine physician must include it in the differential diagnosis at patient presentation. The pain of aortic dissection is classically described as "ripping" or "tearing"; however, this can also be associated with a number of other entities. A study of 464 patients with aortic dissection found that the classic tearing or ripping sensation was reported in only 51% of cases (12). The majority reported the abrupt onset of severe pain, either sharp or dull, located in the anterior or posterior chest (73%). Back pain was experienced in 53% of patients, with 30% reporting abdominal pain and a few experiencing pain across the chest, back, or abdomen (12,14). Type A aortic dissection in the elderly is less likely to be associated with abrupt back and chest pain or to manifest findings such as aortic regurgitation or pulse deficit (10). The nonspecific and variable presentation of aortic dissection makes the identification of risk factors important for early diagnosis; these include a history of hypertension, Marfan syndrome, connective tissue or autoimmune disorder, cocaine or methamphetamine use, and prior cardiac surgery (i.e., valve replacement, cardiac catheterization).

In addition to pain in the chest and back, discomfort may also be localized to the neck, throat, mandible, abdomen, and leg. Patients may also complain of pain in the lower back, pelvis, or a lower extremity of dissection extends beyond the diaphragm. One emergency department (ED) study found that dissection was more likely to be suspected in patients with dissection who presented with both chest and back pain (86%) but less likely to be considered in patients who had only chest pain (45%) or abdominal pain (8%)

(15). Fifteen percent to 20% of dissections are associated with no pain at all. Patients with sudden onset of pain, followed by a pain-free interval, appear to be especially likely to be missed (8).

The patient may appear to be in shock, exhibiting cool and diaphoretic skin, yet with paradoxically normal or elevated blood pressure. Although most patients present this way, nearly one-fourth present with hypotension, presumably due to leaking or rupture. A variety of signs and symptoms are caused by vascular compromise from the dissection. The majority are neurologic and include syncope, altered mental status (especially in women), stroke, seizure, visual disturbances, or paraplegia. Syncope is the initial complaint in 13% of patients, but decreased level of consciousness occurs more frequently. Syncope may be associated with the development of hemopericardium or stroke, and is associated with increased mortality (16).

Cardiovascular collapse is seen most often with Type A dissection. A developing hematoma can cause hoarseness (laryngeal nerve compression), dyspnea, stridor with wheezing (tracheal compression), or dysphagia (esophageal compression). The presence of hypotension in the presence of chest and back pain strongly suggests either a Type A dissection, a rupture of either type of dissection, or a dissection into the mesenteric or brachiocephalic artery. Gastrointestinal symptoms of midepigastric pain, melena, or frank hemorrhage can occur secondary to splanchnic vessel infarctions and are frequently misdiagnosed. Dissection into the renal artery may lead to hematuria, flank pain, oliguria, or uncontrollable hypertension because of excess renin release. Unusual presentations of aortic dissection have included hemoptysis, superior vena cava syndrome, acute arterial occlusion, right atrial or ventricular rupture, testicular pain, and deep-vein thrombosis.

DIFFERENTIAL DIAGNOSIS

Chest pain with associated back pain is the most prevalent symptom of aortic dissection; however, the differential diagnosis of this constellation is broad and contains numerous other life-threatening conditions. Myocardial infarction is the principal diagnosis of

exclusion as well as cerebrovascular accident in patients with neurologic symptoms. In fact both MI and stroke may result from thoracic aortic dissection. Misdiagnosis of either could result in the use of thrombolytic therapy and therein an increased risk of death from exsanguination. Other diagnoses to be considered are hypertensive crisis, pulmonary embolism, thoracic aneurysm, pneumothorax, multilobar pneumonia, mediastinal cyst or tumor, pericarditis, pancreatitis, cholelithiasis, cholecystitis, perforated viscus, esophagitis, peptic ulcer disease, gastritis, and peripheral vascular disease.

The diagnosis of aortic dissection should be considered in the presence of the following: history of hypertension, connective tissue disease, congenital aortic abnormalities, aortic insufficiency, atypical chest or back pain, acute neurologic symptoms, diminished or absent peripheral pulses (especially if they reappear), syncope, chest pain in pregnancy (third trimester and postpartum), chest trauma, flank pain and hematuria without an obvious source, evidence of multiple sites of ischemia, and chest pain following the use of cocaine or methamphetamine.

ED EVALUATION

Patients suspected of aortic dissection should be evaluated quickly and managed aggressively in anticipation of impending leak or rupture. On physical examination, initial hypertension is very common (systolic >150 mm Hg), but the patient may still appear clinically to be in shock. Jugular venous distention should be assessed, as it may signify cardiac tamponade, an expanding hematoma around the aorta with outflow obstruction, or congestive heart failure. Aortic insufficiency murmurs occur in 16% to 20% of patients as a result of proximal dissection causing dilation of the aortic valve ring.

Abdominal examination may reveal decreased or absent bowel sounds, tenderness, or rigidity secondary to ischemia. Rarely, a pulsatile mass is palpable. Examination of the limbs may reveal unequal, decreased, or absent peripheral pulses in 50% of cases, with these findings less likely to be present in the elderly (17). A complete

deficit of pulse is found in only 8% to 10% of patients. A pulse deficit can be easily assessed at the bedside by comparing the measured blood pressure between both arms, or between the arms and legs. Cranial nerve deficits secondary to dissection into the carotid arteries or motor deficits secondary to distal dissection of spinal arteries have also been reported.

Initial laboratory studies should include a complete blood cell count with differential, serum electrolytes, troponin, coagulation studies, lactate, urinalysis, and a 12-lead ECG. A specimen should be sent for type and crossmatch. Lipase and liver function tests should be considered if there is suspicion of intra-abdominal pathology.

Although routine laboratory studies are not usually helpful in the diagnosis of aortic dissection, they may rule out other causes and help guide resuscitation. The hematocrit may be low if there is leakage, rupture, or if a sufficient amount of blood has accumulated in the false lumen. Renal artery involvement may result in increased blood urea nitrogen and creatinine levels as well as hematuria, indicating ischemia or infarction of the kidney. An elevated lactate level may suggest shock or ischemic bowel. A small number of patients dissect proximally into the right coronary artery and suffer a myocardial infarction. Normal troponin levels may help distinguish dissection from MI, but it must be kept in mind that dissection and MI coexist in some cases. EKG changes can be found in 50% of patients with dissection, with approximately 25% demonstrating ECG changes compatible with myocardial infarction or pericarditis (6). In some cases, testing the urine for drugs of abuse may be appropriate. D-dimer has shown promise, in that it is elevated in most patients with aortic dissection. Whether it can reliably exclude this lethal disorder has not been established.

The most readily available radiologic study to assist in the diagnosis of aortic dissection is the chest radiograph. In 65% to 85% of cases, the chest radiograph demonstrates some abnormality. A widened mediastinum is the most common finding, but a left-sided pleural effusion or an indistinct aortic knob may also be seen (Fig. 92.2). The deviation of a calcified aortic intima by >6 mm from the outer wall of the aorta is considered pathognomonic of dissection.

Other findings suggestive of dissection are the double density sign (a false lumen that is less radiopaque than the true lumen), tracheal deviation, and an irregular aortic contour. Unfortunately, a normal chest radiograph does not exclude the diagnosis. If suspicious for dissection, radiographic confirmation is required by either computed tomography (CT) or transesophageal echocardiography (TEE).

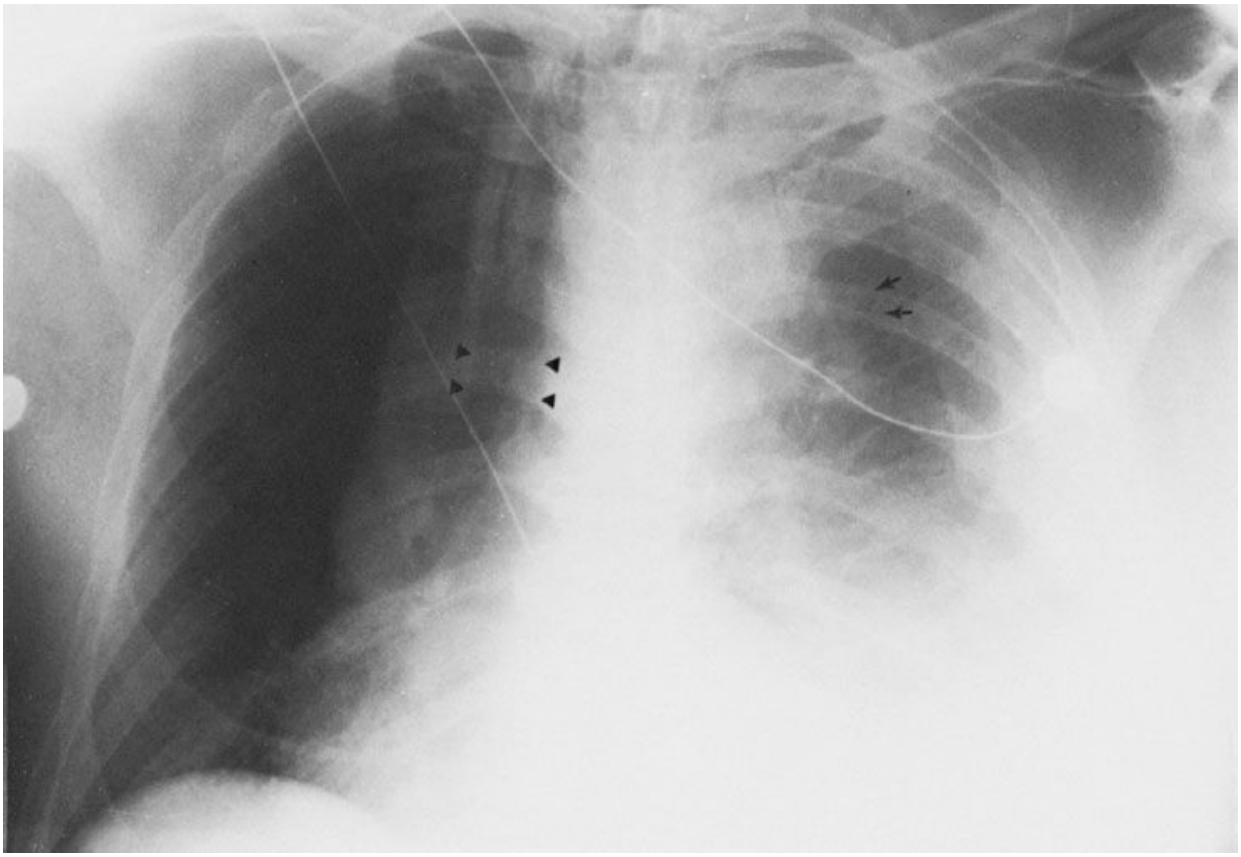

FIGURE 92.2 Chest x-ray film of a 65-year-old woman with type-A dissection. Note the widened mediastinum, indistinct aortic knob (*arrows*), tracheal deviation (*triangles*), and left pleural effusion.

In most institutions, CT angiography (CTA) has supplanted aortography for making the diagnosis of dissection. The advantages of CT include superior visualization of intimal flaps and fluid collection in the pericardium, pleura, and mediastinum; demonstration of distal aortic patency; noninvasiveness; and sensitivity and specificity equal to aortography. Three-dimensional reconstruction of CT images provides delineation of the intimal tear

and assessment of the great vessels, with sensitivity and specificity similar to that of TEE and magnetic resonance imaging (MRI). The main disadvantages of CT include the exposure to contrast material and radiation.

TEE, if readily available, can be used as the initial diagnostic study in suspected dissection, especially for unstable patients who cannot be moved to CT scan. TEE has a sensitivity and specificity of 99% and 98%, respectively. The goals of TEE in aortic dissection are to confirm the diagnosis, differentiate true and false lumens, localize the intimal tear, evaluate left ventricular wall motion, determine the presence of fluid collections, and to detect aortic insufficiency. TEE has a reported diagnostic accuracy of 100% for aortic insufficiency and cardiac tamponade but has limited ability to evaluate the great vessels and coronary vessels. Complications of transient atrioventricular (AV) block, bradycardia, and asthma can occur during introduction of the probe (18). Images may be limited in obese or emphysematous patients. TEE can be combined with CTA.

MRI has high sensitivity and specificity, but it is seldom used in the emergent setting because of cost, length of time needed for the study, and relative unavailability. Emergency physician–performed bedside ultrasound should not supplant more definitive assessment by CTA and/or TEE.

KEY TESTING

- Basic laboratory studies, troponin, EKG
- Advanced imaging with CT angiogram or TEE

ED MANAGEMENT

The patient should be placed in a high acuity area, on a cardiac monitor, with intravascular access established with at least *two* large-bore catheters (16 gauge or larger). The goals of ED management are to reduce the arterial blood pressure and to decrease the forceful contractility of the left ventricle, in an attempt to limit the propagation of the dissection. Systolic blood pressure control is important because the rate of dissection is directly proportional to

the rate of rise of arterial blood pressure. The systolic blood pressure should be maintained at 100 to 110 mm Hg (mean arterial pressure of 60 to 80 mm Hg) or the lowest level compatible with adequate renal and cerebral perfusion. This is best achieved by titrating intravenous (IV) medications. Direct arterial blood pressure monitoring (e.g., through a radial arterial catheter) can aid management but should not delay treatment. If suspicion for dissection is high, treatment should be initiated rapidly and before confirmatory tests are performed.

β-blockers are first line for controlling blood pressure in aortic dissection but are relatively contraindicated with known or suspected cocaine toxicity. Esmolol IV is the drug of choice (0.5 mg/kg loading dose in 1 minute, infusion rate of 0.05 mg/kg/min). Propranolol IV may also be used (0.5 to 1 mg increments at 5-minute intervals) as well as metoprolol or labetalol. Acute congestive heart failure, heart block, and bradycardia are contraindications to β-blocker use. Nitroprusside IV at an initial rate of 0.5 to 1 μg/kg/min or nicardipine IV (5 mg/hr initially) can be added or additional blood pressure control *after* β-blockers have been initiated. Fenoldopam IV (0.1 μg/kg/min initially) is a dopamine-1 agonist that can be used as an alternative to nitroprusside in patients with renal impairment, but it has a longer half-life (5 to 9 minutes) and may cause reflex tachycardia and ECG changes. Verapamil IV or diltiazem IV may also be used if β-blockers are contraindicated. Morphine IV can also assist in reduction of blood pressure by treating pain associated with the dissection. Oral agents should *never* be used in the emergency setting for patients with suspected or confirmed aortic dissection.

CRITICAL INTERVENTIONS

- Aggressive blood pressure control with short-acting agents such as β-blockers IV
- Expedient consultation with a thoracic surgeon for early operative management

DISPOSITION

Management of the patient with aortic dissection requires a multispecialty approach. The radiologist should be consulted emergently to obtain and read the appropriate diagnostic procedures. The cardiothoracic surgeon should also be notified as quickly as possible. Cardiology may need to be consulted to obtain an emergent TEE. Once the diagnosis of dissection has been made, an internist or intensivist may also need to be consulted for medical management, especially if a stable type B dissection is found. Patients with acute aortic dissection should be admitted to an intensive care unit.

Indications for transfer include inadequate facilities or personnel to definitively make the diagnosis or to treat the condition. If transfer is indicated, a unit that can provide the appropriate speed and level of care during transport is highly recommended, such as air transport or critical care transport.

Common Pitfalls

- Failure to consider the diagnosis of aortic dissection. Unexplained, severe, and sustained chest pain (especially with associated back pain) must be evaluated with CT or TEE to definitively rule out dissection.
- Failure to obtain early consultation with a radiologist and cardiothoracic surgeon.
- Failure to arrange rapid transfer to the nearest appropriate hospital, if presenting facility has inadequate resources for diagnosis or management of dissection.

THORACIC AORTIC ANEURYSM

Thoracic aortic aneurysm (TAA) is insidious in onset and presentation. Defined as a localized or diffuse dilation of the aorta, surgical intervention is needed at a diameter of 5.5 cm or greater, except for patients with Marfan or bicuspid aortic valve in which the critical diameter is 5 cm or greater. Dilation is the result of an undermining of the overall strength of the aortic wall by direct loss of supportive proteins such as elastin and collagen. Once the wall of the aorta is weakened, there is progressive alteration in anatomy,

with a growing diameter and thinning of the aortic wall that leads to dilation and rupture. Turbulent flow can lead to thrombus formation. The risk of rupture, dissection, or death increases exponentially when the diameter is >6 cm^3, known as the "hinge point" upon which the tensile strength of the tissue is overcome. Causes for the undermining of the aortic wall are listed in Table 92.1.

TABLE 92.1
Diseases Contributing to Thoracic Aortic Aneurysms

Atherosclerosis
Coarctation of the aorta
Cystic medial necrosis
Giant cell arteritis
Marfan syndrome
Mycotic aneurysms
Seronegative spondyloarthropathies
Syphilis
Tuberculosis
Takayasu arteritis

The incidence of TAA is 10.4 per 100,000 with 3.5 per 100,000 developing dissection or rupture (14). It affects men and women equally and is more common with advancing age. Risk factors are hypertension, advanced atherosclerotic disease, and smoking. The natural history of TAA is one of progressive dilation and rupture, with a 76% mortality rate at 2 years in untreated patients (19). Aneurysm diameter is a significant risk factor for rupture. The median size at time of rupture is 6 cm for ascending aneurysms and 7 cm for descending aneurysms. The average increase in diameter is 0.1 cm per year (0.7 cm ascending and 0.19 cm descending), and the risk of rupture increases dramatically as the diameter increases (19). Rupture occurs at smaller diameters in patients with connective tissue disorders such as Marfan syndrome. Surgical intervention is planned according to the patient's stability at the time of diagnosis and the diameter of the aneurysm as monitored through time, with an annual calculation of risk of rupture (20). Five-year survival from

elective TAA repair is 87%, but only 37% after emergent surgical intervention (21).

The clinical presentation of TAA in the ED is often that of an incidental finding on chest x-ray. Occasionally, patients will present with aortic regurgitation murmurs or with symptoms directly related to impingement of thoracic structures by the aneurysm (e.g., hoarse voice from compression of the recurrent laryngeal nerve or atrial fibrillation from left atrium compression). The rare patient with rupture or impending rupture may present with deep, aching or throbbing chest or back pain with or without hypotension. A sudden escalation of pain and sudden onset of hypotension are signs of aneurysm rupture. Rupture may also present as cardiopulmonary arrest secondary to intrathoracic or intra-abdominal hemorrhage, if the aneurysm extends beyond the diaphragm.

The ED evaluation should focus on imaging to define the aneurysm. CTA and TEE can be used to evaluate suspected aneurysms, depending upon the stability of the patient. If the diagnosis has not been made previously, aneurysms suspected in the ED should be evaluated at the time of presentation, even if they are asymptomatic. Consultation with a thoracic surgeon is imperative for determination of a treatment plan, even if asymptomatic. Patients who do not need immediate surgical repair may need medical consultation for blood pressure control and should have periodic outpatient diagnostic tests to monitor the aneurysm diameter. First-order relatives of patients with known thoracic aneurysms should be screened, because approximately 20% may be found to have aneurysms.

The ED management of the symptomatic patient with rupture or impending rupture requires immediate aggressive resuscitative measures, including close cardiac monitoring including EKG, two large-bore IV access, and resuscitation with fluids and blood. Bedside ultrasound can be of assistance in locating collections of fluid in the chest, abdomen, or pericardium. Emergent involvement of the thoracic surgeon is imperative if surgical repair is a possibility, with prompt transfer to another facility if the necessary imaging, critical care, and surgical expertise are not readily available.

CHAPTER 93

Abdominal Aortic Aneurysm

Matthew R. Lewin and Stephen P. Samuel

The timely recognition of an abdominal aortic aneurysm (AAA or "triple A") is a major challenge to the emergency physician. The presentation may be confusing, diagnosis difficult, and the cost of delayed or missed diagnosis devastating (1). AAA is one of the most common causes of unexpected death after discharge from the emergency department (ED) (2) and is one of the highest risk areas for medical malpractice litigation in emergency medicine (3).

AAA is defined as a 50% or greater increase in aortic diameter or an infrarenal aortic diameter ≥ 3 cm (4). Two percent to 5% of elderly patients have an AAA (5). The majority of patients are male, but the prevalence of AAA increases with age in both sexes (6). As the population continues to age, emergency physicians can expect to encounter patients with AAAs more frequently.

Despite a clear link to atherosclerosis, the etiology of AAA remains incompletely understood. Smoking is the strongest independent risk factor for AAA (7), but familial, biochemical, and hemodynamic factors have been implicated as well and are overtaking smoking as associated causes (8). Evidence suggests that up to 20% of AAAs have a dominant genetic component with incomplete penetrance, highlighting the importance of family history when examining patients with abdominal or back pain (9). Recently, matrix metalloproteinases and localized chronic inflammation are thought to play key role in the pathophysiology of AAA (9).

The natural history of the AAA is one of gradual expansion (although sudden changes in size may occur) followed by rupture, exsanguination, and death. Most AAAs are asymptomatic until rapid expansion or leakage occurs. The appearance of symptoms is associated with an 80% 1-year mortality in untreated patients (33% in 1 month and 74% in 6 months) (10).

The risk of rupture and death depends primarily on aneurysm size. Small aneurysms (3 to 5.4 cm) are at low risk for rupture; between 5.5 and 6.9 cm, the incidence of rupture at 1 year is 9.4% to 10.2%; and for aneurysms measuring $\geq$7 cm, the 1-year rate of rupture climbs to 32.5% (11). Early detection and elective repair of AAAs, now primarily done by interventional radiologists, leads to increased life expectancy, even for elderly patients. Thirty-day mortality after elective surgery ranges from 1% to 7% (12). However, given that rupture of an AAA is inevitable given enough time and that mortality in the setting of rupture exceeds 80%, elective resection is generally recommended for aneurysms of 5.5 cm or more in men and aneurysms $>$5 cm in women (8). Four major trials to date demonstrate no advantage to immediate repair (via open or endovascular surgery) for small AAA (4 to 5.5 cm) and favors image-based surveillance (13).

CLINICAL PRESENTATION

AAAs typically present in three ways: asymptomatic; symptomatic but hemodynamically stable; and ruptured. The latter two are immediately life-threatening complications of AAA for which delayed or missed diagnosis is likely to be catastrophic.

Asymptomatic Aneurysm

Occasionally, an AAA is discovered on routine examination for another, unrelated problem. Frequently, the aneurysm is noted on abdominal plain films, CT scan or other imaging study. The emergency physician's task in this setting is to confirm that the aneurysm is truly asymptomatic and to refer the patient to primary care or outpatient surgical consultation.

Symptomatic Aneurysm

Patients who are hemodynamically stable but who have symptoms potentially referable to an AAA can present in a variety of ways, and are therefore easily misdiagnosed. In fact, almost one half of all symptomatic AAAs are misdiagnosed at their initial presentation (1). The cardinal symptoms of AAA—abdominal, low back, or flank pain—are highly nonspecific (14). Discomfort occasionally radiates to the testis or leg, causing the symptoms to be misattributed to renal colic, inguinal hernia, or lumbar spine disease. The pain is usually not much affected by movement and can vary considerably in location. Radicular findings, isolated hip pain or hematuria may be present, misleading the physician. Of note, the pain of AAA may be associated with syncope at the time of onset (15).

Less common presentations of symptomatic AAA include hydronephrosis or leg swelling (usually left), new onset or worsening of hypertension (secondary to renal artery compression), testicular swelling, or evidence of peripheral embolization. Aortovenous or aortocaval fistulas are uncommon and usually present as high-output failure with marked distention of the lower abdominal and leg veins, accompanied by more typical evidence of AAA, such as abdominal mass and back pain (15).

About 10% of patients with symptomatic AAAs present with severe pain and marked abdominal tenderness (10). Because these patients have the appearance of an acute abdomen, recognizing the urgency of the situation is straightforward, even though the presumptive diagnosis may be erroneous (e.g., perforated viscus). Symptomatic AAA may present acutely as complete aortic occlusion with a clinical picture similar to that of a saddle embolus or acute Leriche syndrome (impotence due to aortoiliac compression). Even with prompt operative intervention, this complication carries an approximate 50% mortality (10).

An uncommon acute presentation of a symptomatic AAA is gastrointestinal bleeding secondary to an aortoenteric fistula, most commonly in a patient who has had previous AAA repair. Such bleeding may be massive and can distract the emergency physician

from suspecting vascular disease. In particular, aortoenteric fistula should be assumed whenever a patient who has had a previous repair of an AAA presents with gastrointestinal bleeding. Emergency physicians should be familiar with identification and management of such postoperative complications of both conventional and endovascular AAA repair. Fortunately, with the increasing utilization of endovascular techniques, postoperative abdominal complications have declined. Nevertheless, aneurysm remodeling and shortening can cause stent-graft dislodgment or kinking, and progression of underlying atherosclerotic disease can cause compression of the lower limbs of the graft (16). Post-AAA endograft complications include pelvic ischemia, impotence, buttock claudication, and colonic ischemia (17).

Ruptured Aneurysm

The classic triad of findings in ruptured AAA is back pain, hypotension, and a pulsatile abdominal mass, but only about one-half of patients who survive to reach the ED manifest all three findings (7). Therefore, the presence of any one of these findings in a patient with a known AAA is sufficient to make the presumptive diagnosis of rupture without confirmatory testing (18). Unfortunately, most patients presenting with a ruptured AAA have no prior knowledge of their aneurysm, thus increasing the need for emergency physicians to be alert to the possibility of ruptured AAA in the presence of any of these presenting findings (19).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AAA includes the large number of causes of shock, abdominal pain, and back pain. If shock is present, it is important to consider AAA along with myocardial infarction, hemorrhagic pancreatitis, perforated viscous, mesenteric infarction, and infection alone or in conjunction with ruptured AAA. In patients whose presentation is less severe, renal or biliary colic, diverticulitis, and lumbosacral disc disease also need to be considered. Because these conditions are much more common than

AAA, aneurysm is often low on the differential. Nevertheless, with its potentially catastrophic outcome, ruptured AAA should always be given due consideration.

ED EVALUATION

Symptoms and signs of AAA are varied and nonspecific. Physical examination is important in early recognition, because about one-half of asymptomatic AAAs are palpable (19). Only 30% to 50% of acute AAA patients present with the classic triad of hypotension, pulsatile mass, and abdominal or low back pain and 30% are misdiagnosed with renal colic, diverticulitis, or GI bleed (20). Most palpable aneurysms are found in the epigastrium, extending to the paraumbilical areas on both sides of the midline. The sensitivity of physical examination depends on the size of the aneurysm, ranging from about 60% for aneurysms between 3 and 4 cm to 82% for those >5 cm (12). Unfortunately, this sensitivity is not sufficient to confidently rule out an aneurysm based on a negative physical examination. *False-positive* physical findings are also common, illustrating the difficulty of the diagnosis (17).

Laboratory studies are rarely helpful in the diagnosis of AAA but should be obtained in the symptomatic patient to evaluate the status of other comorbid conditions (diabetes and renal insufficiency, among others), to investigate other possibilities in the differential, or to guide resuscitation. Blood cell counts and coagulation studies should be evaluated in patients with suspected hemorrhage or coagulopathy, and blood should be made available in the blood bank in such cases, including O type blood for STAT administration if needed.

Radiographic Imaging

Plain films of the abdomen are occasionally helpful in the diagnosis of AAA, in that calcified walls sometimes provide a visible contour of a dilated aorta (12) and is also implicated as a risk factor for rupture of aneurysm (21). Though such fusiform calcifications indicate the presence of an AAA, they do not distinguish enlarging

or leaking aneurysms. Absent or “normal” aortic calcifications are of no value in ruling out the diagnosis. Therefore, plain films should not be routinely ordered to evaluate the presence of an AAA or its complications.

Abdominal ultrasonography is useful in quickly and accurately establishing the presence of an aneurysm with almost 100% sensitivity (Fig. 93.1) (22). Indeed, bedside ultrasonography is a reliable tool for AAA screening in ED (23,24). However, this technique is *not* reliable in determining whether rupture has occurred or in estimating the proximal and distal extent of the aneurysm. Its role in the ED lies in rapidly establishing the presence of AAA at the bedside. Recently, 3D ultrasound imaging was found clinically reliable in quantification of AAA (23,24). Detection of a saccular aneurysm of any size warrants the immediate attention of a vascular surgeon. It is also useful to remember that AAA compressing a ureter can cause hydronephrosis, mimicking urolithiasis.

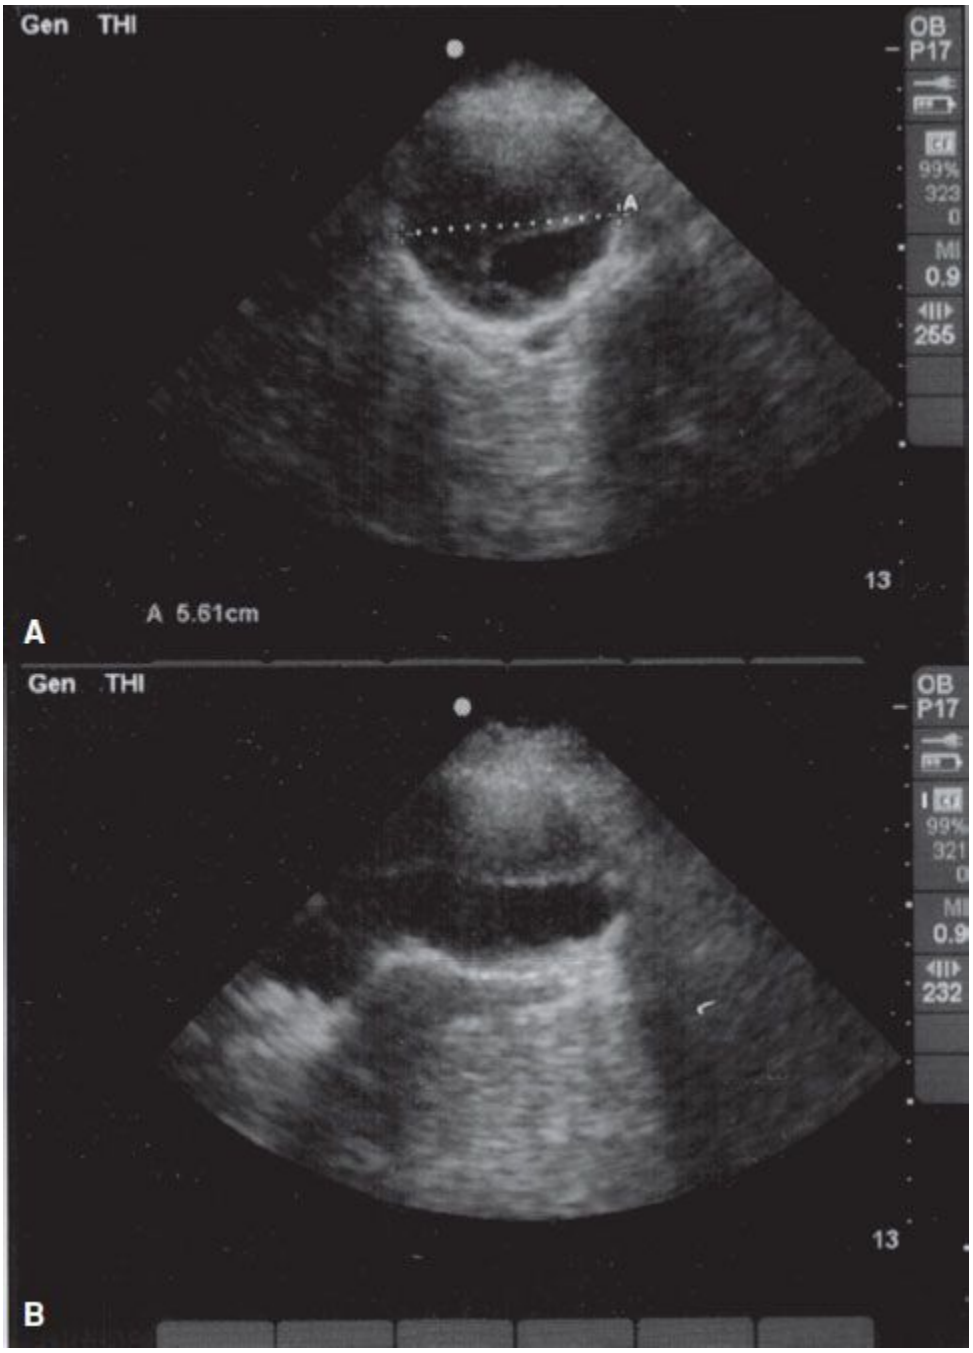

FIGURE 93.1 **A:** Cross-sectional view of large (5.6 cm) AAA with extensive intraluminal clot visualized by ED ultrasound. **B:** The same aneurysm seen in sagittal section. This was an incidental finding in the examination of an elderly patient with an unrelated complaint. *(Courtesy of Dr. Matthew R. Lewin, San Francisco, California)*

CT provides greater detail and more accurate measurements than does ultrasound. It is particularly useful in identifying leakage or rupture, assessing the thickness of mural thrombus, and visualizing blood within the thrombus. This “crescent sign” is thought by some to be a harbinger of imminent rupture (12). In fact, multislice CT has become an integral part of evaluation of AAA due to its ability to assess impending rupture, contained rupture, aortocaval fistula, aorto-left renal vein fistula, aortoenteric fistula, and infection (25). Because CT takes more time, involves intravenous contrast, and requires removal of the patient from the ED, it should be limited to stable patients in whom precise information is necessary, but the speed of CT has increased rapidly and is becoming more routine even in emergency situations. Many hospitals have a CT scanner in or near the ED, making this modality increasingly useful. CT can reliably detect aortic rupture with or without contrast enhancement. The main advantage of contrast is identifying entry and exit points of rupture with greater definition, including information about renal or iliofemoral involvement, mesenteric artery stenosis, or suspected visceral lesions (e.g., horseshoe kidney). Magnetic resonance imaging (MRI) also provides detailed images but is expensive, time consuming, and not universally available. MRI is also contraindicated in patients with pacemakers or ferromagnetic implants or clips, and thus it currently offers no substantive advantage over CT (18). Aortography is useful in selected cases in planning the operative repair of AAAs, but should not be used for the initial diagnosis. CT angiography is highly accurate in the diagnosis and characterization of suspected ruptured AAA (26).

High-speed MRI, 3D reconstruction vascular CTs, and sensitive and specific biochemical markers of aneurysm and dissection are exciting and promising areas of vascular research. Soon, rapid visualization techniques and proteomic approaches may be able to diagnose and track the progression of aneurysms and dissection, even in the ED setting.

KEY TESTING

- Bedside ultrasonography is useful in quickly identifying AAA.
- CT scan accurately defines size and whether rupture has occurred.
- CBC, chemistries, and blood typing and crossmatching should be sent if there is a reasonable suspicion of symptomatic AAA.

ED MANAGEMENT

The ED management of a patient with a suspected AAA must be tailored to the patient's presentation which ranges from asymptomatic to frank shock. The use of fluid resuscitation and appropriate blood pressure maintenance is controversial (27,28). Large volumes of blood or crystalloid may dislodge a metastable clot or result in dilutional coagulopathy. Conversely, older patients (the demographic most commonly presenting with symptomatic AAA) do not tolerate hypotension and its sequelae well, especially in the setting of comorbidities. All patients with suspected ruptured or symptomatic AAA should be placed on cardiac monitoring and receive supplemental oxygen, have at least two large-bore intravenous catheters securely in place, and have packed red blood cells, fresh frozen plasma, and platelets available for emergency transfusion. However, studies have suggested that early transfusion of platelets or fresh frozen plasma is unlikely to improve clinical outcome, and aggressive volume resuscitation should be delayed until proximal aortic control of bleeding is achieved (29–31). The use of medical antishock trousers and aortic cross-clamping has been reported in the setting of profound hypotension. The goals of resuscitation should be established as early as possible in the patient's course and discussed with the surgical and interventional radiology consultants when indicated. There are gender differences in presentation, and women experience more perioperative complications (32). Some patients may wish to decline intervention. A notable example was Albert Einstein, whose original diagnosis was "cholecystitis" and who refused a second surgery after becoming symptomatic after the first repair.

Asymptomatic Aneurysm

If the AAA is clearly unrelated to the patient's presenting complaint, the patient should be referred promptly to a vascular surgeon for further evaluation. An abdominal ultrasound may be useful in establishing the presence or absence of AAA, but it *cannot* rule out aneurysm rupture, leak, or expansion. Again, family history should be obtained for clues to possible syndromic and nonsyndromic causes of AAA.

Symptomatic Aneurysm

An aneurysm producing symptoms should be assumed to be ruptured, rapidly expanding, or otherwise complicated (infected, dissecting). Even when the patient is hemodynamically stable, prompt surgical consultation should be obtained, and preparations for fluid resuscitation and operative repair should be made. Elevated blood pressure should be controlled early, and fluid resuscitation confined to the volume needed to maintain patient's consciousness and systolic blood pressure of 50 to 100 mm of Hg (permissive hypotension) (33). Patients presenting with an acute abdomen or with known AAA accompanied by acute back pain or hypotension require immediate surgery. Operative repair should proceed without the usual preoperative evaluation and preparation, as rupture is either imminent or has already occurred and is temporarily confined to the retroperitoneum (18). In less acute presentations, radiologic imaging may be helpful but should be ordered with caution.

Patients with a history of previous AAA repair, whether open or endovascular, are still at risk for rupture, infection, occlusion, and other vascular catastrophes such as aortoenteric fistula. Graft clots may require thrombolysis, thrombectomy, or emergent surgical revision. As such, an emergency physician should have a low threshold for vascular surgery consultation, even long after AAA repair.

Ruptured Aneurysm

Patients in shock from a ruptured AAA need rapid resuscitation and emergent surgical intervention. Except in unusual circumstances, these patients should be transported to the operating room as quickly as possible without waiting for diagnostic testing or stabilization. A policy of immediate operation in such circumstances maximizes the patient's chances of survival. Even if it is discovered that a ruptured AAA is not present, many of these patients will have another surgical condition requiring operation, so the risk of unnecessary laparotomy is not great.

CRITICAL INTERVENTIONS

- Rapid diagnosis of a patient with a symptomatic or ruptured AAA, with emergent surgical consultation for operative repair.
- Resuscitation of shock with fluids and blood products as necessary. Permissive hypotension should be considered as a strategy to buy time and aid in stabilization.

DISPOSITION

Asymptomatic patients with an aortic diameter of 3 cm or more should be referred to a vascular surgeon for evaluation for elective repair. Recent reports suggest elective repair as first-line treatment even in patients >85 years of age (34). Patients with a symptomatic AAA, regardless of size, should be admitted for surgical evaluation and close observation. These patients will require prompt surgery if it becomes clear that the aneurysm is the source of their symptoms.

Patients who present with rupture of their AAA require emergent surgical consultation and should proceed to the operating room as quickly as possible. If the initial hospital does not have sufficient surgical and critical care resources to treat an AAA, transfer to a more appropriate institution is indicated. The local capabilities, anticipated transport time, likelihood of survival, and patient and family wishes must all be taken into consideration.

Common Pitfalls

- Falsely attributing the referred back pain of an AAA to musculoskeletal causes or another diagnosis. The combination of flank pain and hematuria may be mistaken for renal colic, while left lower quadrant pain and guaiac-positive stool may be mistaken for diverticulitis. Acute low back pain may be mistaken for vertebral or disk disease.
- Failing to diagnose AAA in an obese patient in whom physical examination may be more difficult.
- Assuming that an aneurysm discovered on physical examination is incidental and not the source of the patient's symptoms. Back or abdominal pain in the presence of a pulsatile abdominal mass must be considered a symptomatic AAA until proven otherwise.

CHAPTER 94

Mesenteric Ischemia

Stephanie A. Taft

Mesenteric ischemia occurs when the blood supply to the small and large intestine is compromised, resulting in insufficient oxygen delivery. While there are different mechanisms for the interruption of normal blood flow, the end result is inadequate perfusion and subsequent cell damage and death. In acute mesenteric ischemia (AMI), delay to diagnosis is the rule rather than the exception (1), resulting in persistently high mortality rates of 40% to 70% despite advances in diagnosis and treatment (2). Other factors affecting mortality are old age, signs of peritonitis, and delays in surgical intervention (3). The clinical presentation is highly variable due to the different vessels involved, the location of the affected bowel, and the different levels of illness severity (4). The most common form of bowel ischemia is ischemic colitis (4), which is a distinct entity described below. Mesenteric ischemia can be acute or chronic and can be further categorized as arterial occlusion, venous occlusion, and arterial nonocclusive disease.

ACUTE MESENTERIC ISCHEMIA

Around 40% to 50% cases of AMI are caused by arterial occlusion due to embolism from the heart or a proximal arterial source (3,5). Thrombosis of atherosclerotic arteries accounts for about 25% of cases (3). Mesenteric venous thrombosis (MVT) is less common, accounting for only 10% to 15% of cases (3) while nonocclusive mesenteric ischemia (NOMI) comprises the remaining 20% to 30% of cases (3,4).

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia (CMI) is commonly caused by the progressive stenosis of multiple atherosclerotic mesenteric blood vessels (5).

CLINICAL PRESENTATION

Acute Mesenteric Ischemia

Patients with AMI secondary to arterial embolism often present with *severe abdominal pain with minimal physical signs* and usually have a history of cardiovascular disease (5). Nausea, vomiting, and diarrhea are common complaints (1), and stools may be bloody (6). Unfortunately, key findings in AMI are inconsistently present (1), and the nature, location, and duration of the abdominal pain are variable (5), contributing to the delay in diagnosis. As ischemia progresses, peritoneal irritation gives rise to abdominal tenderness (5). Distension, rigidity, and systemic symptoms may take days to develop and correlate with intestinal perforation (5). Later signs also include confusion, tachycardia, tachypnea, and ultimately circulatory collapse due to dehydration and fluid third-spacing (6). Approximately two-thirds of patients with AMI are women, with a median age of 70 (5).

The clinical presentation of patients with AMI secondary to acute thrombosis is similar to that of arterial embolism. However, patients frequently report preceding symptoms of chronic insufficiency such as postprandial abdominal pain, nausea, and weight loss (6). Arterial thrombosis is almost always seen in the setting of severe atherosclerotic mesenteric arterial disease, most commonly near the origin of the superior mesenteric artery (SMA) (5,6). Gradual development of atherosclerotic disease allows development of collaterals, so significant arterial obstruction is often well-tolerated (6). Acute symptoms occur after rupture of a plaque and subsequent occlusion of a normally patent artery or occlusion of an important collateral (6). Ischemia due to acute thrombosis tends to involve larger portions of both small and large intestines, so the extent of bowel ischemia or infarction is greater than that with embolism (6).

Ischemia due to acute thrombosis also has higher perioperative mortality due to delays in diagnosis, a greater amount of bowel involved, and the need for more complex revascularization (6).

Patients with acute mesenteric venous thrombosis present with acute, severe midabdominal pain that is out of proportion to physical examination (7). Those with subacute or chronic MVT often present with complications of portal hypertension such as variceal bleeding, and the symptoms may evolve over days to weeks (7). Other symptoms such as nausea, vomiting, and constipation or diarrhea may also occur (7). Ascites in a patient with abdominal pain should heighten suspicion for MVT (7). Causes of MVT include any condition that leads to thrombosis. Examples include inherited or acquired hypercoagulable states (such as Factor V Leiden deficiency, polycythemia vera, malignancy, or oral contraceptive use), or local blood vessel injury (from inflammatory conditions such as pancreatitis or surgery), or from stasis due to conditions such as cirrhosis (7).

NOMI should be suspected in patients who develop abdominal pain or distension in the context of low-flow states or shock, particularly cardiogenic shock, or in patients receiving vasopressors or other vasoconstricting substances, such as cocaine or ergotamine (5). Ischemia occurs without identifiable blood vessel occlusion (3), usually as a result of low-flow states and subsequent severe prolonged vasospasm (5). NOMI is seen most commonly in elderly, critically ill patients. These patients are often intubated and sedated, so the only clue is deterioration of clinical status (6).

Chronic Mesenteric Ischemia

CMI is characterized by postprandial abdominal pain and weight loss which occurs over months to years (5). Patients with CMI often have a history of cardiovascular disease or vascular surgery (5). Because many people who have atherosclerosis of the mesenteric vessels are actually asymptomatic due to collateral circulation (5,9), CMI is diagnosed by demonstration of arterial lesions in the context of abdominal pain, weight loss, history of cardiovascular disease,

and no other obvious cause of symptoms (5). Other GI symptoms such as vomiting and diarrhea are uncommon (5). Rare causes include Buerger's disease, fibromuscular dysplasia, or dissection (5). Some cases progress to AMI while the remainder have progressive weight loss and ultimately die (5).

Ischemic Colitis

Ischemic colitis (IC) is actually the most common form of mesenteric ischemia (4). It is characterized by a sudden onset of mild left lower quadrant abdominal pain followed by mild hematochezia (4). It is most often due to an acute, self-limited compromise of blood flow which is inadequate to meet the metabolic demands of part of the colon. It can be seen in conditions such as congestive heart failure, hypotension, hypovolemia, sepsis, vascular occlusion, vasculitis, or drug use (4,17). The most susceptible areas are the splenic flexure, descending and sigmoid colon, but right-sided (ascending colon) IC is usually associated with more severe colitis and worse outcome (4,18).

DIFFERENTIAL DIAGNOSIS

Mesenteric ischemia is a diagnostic challenge, partly because the differential is extensive and includes nearly any disorder that causes abdominal pain (see Chapter 10), and the physical signs may be nonspecific. While many other conditions are more common than acute ischemia, the incidence of mesenteric ischemia increases with advancing age (10).

ED EVALUATION

Laboratory Testing

There is no sufficiently sensitive or specific serum marker that can identify AMI early (11). The classic findings of elevated lactate, leukocytosis, and acidosis are all insensitive and nonspecific (12). There are also no diagnostic laboratory tests for CMI (5).

Imaging

Contrast-Enhanced Multidetector Computed Tomography

Computed tomography (CT) is the imaging modality of choice in both AMI and CMI (9). CT is able to evaluate the vascular system and the bowel wall and may also identify an alternative etiology (13). In AMI, CT demonstrates a progression of findings, starting with mildly dilated loops of bowel, and a normal or slightly thinned bowel wall (8,13). This is followed by further bowel dilation and progressive thinning of the bowel wall with poor contrast enhancement (13). If reperfusion occurs, the bowel wall thickens due to edema and hemorrhage; however, the bowel wall can still perforate (13). Pneumatosis intestinalis with portomesenteric venous gas often indicates transmural infarction but can also be seen in other conditions, such as inflammatory bowel disease or connective tissue disorders (13). These findings must be interpreted in the correct clinical context and in association with the previously mentioned CT findings suggesting mesenteric ischemia (13). In the absence of other findings of AMI, isolated pneumatosis intestinalis does not necessarily indicate acute ischemia (13). While intravenous (IV) contrast is necessary for CT, oral contrast is neither necessary nor often feasible (13).

In the case of acute MVT, bowel wall thickening is the most common finding, and mesenteric haziness and ascites are also present in most patients (13). In the case of NOMI, CT findings are similar to that of acute arterial occlusive disease but no focal occlusion can be found (13).

Plain Abdominal X-Rays

Plain films are usually nonspecific and do not contribute to diagnosis (5).

Duplex Ultrasound

Ultrasound may be useful in supporting the diagnosis of CMI but has no role in AMI (5). It may be able to identify proximal occlusive lesions but cannot directly diagnose mesenteric ischemia. It also

requires ideal exam conditions which include fasting prior to the exam and absence of significant abdominal distension (5,14).

Magnetic Resonance Angiography with Gadolinium

Magnetic resonance angiography is sensitive and specific but generally not readily available and takes too long to perform in a critically ill patient (4,9). It is more useful in diagnosing CMI (5,9,14).

Angiography

Traditional angiography is often diagnostic and may be therapeutic if coupled with endovascular therapy (see below), but it is resource-intensive and not always readily available. Angiography is no longer the gold standard (15).

For patients with ischemic colitis, CT is usually nonspecific but suggestive (4,17). Colonoscopy is the test of choice (17) but is not performed on an emergent basis. Angiography is not indicated (4).

KEY TESTING

- Contrast-enhanced CT.
- Lactate and other basic studies often ordered in the evaluation of abdominal pain.

ED MANAGEMENT

Management in the ED is focused upon resuscitation and basic supportive care. The goal is to minimize the amount of bowel that progresses from ischemia to infarction (5). Appropriate care may include some or all of the following measures depending upon the degree of shock.

Intubation may be necessary for airway protection, oxygenation, or ventilation. Fluid resuscitation should be aggressive, beginning with a bolus of crystalloid. Bedside ultrasound may be useful early on to exclude other pathology such as abdominal aortic aneurysm and to help evaluate the hydration status of the patient. Broad-spectrum IV antibiotics should be administered early, due to the high risk of bacterial translocation across bowel wall (14). If

vasopressors are required, pure alpha-adrenergic agents such as phenylephrine should be avoided because they may produce mesenteric vasoconstriction and worsening ischemia (3). Treatment of the underlying shock state is the most important treatment principle in cases of NOMI (5). CT scanning should be accomplished as soon as reasonably possible, given the patient's condition. Emergent surgical consultation should be obtained, even prior to a definitive diagnosis if the index of suspicion is high or if there are peritoneal findings (3). Anticoagulation should be initiated if there are no contraindications, but this should be done in consultation with the surgeon. In the case of MVT, hematology consultation may be useful to initiate appropriate thrombophilia screening prior to starting anticoagulation (7).

Most patients with ischemic colitis respond within 1 to 2 days to basic supportive care (i.e., bowel rest, IV fluids, empiric antibiotics) (17). In 20% of cases, surgery is required because of deterioration or peritonitis (17).

For patients with *chronic ischemia,* timely treatment is key for the prevention of acute ischemia (10). Percutaneous endovascular treatment or surgery may be appropriate, depending on the clinical presentation. Recurrence is more common after angioplasty than surgery, but these recurrences can also be treated percutaneously (5). Surgical treatment or revascularization may be accomplished by endarterectomy or bypass grafting (5). Surgery has a good success rate with lower recurrence than percutaneous intervention but has its own associated morbidity and mortality (5).

Beyond the diagnostic and resuscitation issues in the ED, there are several important options and considerations for more definitive care in patients with mesenteric ischemia.

Percutaneous Endovascular Treatment (Angiography)

Angiography may be used for directed lytic therapy, vasodilator (papaverine) therapy, angioplasty, and/or stenting. This modality is evolving into first-line treatment in select patients (1). It is noteworthy that angiography carries a higher risk of reperfusion

syndrome than with surgery. Reperfusion syndrome occurs due to the sudden release of endotoxins, resulting in disseminated intravascular coagulation, adult respiratory distress syndrome, and cardiovascular collapse (5).

Surgical Treatment

Laparotomy allows direct visualization and assessment of bowel viability, revascularization (balloon catheter thromboembolectomy or bypass grafting), and resection of infarcted bowel (10). A second operation is often scheduled to re-assess the viability of bowel, avoiding resection of potentially viable bowel during the first operation while allowing further resection of nonviable bowel (5).

CRITICAL INTERVENTIONS

- Fluid resuscitation, may need up to 100 mL/kg (16).
- Broad spectrum IV antibiotics.
- Anticoagulation (in selected cases).
- Surgical consultation.

DISPOSITION

Patients with AMI should be admitted to the hospital and may require surgery. Because the diagnosis is often delayed, these patients are often very sick and require intensive care.

Common Pitfalls

- Allowing a benign abdominal examination to direct the management of a patient with risk factors for AMI. Intervention is most effective when there are few findings on examination.
- Failing to recognize that acute abdominal pain in a patient with a previous diagnosis of CMI is AMI until proven otherwise.
- Relying on a blood gas or serum lactate to rule out mesenteric ischemia. Both are insensitive and become abnormal late in the disease (1).
- Allowing elevation of serum biomarkers to lead to misdiagnosis: elevation of troponin, amylase, lipase, and liver transaminases

have all been seen relatively commonly in AMI (1).

- Failing to interpret CT results correctly in the context of a clinical presentation suggestive of AMI. Early mesenteric ischemia can look similar to adynamic ileus on CT (13).

CHAPTER 95

Peripheral Arterial Disease

Dusadee Sarangarm and Darren Braude

Peripheral arterial disease (PAD) is usually secondary to atherosclerosis and occurs most frequently in the lower extremities. PAD is analogous in many ways to coronary artery disease (CAD). Like CAD, PAD is often asymptomatic in patients with known cardiovascular disease or risk factors. Stable angina corresponds to noncritical ischemia and presents as predictable claudication. Unstable angina corresponds to the progression of chronic PAD to critical limb ischemia and presents as rest pain, ulceration, or gangrene. Myocardial infarction corresponds to acute, critical limb ischemia caused by thrombus or embolism. Irreversible damage to nerves and muscle may develop within 6 hours and up to 20% of patients may die (1).

CLINICAL PRESENTATION

PAD may be categorized as acute or chronic, critical or noncritical, and limb-threatening or not. Acute ischemia most often occurs secondary to in situ expansion of an atherosclerotic thrombus or less commonly due to an embolus from a more proximal source. Chronic, *noncritical* ischemia can present as intermittent claudication (IC) and asymptomatic arterial insufficiency. Chronic, *critical* ischemia can present as rest pain and/or skin ulcerations, infections, or necrosis. Limb-threatening ischemia can be caused by

both acute ischemia of an extremity and chronic, critical ischemia (Table 95.1).

TABLE 95.1
Classification of Peripheral Arterial Disease

Limb-Threatening Ischemia
Acute ischemia: thrombus, embolism
Chronic critical ischemia: thrombus, rest pain
Ischemic skin changes: ulcers, gangrene
Non-Limb-Threatening Ischemia
Chronic noncritical ischemia: intermittent claudication

Because most PAD in developed countries is related to underlying atherosclerosis, the typical patient has known atherosclerotic disease or risk factors including diabetes, obesity, smoking history, hypertension, hyperlipidemia, renal insufficiency, and hyperhomocysteinemia; other risk factors include advanced age, male sex, and non-White ethnicity (1,2,3).

Acute Ischemia

Patients with acute ischemia usually present to the ED because of severe pain in a lower extremity. Pain is usually not well defined and in most cases extends above the ankle, depending on the location of the obstruction and degree of collateral flow. Patients with coexisting diabetic neuropathy, however, may not have typical pain. Patients may also complain of paresthesias, weakness, numbness, and/or a cold, white, or discolored extremity.

Acute ischemia is usually caused by an arterial embolism or thrombus of a native artery or bypass graft. Thrombosis is much more common than embolism. Patients with an arterial thrombosis become symptomatic from thrombus extension and subsequent arterial occlusion. Most patients will have prior chronic arterial insufficiency with claudication, rest pain, typical trophic skin changes, and/or prior bypass grafting. Because long-standing disease has led to the development of collateral circulation, symptoms and

physical findings in thrombosis are typically not as dramatic as with embolism.

Arterial embolism arises from the heart in most cases, often from ventricular thrombus such as in postmyocardial infarction ventricular aneurysm or from atrial thrombus in the setting of mitral valve disease or atrial fibrillation. Unless the patient has significant coexisting lower extremity atherosclerosis, there typically is no established collateral circulation to deliver blood distally. Thus, arterial embolism usually presents in a more dramatic fashion than thrombosis. The hallmarks of acute ischemia are sudden onset of symptoms without preceding symptoms of chronic PAD, an identifiable embolic source, and a normal circulatory examination of the unaffected leg.

Chronic Critical Ischemia

Patients with chronic, critical ischemia usually present to the ED due to new or worsening rest pain or skin changes. As circulation is affected by gravity, rest pain typically occurs as the patient is sleeping or when the patient is supine. Pain occurs distally in the forefoot or toes but not usually in the calves. Because the pain is exacerbated by leg elevation and improved with dependency, many patients will sleep in a chair or prefer to hang the affected leg over the side of the bed. Symptoms worsen in the cold and the pain is often severe. Associated ischemic peripheral neuropathy may cause sharp shooting pains and sensations of heat and cold.

Chronic Noncritical Ischemia

Patients with chronic, noncritical ischemia usually present to the ED because of new or worsening claudication, which is essentially angina of the lower extremities. Patients classically report calf cramping or aching after a predictable amount of activity. This prompts the patient to stop activity, thereby relieving the pain. Depending on the site of the occlusion, claudication may occur in the calf, hip, buttock, or thigh. In general, foot claudication is rare with atherosclerosis.

DIFFERENTIAL DIAGNOSIS

Acute Thrombus or Embolus

If there is involvement of both legs, the clinician should consider a low cardiac output state or an aortic dissection tracking into the bilateral iliac arteries. If only one lower extremity is involved, the differential diagnosis includes conditions that mimic ischemia, such as phlegmasia cerulea dolens and acute compressive neuropathy, as well as nonatherosclerotic causes of true ischemia, such as phlegmasia alba dolens, arterial trauma, aortic dissection, arteritis, hypercoagulable states, and vasospasm.

Intermittent Claudication

Calf claudication in patients with atherosclerotic risk factors may be confused with venous claudication, compressive neuropathy, calf spasms, or symptomatic Baker's cyst. Venous claudication follows treatment for deep venous thrombosis, resolves slowly when exercise stops, improves with limb elevation, and is usually associated with edema. Compressive spinal neuropathy usually produces distinctly dermatomal sharp pain, is associated with back pain, and does not resolve immediately when activity stops. The discomfort from a Baker's cyst persists at rest.

Hip, thigh, or buttock claudication may be confused with arthritis of the hip and spinal stenosis. Pain from arthritis is not consistently reproduced with activity, often present at rest, and not relieved quickly with rest. Spinal stenosis symptoms are dermatomal, usually associated with back pain, and more typically relieved by bending forward than by stopping activity.

Rest Pain

Any distal sensory neuropathy may present with pain primarily at night. This pain tends to be symmetric, foot-based, shooting pains that are neither exacerbated by elevation nor relieved with dependency; an exception is in the case of ischemic neuropathy associated with chronic arterial ischemia. Other important causes of neuropathy include diabetes, vitamin deficiency, and alcohol abuse. Additionally, gout may cause extremity pain at rest, although this

pain persists despite dependency, is localized to a joint, and is almost always associated with visible findings. Disc herniation of the lumbosacral nerve roots may also produce extremity pain at rest. This pain usually persists with dependency, follows a dermatomal pattern, is associated with back complaints, and presents with a normal vascular examination. Some confusion may arise with the straight-leg raise examination maneuver as it can cause pain in patients with rest pain, as well as in nerve root compression. Reflex sympathetic dystrophy can present with burning pain and skin changes though the pain is not exacerbated by elevation and pulses should be normal. Finally, simple night cramps cause calf rather than foot pain that is relieved with massage, not exacerbated by elevation, and is not associated with pulse deficits.

Ulcers and Gangrene

Ulcers secondary to arterial ischemia must be differentiated from ulcers secondary to other causes, such as venous stasis and diabetes. Ulcers related to venous insufficiency are the most common, tend to occur more proximally, produce less pain, are relieved with elevation, coexist with edema and stasis dermatitis, and have a wet base with copious granulation tissue. The ulcers of diabetes may occur in the same distal pressure point locations as PAD-associated ulcers but tend to be painless, deep, and surrounded by significant callus and/or inflammation. The primary differential of dry gangrene is frostbite. Wet gangrene may originate in other skin ulcers or wounds.

ED EVALUATION

Acute, critical PAD is primarily a clinical diagnosis based upon history and physical examination, including the ankle-brachial pressure index (ABI). The 2011 American College of Cardiology Foundation and American Heart Association guideline update defines patients with suspected lower extremity PAD as individuals with one or more of the following signs or symptoms: exertional leg symptoms, nonhealing wounds, age 70 and older, or 50 years and

older with a history of smoking or diabetes (10). In patients with clinical evidence of acute ischemia, vascular surgery consultation should precede diagnostic studies and may require immediate transfer in some settings. In cases of diagnostic uncertainty, or when an alternative emergent diagnosis such as aortic dissection is highly likely, the ED physician may order imaging studies prior to consultation in the patient with previously undiagnosed PAD and no evidence of critical ischemia. However, diagnostic tests should not delay consultation or transfer if acute, critical PAD is suspected. Definitive diagnostic testing should ideally be at the discretion of the vascular surgery consultant given individual practitioner preference, institutional resources, associated delays, and potential adverse effects.

Examination of the lower extremities should include bilateral inspection for sores, edema, dermatitis, gangrene, and signs of infection; palpation of skin temperature; assessment of capillary refill time; palpation of the femoral, popliteal, dorsalis pedis, and posterior tibial pulses; auscultation of the femoral artery; and motor and sensory examinations. The abdomen should be examined for masses or bruits suggestive of abdominal aortic aneurysm. Capillary refill has not been found to be useful in assessing chronic peripheral vascular disease while the most useful findings to confirm PAD are pulse deficit, bruit, and cool skin (4,5).

The signs and symptoms in acute arterial occlusion resulting from an embolus can be dramatic and reflect the “six Ps” of ischemia: pain, pallor, pulselessness, poikilothermia, paralysis, and paresthesia.

If acute ischemia is embolic in nature, without pre-existing PAD, the unaffected extremity tends to be normal on examination. The affected extremity is white or cyanotic, cool to the touch, and pulseless without appreciable new swelling. There will usually be some component of neuropathy with weakness and sensory deficits. Sensory deficits begin with diminished light touch, two-point discrimination, and proprioception. Loss of deep-pain, pressure sensation, and motor deficits reflect advanced ischemia and possibly irreversible ischemia. The intrinsic muscles of the feet are the most

sensitive to ischemia and are tested by having the patient spread their toes.

In arterial thrombosis, findings are usually more subtle than with embolus owing to collateral blood flow and/or slower onset, although the major pulses distal to the obstruction will typically be absent. Unfortunately, there is variability in the presence of peripheral pulses and their detection. Comparison with the unaffected extremity and use of a Doppler are very helpful. The presence of pulses detected on Doppler indicates blood flow but does not necessarily exclude ischemia. Both the affected and the unaffected extremity should show findings of chronic PAD including atrophy of calf muscles, loss of hair over the dorsum of the foot, thickened toenails, shiny skin, diminished pulses, and possibly skin ulcers. Edema may be present as patients prefer to keep their extremities dependent.

Patients with IC will usually have a normal examination at rest, although they may have some subtle findings of chronic ischemia. Further in the disease process, patients with rest pain will show many of the changes noted previously for chronic PAD. These patients do not have complete occlusion; so capillary refill should be present, although delayed, and pulses will be present, at least by Doppler. Another clinical finding of severe ischemia frequently cited is Buerger's sign. A positive test is the observation of pallor with foot elevation and exaggerated delayed erythema with subsequent dependency (5). This sign is not well validated (4).

Skin ulcerations from arterial insufficiency tend to occur distally at pressure points, such as at the tips of the toes, between the toes, or on the heel. These ulcers often have an irregular border with a pale base and may show signs of infection. Plain radiography is appropriate to screen for underlying osteomyelitis when the ulcer appears sufficiently deep or infected. Gangrene is rarely missed when the distal extremities are examined. Uninfected gangrene is dry while discharge, weeping, crepitance, lymphangitis, and cellulitis suggest infection.

Ankle-Brachial Pressure Index

The ABI is a rapid, objective screening measurement of arterial insufficiency and should be assessed in any patient in whom arterial insufficiency is suspected. If the ABI can be measured, the limb is not immediately threatened, but may still be ischemic. If arterial signals are absent, limb loss is probable without emergent revascularization. Absent venous pulsations indicate severe ischemia. It is helpful to check the ABI in the unaffected leg to ascertain whether the patient has underlying arterial disease or noncompressible vessels. The technique and interpretation of ABI measurement are summarized in **Tables 95.2** and **95.3** (6,7). While the typically used ABI cut-off of 0.9 maximizes sensitivity and specificity, any value <1.0 in a symptomatic patient should be considered sufficient evidence of arterial insufficiency (6,7).

TABLE 95.2
Technique for the Measurement of Ankle-Brachial Pressure Index

Place patient supine
Measure systolic blood pressure at brachial artery of both arms by using Doppler
Select higher value of the two pressures
Measure systolic blood pressure at the posterior tibial and dorsalis pedis arteries of affected leg by using Doppler
If neither is obtainable, limb is immediately threatened, otherwise select higher value of the two pressures
Divide higher ankle pressure by higher brachial pressure

TABLE 95.3
Interpretation of Ankle-Brachial Pressure Index Results

ABI	Interpretation
≥1.4	Abnormal (increased risk for PAD, noncompressible vessels)
1.0–1.39	Normal
0.91–0.99	Borderline
≤0.9	Abnormal (increased risk for PAD)
0.41–0.89	Mild to moderate disease
≤0.4	Severe disease

Imaging Studies

While catheter angiogram remains the gold standard, noninvasive studies are being increasingly used. According to the American College of Radiology 2012 guideline, lower extremity magnetic resonance angiography (MRA) and computed tomography angiography (CTA) have a higher level appropriateness rating than catheter arteriography as the initial radiologic examination for patients with suspected PAD (9). The increased availability of CTA has likely contributed to its increasing use, while MRA has been shown to be more cost-effective and safer than the gold standard of angiography. In addition, these noninvasive diagnostic modalities have been shown to have high sensitivity and specificity (90% to 100%) for the detection of stenosis >50% diameter when compared to catheter angiogram (9). Ultrasound is preferred in patients with moderate to severe renal insufficiency, as both CT contrast and gadolinium are associated with complications in these patients (8).

KEY TESTING

- Determination of ABI
- Doppler of extremity pulses
- Angiography, MRA, or CTA in consultation with a vascular surgeon

ED MANAGEMENT

Supportive care for patients with PAD includes keeping the affected limb dependent and warm, providing analgesia as needed, and maximizing cardiac output. Aspirin or clopidogrel is indicated in all

patients with symptomatic PAD to reduce risk of further vascular injury such as MI and ischemic CVA although the role of these drugs in the acute setting has not been adequately investigated (1,7,10,11).

Acute Ischemia

In the absence of contraindications, patients with acute critical ischemia should receive anticoagulation with unfractionated heparin despite little objective evidence (1,7,11). Supplemental oxygen may be helpful and should be provided when acute ischemia is considered. Options for definitive therapy include surgical or interventional procedures at the discretion of the vascular surgeon. Considerations include degree and duration of ischemia, contraindications, local resources, and results of imaging studies. In patients with severe ischemia, angiography may be performed intraoperatively to minimize delay in care. Surgical options include direct removal of the occlusion (most common with established thrombus), bypass grafting, primary amputation, and Fogarty catheter embolectomy (most common with embolus or suspected new thrombus). Interventional options include direct intra-arterial administration of thrombolytics, mechanical thrombectomy, thromboaspiration, and angioplasty. There is currently no accepted role for intravenous thrombolytics, although this treatment merits discussion with a vascular surgeon if definitive care is expected to be significantly delayed (7,10).

Chronic Critical Ischemia and Rest Pain

Patients with rest pain in the dependent position should be treated as for acute ischemia. Patients experiencing rest pain only when the foot is elevated represent an intermediate group and definitive therapy for this group may involve pharmacotherapy, endovascular procedures, or surgery though these measures may not need to be started emergently. At a minimum, telephone consultation with the patient's primary care physician and/or vascular surgeon is appropriate. After consultation, these patients may be discharged

home on aspirin 75 to 100 mg per day with an adequate follow-up plan and return precautions (11). Should the patient have an allergy to aspirin, clopidogrel 75 mg per day has been found to be a safe and effective alternative (11).

Chronic Ischemia with Ulcerations or Infection

Patients with uninfected ulcerations require wound debridement and dressing, close monitoring for the development of infection, analgesia, and at a minimum, telephone consultation with a vascular surgeon. Admission should be considered but is not mandatory when adequate follow-up is assured.

Patients with infected ulcerations need supportive care, aggressive wound management, systemic antibiotics, admission, and vascular surgery consultation for possible revascularization. Appropriate empiric antibiotic choices should take into account risk factors for gram-negative infections such as diabetes, recent hospitalization, local epidemiology, resistance patterns, and the rising incidence of methicillin-resistant *Staphylococcus aureus.* A reasonable choice for intravenous therapy is ampicillin- sulbactam (1.5 to 3 g q6 h) plus clindamycin (900 mg q8 h) plus ciprofloxacin (400 mg q12 h) (12). If there is a high suspicion for hospital-acquired methicillin-resistant *Staphylococcus aureus,* vancomycin (dosing dependent on renal function) may be substituted for clindamycin.

Patients with dry gangrene require supportive care and timely surgery consultation. Patients with evidence of necrotizing infections (gas gangrene, wet gangrene, or sepsis) require intensive care unit admission, immediate surgical consultation, and broad-spectrum antibiotics to cover gram-negative infection, *Staphylococcus aureus, Streptococcus* sp, and *Clostridium* sp.

Chronic Noncritical Ischemia and Intermittent Claudication

Although this is a nonemergent condition, these patients require close follow-up with their primary care physician and/or vascular surgeon. In the meantime, they should be reassured that walking,

despite causing pain, is not harmful. Pharmacotherapy may be deferred to follow-up, though it is reasonable to start patients without contraindications on 75 to 100 mg per day of aspirin (1,7,10).

CRITICAL INTERVENTIONS

- Aspirin and weight-based heparin (80 units/kg bolus followed by 18 units/kg/hr continuous infusion) for acute ischemia and rest pain that persists in the dependent position.
- Emergent vascular surgery consultation, including transfer as necessary, for limb-threatening ischemia or infection.
- Supportive care, keeping affected extremity warm and dependent, maximizing cardiac output, and providing supplemental oxygen.
- Early initiation of antibiotics for patients with signs of infection.

DISPOSITION

All patients with PAD require vascular surgery consultation. The emergency physician must decide according to the acuity of the situation whether that consultation must take place emergently in the ED or on an outpatient basis. In some situations, the patient may be admitted to their primary care provider or hospitalist with inpatient vascular surgery consultation.

Emergent vascular surgery consultation is appropriate for patients with acute ischemia or evidence of serious infection in an ischemic extremity. If vascular surgery consultation is not available, the patient should be transferred expeditiously. Patients with chronic critical ischemia require emergent vascular surgery consultation in most cases. Patients with rest pain that is well controlled with supportive measures, and patients with uninfected ulcers without gangrene, may be candidates for admission with urgent vascular surgery consultation as an inpatient.

Patients with noncritical ischemia may be discharged home with close outpatient follow-up. Consultation with a vascular surgeon before discharge is recommended when possible.

Common Pitfalls

- Delaying consultation or transfer for testing and definitive diagnosis.
- Failing to consider diabetic neuropathy masking the pain of an ischemic extremity.
- Failing to elicit a history of claudication because the patient's baseline activity is limited.
- Failing to recognize IC can occur in the hip, buttock, or thigh.

CHAPTER 96

Deep Venous Thrombosis and Thrombophlebitis

Carolyn Chooljian

Deep venous thrombosis (DVT) of the lower extremity is a relatively common diagnosis made in the emergency department (ED), with an annual incidence of 67 per 100 000 in the United States. Two million patients are diagnosed with DVT and 600 000 have pulmonary embolism (PE) each year. Thromboembolic disease is responsible for an estimated 200 000 deaths annually and ranks third only to myocardial infarction and stroke as a life-threatening cardiovascular disease in the United States (1). Millions more experience sequelae such as stasis dermatitis and venous ulcers. The risk for development of DVT as described by Virchow is the triad of stasis, hypercoagulability, and endothelial injury. Additional conditions that either cross categories or separately place patients at risk are listed in Table 96.1. These risk factors are additive in nature and have been used to develop a prediction tool to establish likelihood of the disease in patients.

TABLE 96.1
Risk Factors for Deep Venous Thrombosis

Stasis	Coagulation disorders
Immobility	Protein S deficiency or resistance
Bed rest (≥3 d)	Protein C deficiency
Prolonged sitting owing to long rides (plane, car, or train)	Antithrombin III deficiency
Paralysis	Factor V Leiden
CNS injury	Increased estrogen
Cast	Pregnancy
Endothelial Injury	Postpartum <3 mo
Intravenous drug abuse	Oral contraceptives
Vascular trauma	Disorders of fibrinogen or plasminogen
Recent surgery	Antiphospholipid antibodies (lupus anticoagulant and anticardiolipin)
Central lines	**Multifactorial**
Hypercoagulability	Recent trauma
Malignancy	Recent surgery
Previous thromboembolic disease	Age >60 yr
Inflammatory conditions (e.g., SLE)	Cardiac disease (especially CHF)
Nephrotic syndrome (loss of antithrombin III)	Obesity
	Venous insufficiency
	Smoking

CNS, central nervous system; SLE, systemic lupus erythematosus; CHF, congestive heart failure.

The initiating stimulus for thrombus formation is often an intimal defect. The dynamic interplay of coagulation and fibrinolytic forces then results in clot propagation or dissolution. Conditions affecting the balance of these forces are what place patients at increased risk for symptomatic thrombus formation. If the process is of sufficient severity or duration, the associated vein can become inflamed; the condition is then referred to as thrombophlebitis.

It is useful to divide DVT of the lower extremities into two categories: distal and proximal. Distal DVT is confined to the calf veins and proximal DVT involves the popliteal, femoral, and/or iliac veins. Most DVTs start in the calf. Isolated calf DVT is usually silent and rarely causes clinically significant PE. About 25% of untreated symptomatic calf DVT progresses to the proximal veins within 1 week (2). Up to 40% of patients with DVT have clinically silent PE (3). PE occurs in 50% of proximal vein DVTs, which are the source of most fatal emboli, and over 90% of acute PE are from proximal

lower extremity DVT (4). Although isolated superficial thrombophlebitis generally does not pose a significant risk for embolization, 23% of patients with symptoms of superficial thrombophlebitis have been shown to have involvement of the deep system as well (5).

Superficial thrombophlebitis involving the proximal saphenous vein or saphenous–femoral junction has a much higher risk of progression to DVT (6). In addition, patients with a first episode of DVT complicated by superficial thrombophlebitis have a 2-fold increased risk of recurrent DVT compared to patients without superficial thrombophlebitis (7). Although embolization to the lung is the most serious complication of DVT, it can also result in other complicating conditions. Venous hypertension and persistent clot can destroy valves, thereby leading to a postthrombotic syndrome (chronic leg pain and venous stasis) that occurs in 28% of patients after symptomatic DVT. Other patients develop only recurrent edema. Occasionally, acute cases can develop a compartment syndrome of the thigh or lower leg.

CLINICAL PRESENTATION

Patients with DVT can present with a symptom complex that ranges from completely occult to obvious. Most commonly, they present with lower extremity pain and swelling that may worsen with standing or walking. Manifestations are almost always unilateral, except in the rare life-threatening case of inferior vena cava (IVC) involvement. Generally, DVT symptoms develop over a period of several days, whereas sudden severe pain is more likely related to an injury. Associated symptoms, such as chest pain or dyspnea, may also be present, particularly as they relate to the presence of PE. Risk factors can be identified in the majority of patients.

DIFFERENTIAL DIAGNOSIS

Several medical conditions can present with symptoms suggestive of DVT (Table 96.2).

TABLE 96.2
Differential Diagnosis of Deep Venous Thrombosis

Postthrombotic syndrome
Leg swelling in paralyzed limb
Cellulitis/abscess
Muscle injury/hematoma
Popliteal cyst (Baker cyst)
Superficial thrombophlebitis
Septic thrombophlebitis
Congestive heart failure
Lymphedema
Malignancy (obstructive)
Capillary leak syndrome
Fracture
Sciatica
Acute arthritis
Myositis
Pregnancy
Superior vena cava syndrome (upper extremity DVT)

DVT, deep venous thrombosis.

Many of these conditions generally cause bilateral leg swelling resulting from either increased production of edema fluid or an IVC obstructive process. However, if prior DVT has resulted in damage to the venous valves, these conditions can exacerbate asymmetric swelling. In addition, abdominal masses (e.g., a gravid uterus) can occasionally compress a single iliac vein, resulting in unilateral venous stasis. One of the most difficult conditions to distinguish from DVT is the postthrombotic syndrome. Recurrent DVT in the same leg predisposes to postthrombotic syndrome. Patients with prior DVT can develop recurrent unilateral pain and swelling that is clinically indistinguishable from acute DVT. Other conditions that are most often confused with DVT are cellulitis, *superficial thrombophlebitis,* and *septic thrombophlebitis.* There is much clinical overlap among these conditions, and a low threshold for objective diagnostic testing is required.

ED EVALUATION

The clinical evaluation of the patient with possible DVT focuses both on identifying findings consistent with DVT and on diagnosing alternative conditions that may explain the patient's presentation. It is important to question the patient about risk factors for DVT (Table 96.1) including a family history. As many as one-fourth of patients with acute DVT have a history of prior DVT. The physical examination can provide useful findings but must be interpreted with caution. Although patients with cellulitis and other infections usually have a fever, DVT can also result in an elevated temperature, although often only low grade. Unilateral warmth and erythema are common with both DVT and cellulitis. The presence of an abscess, enlarged lymph nodes, and ulcerations can be important clues for distinguishing an infectious etiology. A difference of 3 cm in the circumference of the calves, measured 10 cm below the tibial tuberosity, or 3 cm in the circumference of the thighs, measured equally from the patella, is clinically significant and one of the most specific findings for DVT. The presence of palpable "cords" in the thigh is considered fairly specific but quite insensitive for thrombosis. In the popliteal fossa, they can easily be confused with a Baker cyst. Homan sign was classically taught as being important in the evaluation of DVT, but it is now well known that its sensitivity and specificity are only about 50%.

The assessment for DVT begins with an estimation of the probability of disease based on the presence of patient-based clinical variables. This can be combined with the measurement of a derivative of cross-linked fibrin, the D-dimer. D-Dimer levels are nonspecific, being elevated in DVT as well as infection, cancer, trauma, and other inflammatory states. Different D-dimer assays exist and can be divided into high-sensitivity (ELISA, second-generation latex agglutination-immunoturbidometric) and moderate-sensitivity (non-ELISA) forms (8,9).

Wells et al. described a clinical predictive model with a relatively simple scoring system that accurately identified patients at low, intermediate, or high risk of DVT (10). This model was subsequently

combined with D-dimer testing to further stratify patients' risk of DVT (11,12). A simplification of the Wells model divided the probability estimate into two categories: DVT likely or DVT unlikely (see Table 96.3) (13). A meta-analysis showed that the combination of a low-probability clinical estimate and a negative high- or moderate-sensitivity D-dimer was sufficient to exclude DVT without further testing. In cases where the D-dimer assay used had high sensitivity, a negative result also reduced the probability of DVT to $\leq$1% in moderate-risk patients. No D-dimer assay was adequate to eliminate DVT in high-risk patients to this level of probability and therefore it is not recommended to use D-dimer alone in assessing these patients (10,14).

TABLE 96.3
Clinical Model for Predicting Pretest Probability of Deep Venous Thrombosis

Clinical Feature	Score
Active cancer (treatment within 6 mo)	1
Paralysis, paresis, or recent cast immobilization of lower extremity	1
Recent bedridden (>3 d) or major surgery within previous 12 wk requiring general or regional anesthesia	1
Localized tenderness along deep venous system	1
Entire leg swollen	1
Calf swelling >3 cm compared to unaffected extremity (measured 10 cm below tibial tuberosity)	1
Greater pitting edema in the affected leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented DVT	1
Alternative diagnosis as likely or more than that of DVT	–2
A score of ≥2 indicates that the probability of deep-vein thrombosis is likely	
A score of <2 indicates that the probability of deep vein thrombosis is unlikely	
In patients with symptoms in both legs, the more symptomatic leg is used	

Adapted from Wells PS, Anderson DR, Rodger M, et al. Evaluation of D-dimer in the diagnosis of suspected deep vein thrombosis. *N Engl J Med*. 2003;349(13):1227–1235; Carpenter JP, Holland GA, Baum RA, et al. Magnetic resonance venography for the detection of deep venous thrombosis: Comparison with contrast venography and duplex Doppler ultrasonography. *J Vasc Surg*. 1993;18:734–741.

Diagnostic studies for DVT include ultrasonography, contrast venography, impedance plethysmography, magnetic resonance venography (MRV), and computerized tomography venography (CTV). The primary imaging study to identify patients with DVT is ultrasonography. Lack of vein compressibility is highly sensitive (>95%) and specific (>95%) for proximal DVT. Ultrasound does not detect isolated thrombi in the iliac or femoral veins in the adductor canal. Ultrasound can also occasionally identify other conditions such as tumors, cysts, or aneurysms. In addition, the test is less accurate in the second half of pregnancy and for pelvic vein thrombus, for which the Doppler mode of the duplex ultrasound scan can be helpful. In these situations, or in patients felt to be at very high risk for DVT, it is recommended to use additional tests such as venography or close outpatient follow-up with serial ultrasound examinations within 5 to 7 days (14).

Patients with high clinical probability for DVT who have been evaluated and found to have a negative D-dimer and negative duplex ultrasound have a <1% probability of DVT and do not require serial ultrasound studies (10,15). However, if the initial ultrasound study is negative in a high-probability patient and the D-dimer is elevated, a repeat ultrasound should be obtained on day 5 to 7. MRV has a sensitivity of 100% and specificity 98% to 99% for pelvic and proximal DVTs, as well as 68% for calf DVTs. Advantages of MRV include the ability to distinguish between acute and chronic DVT, evaluate the pelvis and is the test of choice in pregnancy (16,17). CTV evaluates pelvis, thighs, and calves and has similar sensitivity and specificity to US for proximal DVT. It can be done with CT angiography for PE. CTV can diagnose pelvic and calf DVTs. Disadvantages of CT include radiation exposure and cost (18). DVT can also develop in the upper extremities, usually in the subclavian or axillary veins (19). Ultrasound may not be as sensitive as in the lower extremity, but it is still recommended as the first-line diagnostic test. Inadequate or negative examinations in high-risk patients may be followed with contrast venography.

KEY TESTING

- D-dimer
- Ultrasonography

ED MANAGEMENT

Patients with isolated DVT rarely require immediate lifesaving interventions. Treatment is important to prevent clot extension, acute PE, thrombosis recurrence, postthrombotic syndrome and chronic thromboembolic pulmonary hypertension. Many of these patients have occult PEs and all are at risk for new emboli. When a PE is strongly suspected, starting heparin prior to imaging studies is appropriate. In addition, occasional patients can present with complete venous obstruction, a condition referred to as “phlegmasia dolens.” These patients should also undergo immediate heparinization and fluid resuscitation prior to imaging studies when

the diagnosis is suspected. They may also require thrombolytics and occasionally, urgent thrombectomy.

For most patients, the initial treatment for DVT is anticoagulation with a non-vitamin-K-dependent anticoagulant, usually a form of heparin for a short time, in addition to a vitamin K antagonist, for example, coumadin. Combination therapy was shown to be superior by a randomized controlled trial in which recurrent DVT had three times greater incidence if only a vitamin K antagonist was used (20). Heparin blocks extension of thrombus and reduces the risk of further emboli. It does not actively lyse clot but allows the body's own fibrinolytic mechanism to operate over a period of several days to weeks. Heparin can be given in the unfractionated form, which is usually delivered by intravenous infusion or subcutaneously with one of the low-molecular-weight forms. *Unfractionated heparin* (UFH) is best dosed on a weight-based regimen. One of the most commonly used regimens is an 80-U/kg bolus followed by an 18-U/kg per hour infusion (21). Complex nomograms are reliable at attaining therapeutic anticoagulation adjustment while monitoring the aPTT. The efficacy of heparin therapy depends on achieving a critical therapeutic level of 1.5 to 2.5 above the normal aPTT (22).

Low-molecular-weight heparins (LMWHs) are fractionated versions of standard heparin that have a more predictable effect and have fewer side effects or complications. Compared to controls treated with UFH in the inpatient setting, these outpatient protocols have demonstrated very favorable outcomes with respect to short-term (2 weeks) events such as PEs, propagation of thrombus, and minor bleeding (23). Advantages over UFH include greater bioavailability, once or twice a day dosing, lack of need for laboratory monitoring except in certain circumstances (severe renal failure, pregnancy—which may require monitoring Factor anti-Xa levels), and lower risk of heparin-induced thrombocytopenia (HIT). Enoxaparin and dalteparin are two LMWHs used in the treatment of venous thromboembolism. The recommended dosing for these medications is as follows: enoxaparin, 1 mg/kg/dose every 12 hours or 1.5 mg/kg once daily subQ for inpatient treatment and 1 mg/kg/dose subQ every 12 hours for outpatient treatment. Dalteparin dosing is

200 U/kg once daily subQ or 100 units/kg twice daily subQ. These medications are predominantly eliminated by the kidneys. In patients with renal impairment and creatinine clearance >30 mL/min no specific adjustment is recommended, but in patients with severe renal failure lower doses should be used and anti-Xa levels monitored. Enoxaparin is not approved by the FDA for use in dialysis patients.

Fondaparinux is a synthetic heparin pentasaccharide analogue that binds to antithrombin and is given subcutaneously. It has been found to be effective in the treatment of venous thromboembolism (24). Dosing is weight based: <50 kg, 5 mg once daily; 50 to 100 kg, 7.5 mg once daily; >100 kg, 10 mg once daily. It should be adjusted in renal insufficiency and is contraindicated in severe renal failure. In patients with HIT, direct thrombin inhibitors (DTIs) should be used. Two direct thrombin inhibitors approved in the United States for use in patients with HIT are lepirudin and argatroban (25). Thrombolytic therapy has a role in treating limb-threatening thrombosis of the iliofemoral system, and can be considered in this setting, but is otherwise discouraged in the treatment of DVT (26).

Once a non-vitamin K anticoagulant has been initiated, warfarin (5 to 10 mg orally) may be begun, although this is generally not administered in the ED.

Those patients with absolute contraindications to anticoagulation require inferior vena caval interruption with an IVC filter (27). These devices are approximately 95% effective in preventing further PEs but have a 10% complication rate on insertion. However, this rate is not appreciably higher than that of full anticoagulation.

DVT below the knee should be managed in the same way as proximal DVTs. Similarly, there has been controversy regarding the ideal treatment of *superficial thrombophlebitis* of the leg. Though the danger of acute embolism may be less than that of calf DVT, propagation to the deep system must be ruled out at the time of the ED visit and close follow-up must be arranged. Compression bandages, anti-inflammatory drugs, and elevation are standard recommendations but anticoagulation should be considered in

patients with a prior history of DVT. If the patient is an intravenous drug user or appears toxic, *septic thrombophlebitis* must be ruled out. Septic thrombophlebitis most commonly occurs at a site of intravenous catheter placement, and because the most common causative organism is *Staphylococcus aureus,* appropriate antibiotic therapy should be administered.

Postthrombotic syndrome occurs in 20% to 50% of patients with lower extremity DVT, usually within the first 2 years but has been seen as late as 8 years out (28). Endovascular interventions to reduce the thrombus burden have been shown reduce the incidence and severity of postthrombotic syndrome (29,30). Endovascular interventions may include catheter-directed thrombolysis and thrombosuction to prevent postthrombotic syndrome. The American College of Chest Physicians recommend consideration of catheter-directed thrombolysis or pharmacomechanical thrombolysis if appropriate expertise and resources are available for patients who have iliofemoral DVT, symptoms less than 14 days, good functional status, life expectancy $>$ 1 year, and low risk of bleeding (31).

Patients referred for endovascular intervention consultation should be started on anticoagulation therapy in the ED.

CRITICAL INTERVENTIONS

- Anticoagulation with UFH, LMWH, or fondaparinux should be initiated in the ED.
- Traditional loading doses of heparin result in inconsistent anticoagulation of many patients. Weight-based dosing is more effective.
- LMWHs or fondaparinux are effective and allow outpatient therapy in appropriate cases.
- Isolated DVT distal to the knee is not as benign as previously thought. It should be treated more like proximal DVT in terms of therapeutic aggressiveness.
- Early consultation to consider catheter-directed thrombolysis or pharmacomechanical thrombolysis in appropriate patients with

extensive acute proximal DVT in addition to anticoagulant therapy.

DISPOSITION

Historically, all patients with proximal lower extremity or upper extremity DVT required admission to the hospital. However, many institutions now have protocols by which a select subset of patients is discharged directly home from the ED on subcutaneous LMWH with close outpatient follow-up. This practice is supported by the American College of Physicians and American Academy of Family Physician guidelines if the required support systems are in place (17). Referral for possible endovascular intervention to prevent postthrombotic syndrome should be made early in the course. Outpatient treatment is not appropriate in cases of massive DVT (e.g., iliofemoral DVT), symptomatic PE, patients at high risk of bleeding, and those with other conditions who would require hospitalization. Conversely, the treatment of patients with DVT distal to the knee was historically similar to that of superficial thrombophlebitis. Now, with increasing concerns that these patients have risks for embolization that are only modestly lower than those patients with proximal DVT, it is recommended they be treated as those with proximal DVT or entered into a close outpatient follow-up protocol. Patients with *phlegmasia dolens* require more aggressive therapy. Emergent vascular surgery consultation and intensive care admission is indicated. Transport to a higher level of care should be considered if vascular surgery is unavailable.

Common Pitfalls

- Patients with a painful or swollen leg should be considered to have DVT until proven otherwise. Clinical evaluation alone is not sufficient to rule out the diagnosis.
- The traditional physical examination findings of DVT are notoriously inaccurate. The Homan test should be abandoned, and the presence of a palpable cord is not reliable.

- A negative highly sensitive D-dimer (ELISA, second generation latex agglutination-immunoturbidometric) test is useful only in patients with a low and intermediate clinical risk of DVT. It should not be used to exclude the diagnosis in high-risk patients. Moderate-sensitivity (non-ELISA) D-dimers are only adequate in assessing low clinical risk patients.
- A negative ultrasound combined with a negative moderate or high-sensitivity D-dimer leaves a $<1\%$ probability of DVT even in a high clinical probability patient. In these patients further ultrasound testing may not be needed (18).

CHAPTER 97

Vascular Graft Complications

Hoori Hovanessian

Vascular disease is a progressive, degenerative condition that disproportionately affects a subset of patients with other comorbid conditions, such as diabetes and hypertension. When vascular disease progresses despite medical management, surgical treatment often becomes necessary. Although surgery significantly improves quality of life, it is important to realize that the underlying disease continues to progress. These patients are frequent consumers of health care due to disease progression, early or late postoperative complications, or other illness. Knowledge of the pathologic processes that affect the vascular system as well as potential postoperative complications is essential for emergency physicians (EPs).

VASCULAR GRAFTS

Vascular pathology can be subdivided into aneurysmal and occlusive diseases. Aortic aneurysm and aortic dissection have potentially life-threatening consequences. When an aortic aneurysm becomes symptomatic or reaches a predetermined size, aneurysm repair is undertaken with graft replacement. Conventional treatment of aortic dissection involves resection of the damaged segment of the aorta and closure of the entrance into the false lumen. Closure of the lumen can be accomplished by placing sutures or by using biologic glue to seal the layers of the dissected part of the aortic

wall. The diseased section of the aorta that is removed is replaced by a prosthetic graft.

Patients with occlusive disease of the vasculature may undergo extra-anatomic and infrainguinal procedures. Extra-anatomic procedures do not conform to the pre-existing anatomy and include femoral–femoral, axillofemoral, and iliofemoral bypasses. Prosthetic grafts are preferred in extra-anatomic reconstruction. Infrainguinal arterial occlusive disease can affect the femoral, popliteal, or tibial arteries. In these cases, autogenous veins are used in below-the-knee reconstructions, whereas both autogenous and prosthetic grafts are used in above-the-knee repairs (1). Polytetrafluoroethylene (PTFE) is the most commonly used synthetic graft. Tissue can grow through the interstices of the graft, incorporating the graft into tissue, theoretically decreasing the chance of thrombosis and infection.

With the advent of endovascular repair techniques, the treatment of aneurysms, dissection and aortoiliac obstructive disease has been undergoing rapid evolution, with endovascular procedures supplanting conventional surgery in many cases. Endovascular aortic aneurysm repair is performed much more frequently than open repair. Thoracic endovascular aortic repair (TEVAR) is now recommended as first-line therapy for thoracic aortic aneurysms (1). TEVAR has been gaining popularity due to decreased perioperative morbidity and mortality compared to open surgical repair (2). Originally utilized as a treatment for aneurysms, its use has expanded to include the treatment of aortic dissections, transections, and penetrating aortic ulcers. Endovascular procedures also outnumber surgical procedures in the treatment of select types of aortoiliac occlusive lesions (3).

It is also important for the EP to be familiar with complications associated with dialysis shunts. Vascular access for dialysis can be obtained through the formation of an arteriovenous fistula (AVF), whereby an artery and vein are anastomosed. Alternatively, a prosthetic graft can be used to join an artery and vein. Common locations for the creation of both native fistula and graft are the radiocephalic (wrist) and brachiocephalic (upper arm) regions. AVFs are currently preferred over prosthetic grafts because of their lower

complication rates (less potential for thrombosis and lower infection rate) as well as their overall longevity. Prosthetic grafts may be the only option for patients with failed AVFs and those with poor peripheral veins.

GRAFT COMPLICATIONS

The complications of vascular grafts range in presentation from relatively straightforward to subtle and complex. They can be divided into the following categories: (i) stenosis, thrombosis, and occlusion, (ii) infection, (iii) erosion into contiguous structures with fistulization, (iv) pseudoaneurysm formation, (v) hemodynamic complications (dialysis access grafts), and (f) complications associated with endovascular grafts.

Stenosis, Thrombosis, and Occlusion

Early failure of vein grafts generally indicates a technical problem such as a kink or twist within the graft or incompletely lysed valves when autogenous grafts are used. Later failures are usually a result of intimal hyperplasia at the anastomotic sites (1). Failures that occur beyond 2 years are generally a result of progressive atherosclerosis. Graft thrombosis is the most common complication associated with permanent vascular access. Stenosis is the leading cause of thrombosis, accounting for up to 85% of thromboses. Graft thrombosis may result in a relatively sudden return of the patient's previous symptoms. These may include claudication or ischemic rest pain that is localized to the forefoot. Pain caused by arterial insufficiency is usually severe unless it is masked by neuropathy. Signs may include skin breakdown with the formation of nonhealing ulcers. Such ulcers may also form between adjacent toes as a result of mild friction. Superinfection of these ulcers as well as osteomyelitis is a well-documented resultant complication. Painful toes that have a cyanotic appearance are suggestive of microemboli.

Dialysis access graft thrombosis is common despite the fact that heparin is used routinely and uremic patients already have an increased bleeding tendency. Complication-free graft use of 51% at

2 years and 39% at 3 years has been reported with polytetrafluoroethylene grafts (4). Thrombosis and occlusion occur secondary to intimal hyperplasia and can be accelerated by hypotension, dehydration, and by excess pressure applied to the graft site (e.g., by bandages or perigraft hematomas). Patients may complain of a sensation of coldness, tingling, or numbness and weakness of the involved extremity.

Because the signs and symptoms associated with vascular graft complications overlap with other more common medical problems, the differential diagnosis is vast. Limb weakness may result from a cerebrovascular accident or a nerve compression syndrome. Embolic events may be caused by atrial fibrillation or endocarditis.

The ED evaluation of the patient with suspected graft occlusion should include a careful examination of distal pulses by palpation, hand-held Doppler, and duplex ultrasonography. Neurosensory examination is less useful in patients with neuropathy but should be attempted. Skin temperature and the color of the affected limb should also be evaluated. The limb may become pale on elevation with a dusky or cyanotic rubor with dependency. Findings in the affected extremity should be compared to findings on the contralateral side. An ankle-brachial index (ABI) measurement can also provide important information. (The technique and interpretation are described in Tables 95.2 and 95.3.) The loss of a previously palpable pulse or a change of 0.15 from a previous ABI requires further evaluation with duplex ultrasonography or angiography. Finally, low cardiac output (hypovolemic or cardiogenic) may enhance thrombosis and accelerate occlusion, resulting in acute limb ischemia. The patient should be evaluated for evidence of volume depletion (blood loss, dehydration), sepsis, or cardiac insufficiency.

The ED management should include optimization of the patient's volume status. Heparinization to prevent further thrombosis should be counterbalanced against the timing of angiography and the possible use of thrombolytic agents. This decision should be made in conjunction with the vascular surgeon, so consultation should be obtained early. Treatment options include percutaneous or surgical

thrombectomy; thrombolytic agents or mechanical dissolution in the case of thrombosis; and angioplasty, endovascular stent placement, or surgical revision in cases of stenosis. Angioplasty has a higher success rate in stenoses involving less than 60% of the lumen. Surgical revision and repair are preferred in cases of high-grade stenosis.

Infection

The incidence of infection after arterial reconstructive surgery with the use of synthetic grafts ranges from 1% (aortic and iliac artery repair) to as high as 5% (in situations wherein the graft is placed in the inguinal area) (5). Infection is a significant problem in patients with prosthetic dialysis access grafts, with an incidence of 3% to 6% (6,7). Risk factors for vascular graft infections include diabetes, renal failure, obesity, use of prosthetic (vs. native) grafts as well as infrainguinal procedures and surgical revisions (especially if done within 30 days of the original operation). The incidence is higher in patients with acquired immunodeficiency syndrome or a history of intravenous drug abuse.

Intraoperative contamination is likely the most common mechanism for early graft infection. Spread of pathogens from contiguous infected or colonized tissue may explain the relatively higher rate of infection in the groin. Other mechanisms may include hematogenous spread of microorganisms as well as erosion of the graft into contiguous bowel lumen, resulting in direct graft contamination.

Patients with graft infections may present with frank sepsis, an infected wound, or overlying cellulitis. More subtle presentations may include low-grade fever, vague abdominal discomfort, or malaise. Still more complicated presentations may include bleeding, evidence of distal emboli, or the presence of an abdominal mass as a consequence of a false aneurysm. Aortoenteric fistula (AEF) may be the presenting sign in approximately 30% of aortic graft infections (8).

In the ED evaluation of a patient with any type of suspected graft complication, the physician should consider an infectious source, because it may be the underlying cause of graft thrombosis, AEF, or false aneurysm formation. The most common responsible organism is *Staphylococcus aureus* (with methicillin-resistant staphylococcus aureus (MRSA) becoming increasingly common). Other implicated agents include coagulase-negative staphylococci, enterococci, *Pseudomonas aeruginosa, Enterobacteriaceae,* and *Bacteroides* species. Polymicrobial infections occur in 12% to 37% of patients (5). Blood cultures should be obtained, although they may be negative if the lumen is not involved. Computed tomography (CT) scanning may reveal perigraft inflammation or fluid collection, or air adjacent to the graft. Sterile perigraft fluid can be seen on a CT for up to 3 months following graft placement. However, an increase in the volume of the perigraft fluid or persistence of the fluid beyond 90 days may be indicative of infection (9). In the case of grafts that are located close to the skin, the diagnosis is relatively easy in the presence of cellulitic changes, fluctuance, or obvious drainage of pus from the vicinity of the graft site. However, local signs of infection may be absent initially. Graft infection should be considered in any febrile patient, even in the absence of any local findings. Finally, occult infection may be present in old, nonfunctioning dialysis access grafts. The graft may have become seeded from a previous episode of bacteremia or may have become directly inoculated from needle puncture at the time the graft was in use. This source of potential infection should be considered in dialysis patients, as well as in renal transplantation patients, with fever of unclear etiology (10). The diagnosis can be established on an inpatient basis by using indium-111 scanning, which has a sensitivity and specificity over 90% (10).

As with graft thrombosis, the ED management should include optimization of the patient's fluid status to prevent accelerated graft thrombosis and occlusion secondary to poor perfusion through the graft site. Incision and drainage of suspected abscesses in the vicinity of a graft should not be attempted in the ED, as it can result in catastrophic hemorrhage. Empiric antibiotic therapy should be

initiated early. Definitive treatment by a surgeon ranges from local incision and drainage to complete graft removal with debridement of the surrounding infected tissues. Infection in native fistulas can usually be treated with intravenous antibiotics, requiring surgical drainage only in select cases. Therapy should be guided by results obtained from the culture of the infected tissue at surgery following surgical repair. Infections with MRSA and *Pseudomonas* are associated with higher rates of treatment failure (11,12). Therefore appropriate broad-spectrum antibiotic therapy (such as vancomycin or linezolid for gram-positive coverage and ceftazidime, cefepime, piperacillin-tazobactam, or ticarcillin-clavulanate for gram-negative coverage) should be initiated pending blood culture results.

The rate of endograft infections is low (0.2% to 0.7%) (13). Patients have presented with signs and symptoms of severe sepsis, AEFs, as well as nonspecific symptoms such as malaise (13). Because of the low rates of infection with this relatively new procedure, experience is limited and clear-cut management guidelines are not available. These patients have been managed both conservatively as well as with surgery. Consultation with the vascular surgeon is of paramount importance.

Erosion into Contiguous Structures with Fistulization

Erosions of the prosthetic graft into the bowel can result in the formation of an AEF. Most commonly these occur between an aortic prosthetic graft and the distal duodenum. However, such fistulization has been reported after aortoiliac and aortofemoral procedures as well as after renal vascular graft placement. Fistulization to the bowel at sites other than the duodenum may also occur. Mechanical trauma, prosthetic graft or perigraft infection, and pressure necrosis all contribute to fistulization.

The time frame for AEF development is wide. Fistulization may occur several days to many years after the initial surgery (14). Clinical presentation is commonly that of gastrointestinal bleeding: hematemesis, hematochezia, melena, or occult blood loss. Patients may present with self-limited herald bleeding several hours to days

before exsanguinating hemorrhage ensues. Some patients may have nonspecific symptoms of back or abdominal pain. Because fistulization may be secondary to graft infection, other signs and symptoms may include fatigue and malaise, low-grade fevers, and leukocytosis.

AEF should be considered in the ED evaluation of any patient with gastrointestinal bleeding and a history of aortic repair with graft placement. In the stable patient, workup for other sources of bleeding should be initiated, as other sources of bleeding are more common than AEF. Laboratory studies should include a complete blood count, type and cross, coagulation studies, electrolytes, blood urea nitrogen (BUN), creatinine, and glucose. Endoscopy (upper and lower) is important primarily in evaluating other, more common causes of gastrointestinal bleeding. If endoscopy does not yield a clear-cut answer, abdominal CT with oral and intravenous contrast should be obtained to evaluate for inflammatory changes around the anastomotic sites (14,15).

The ED management should initially focus on stabilization and resuscitation. Unstable patients with suspected AEF require emergency laparotomy to control the bleeding. The patient's hemodynamic status should be evaluated and blood loss replaced before surgery. Even in stable patients with an AEF, surgical consultation should be obtained early as the treatment is invariably surgical. Occasionally, grafts erode through the skin. These grafts should be considered infected, and the patient should receive antibiotics. A vascular surgeon should be consulted for urgent repair.

Pseudoaneurysm

Disruption of the suture line (dehiscence) at the site of an anastomotic junction may give rise to a false aneurysm (pseudoaneurysm). False aneurysms most commonly occur in femoral artery graft anastomoses. Leaking blood is contained by the adjoining tissues as well as by fibrous scar formation. Infection is an important cause of pseudoaneurysm formation.

Patients with pseudoaneurysms may complain of pain in the groin, back, or abdomen. They may harbor a pulsatile mass in these locations. Other presentations may include hemorrhage (ranging from occult to life-threatening) caused by rupture of the false aneurysm or signs and symptoms associated with distal emboli. False aneurysms occur most commonly in the groin.

Repeated needle puncture for dialysis access can weaken the vessel wall, thereby leading to aneurysm formation. Pseudoaneurysms can form when the graft material is lacerated with the dialysis needle. In both cases, a pulsatile mass may be present. Pseudoaneurysms may expand and eventually rupture, resulting in significant hemorrhage. Pseudoaneurysm expansion can also threaten the viability of the overlying skin, thereby exposing the underlying graft to infection.

The ED evaluation of the patient with a suspected pseudoaneurysm should include imaging by duplex ultrasound, CT, magnetic resonance imaging, or angiography. Ultrasonography can gauge the size of a pseudoaneurysm and determine the presence of any hematoma and the status of the surrounding vasculature.

Surgical consultation is essential, although other management options such as thrombin injection and embolization procedures are currently being evaluated. In addition, antibiotics should be considered if the pseudoaneurysm is thought to have an infectious etiology. Treatment of vascular access graft aneurysms and pseudoaneurysms involves surgical repair.

Hemodynamic Complications of Vascular Access Grafts

Patients with borderline cardiac reserve and an excessive flow rate through their shunt (>500 mL/min) may exhibit signs and symptoms of congestive heart failure. An arterial steal syndrome with resultant distal ischemia may occur in patients with shunts. The incidence is somewhat higher in patients with proximal than those with distal access sites. The steal syndrome occurs when the blood flows from the artery into the low-resistance vein with less arterial blood available distal to the site of the shunt (1). Though

surgical correction may be required in severe cases, milder symptoms of paresthesias and coolness to touch can improve gradually with development of collateral blood flow. An alternate complication can occur with high-pressure arterial flow into the low-pressure venous system: Venous hypertension distal to the shunt ensues with swelling of the distal tissue and eventual skin induration and hyperpigmentation (1). Shunt repair may be necessary if the steal syndrome and venous hypertension cause clinical symptoms.

Neurovascular problems associated with vascular access include pain, weakness, muscle atrophy, and paresthesias. These hemodynamic and neurovascular complications are more problematic with fistulas but do occur with prosthetic grafts as well.

Complications Associated with Endovascular Grafts

Several early complications have been described in this emerging area of vascular repair. Limb ischemia or occlusion may require subsequent extra-anatomic (femoral–femoral) bypass, thrombectomy and angioplasty, or thrombolysis. These complications may occur intraoperatively (during endovascular graft placement) or over a year later (16). These complications are a result of vascular trauma as well as underlying peripheral vascular disease. Endoleaks, which complicate 10% to 20% of repairs, are defined as incomplete exclusion of the aneurysm with persistent leakage of blood into the aneurysmal sac (17). This can result in enlargement of the sac and/or increased pressure in the sac, ultimately leading to aneurysmal rupture. Several types of endoleaks have been defined including those that occur at the site of attachment of the graft to the aorta (from incomplete seal of the endograft) or through the stent graft itself (via a tear or fracture) (18). Other potential complications include distal embolization, graft occlusion, kinking, migration or prolapse into the aneurysm, and infection. Device migration may occur intraoperatively or over time. Device manufacturers are addressing this problem. Migration of the stent graft may present as an endoleak. Stent graft erosion into the

esophagus has also been reported (19). More commonly observed complications of TEVAR include spinal cord ischemia and stroke. The incidence of paraplegia or paraparesis after TEVAR with stent grafts varies from 0% to 8% and typically extends from the lumbosacral to the high thoracic cord levels (20). The incidence of stroke due to embolization of atheroma or thrombus formation after instrumentation and disruption of plaques varies from 2.3% to 8.2% (21).

Endovascular repair continues to evolve with advances in the design of endografts. Research is also ongoing in the design of more complex endografts, intended for situations where aortic pathology involves branch vessels. Long-term complications remain unknown given the relative infancy of this field. In general, however, endovascular procedures have been associated with lower complication rates, shorter hospital stays, as well as lower costs.

CRITICAL INTERVENTIONS

- The patient's hemodynamic status should be evaluated and fluid losses replaced.
- In patients with massive gastrointestinal hemorrhage and an intra-abdominal graft, emergent vascular consultation should be obtained and the patient readied for surgery.
- Empiric antibiotic therapy should be initiated in any febrile or septic-appearing patient with a fever of unknown etiology and the presence of a vascular graft, whether functioning or nonfunctioning. Given the higher complication rates with MRSA and *Pseudomonas* infections, antibiotic coverage should be provided for these organisms.

DISPOSITION

Most graft complications require surgical consultation and management in a hospital setting. After diagnosis and initial measures such as the initiation of antibiotic therapy and replenishment of fluid and blood loss, stable patients should be

admitted and managed by a vascular surgeon. Unstable patients require resuscitation prior to emergent surgical intervention.

Diagnostic and management decisions should ideally be made in conjunction with a vascular surgeon as well as an interventional radiologist skilled in these relatively novel procedures.

Common Pitfalls

- Failure to consider graft thrombosis when a patient with a vascular graft has a recurrence of claudication, rest pain, skin breakdown, or nonhealing ulcers
- Failure to exclude infection when evaluating patients for any type of graft complication
- Failure to evaluate the ABI and compare it to the previously obtained values
- Failure to consider AEF in any patient with gastrointestinal bleeding and a history of aortic repair
- Failure to consider a pseudoaneurysm in patients with a history of vascular repair and complaints of abdominal or groin pain, hemorrhage, or pulsatile mass
- Failure to appreciate that low-flow states may contribute to vascular access thrombosis

SECTION X
Gastrointestinal Emergencies

Section Editor: GREGORY W. HENDEY

CHAPTER 98

Esophageal Disorders

Kathryn A. Volz and Leon D. Sanchez

Esophageal disorders encompass a large differential in the emergency department with some life-threatening presentations as well as many benign disorders that require outpatient work up. Complicating matters further are significant overlap in symptoms with many life-threatening disorders including cardiac, vascular, and respiratory pathologies.

ESOPHAGITIS

Clinical Presentation

Patients may present with pain on swallowing (odynophagia), with or without difficulty in swallowing (dysphagia). Pain may be described as a retrosternal ache, a burning sensation, or a stabbing pain with radiation to the back. Patients with severe cases may present with anorexia or weight loss.

Patients with a history of immunosuppression are at increased risk of infectious esophagitis. Candida or herpes esophagitis may present with lesions present in the oropharynx as well. However, approximately 25% of patients with candidal esophagitis do not have oral thrush, so its absence does not rule out this entity (1). While immunocompetent patients usually report recent upper respiratory infection and have visible herpetic lesions, these lesions can be absent in immunocompromised patients. Herpes esophagitis should be suspected when symptoms do not improve with typical antifungal medications in immunocompromised patients (2). In esophageal candidiasis, odynophagia is usually mild. If symptoms

are so severe that the patient consciously limits oral intake, ulcerative esophagitis of some other etiology is likely. Patients with AIDS often have coinfection with more than one infectious source (3).

Most important immediate consequences of esophagitis are local pain and impaired oral intake. Rarely, the initial manifestation of esophageal disease is GI bleeding. Complications of candidal or viral esophagitis are uncommon and include hemorrhage, perforation, esophageal narrowing with stricture formation, and dissemination of infection.

Patients with pill esophagitis may give history of taking a new medication, with common offending agents including doxycycline, potassium chloride, quinidine, alendronate, ferrous sulfate, aspirin, and nonsteroidal anti-inflammatory agents. In all, more than 70 medications have been reported to cause esophageal injury (4). The elderly are at increased risk for pill esophagitis. Patients typically report retrosternal pain, odynophagia, and dysphagia that are temporally related to ingestion of medication. They may give a history of taking the medication with little or no water.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of esophagitis includes gastroesophageal reflux disease (GERD), esophageal dysmotility disorders, esophageal perforation, gallbladder disease, pharyngitis, abscesses, food impaction, or esophageal foreign body. Coronary artery disease, aortic pathology, and pulmonary embolism can present with similar symptoms and must be considered.

ED EVALUATION

The initial history should first focus on the duration and severity of the symptoms and on the patient's ability to maintain normal oral intake. The patient should be questioned about human immunodeficiency virus infection, malignancy, or other sources of immunosuppression. Other relevant questions include whether there is an association of symptoms with pill ingestion, food bolus, foreign

bodies, or symptoms suggestive of esophageal reflux. Myocardial ischemia should be considered.

Physical examination should concentrate initially on the patient's state of hydration. Vital signs should be noted, as well as skin turgor and the condition of the mucous membranes. One clue to the severity of the patient's symptoms may be the ability to swallow their own saliva. The oropharynx should be examined for candidal or herpetic lesions. A soft-tissue lateral neck radiograph or neck computed tomography (CT) scan should be obtained if mass or abscess is a consideration. Other life threats including cardiac causes of the patient's symptoms should be excluded.

KEY TESTING

- Chest X-ray to evaluate for evidence of esophageal perforation or foreign body
- EKG to evaluate for cardiac ischemia
- Cardiac markers, D-dimer, and advanced imaging as appropriate depending on suspicion of other pathology

ED MANAGEMENT

A number of antifungal agents have been used to treat oral and esophageal candidiasis. Fluconazole is currently the drug of choice (5,6). Other antifungal options exist, but they are generally tolerated less well and have more undesirable side effects. Patients requiring IV therapy or with resistance to azoles may benefit from use of echinocandins such as caspofungin (7). All systemic antifungal prescriptions should be written with care and checked against the patient's other medications, for many can cause potentially serious drug–drug interactions.

Foscarnet and ganciclovir appear to be similarly effective and safe in the treatment of AIDS-related CMV esophagitis (8). Herpes simplex virus (HSV) esophagitis may be self-limited in the immunocompetent host, but therapy with oral or IV acyclovir should be instituted in immunocompromised patients.

In patients presenting with mild esophageal symptoms that do not limit oral intake, an empiric trial of antifungal therapy with fluconazole is reasonable regardless of the presence or absence of oral candidiasis. If symptoms improve a presumptive diagnosis of esophageal candidiasis may be made. If a patient does not respond within 72 hours, endoscopy should be considered.

Pill esophagitis is easily treated by discontinuing the offending medication or changing to liquid or tablet (as opposed to gelatin) form when possible. Patients should be instructed to avoid taking pills before bedtime, take pills with plenty of water, and avoid lying down after taking pills. The condition usually resolves within 3 to 4 days without any intervention (4), provided the medication is discontinued, but complete resolution may take several weeks. The most common complication is stricture formation.

CRITICAL INTERVENTIONS

- Admit patients with dehydration due to severe odynophagia for IV rehydration.
- Treat patients with suspected candidal esophagitis with fluconazole.
- Admit immunocompromised patients for further evaluation and treatment.

DISPOSITION

Immunocompetent patients with mild symptoms may be treated as outpatients. Referral to a gastroenterologist and follow-up are appropriate for these patients, as well as for those who do not respond to initial therapy.

Patients who are experiencing severe difficulty with swallowing and are unable to maintain hydration require hospital admission. Immunocompromised patients should be strongly considered for IV antiviral or antifungal therapy and admission.

Patients with pill esophagitis should be referred to their primary care physician to ensure that timely resolution of symptoms occurs.

ESOPHAGEAL DYSMOTILITY

Clinical Presentation

Motility disorders including achalasia, diffuse esophageal spasm, nutcracker esophagus as well as obstructive causes including esophageal web, rings, strictures, and tumors comprise the second group of esophageal disorders which can present as chest pain as well as dysphagia, regurgitation, and heart burn. Weight loss is also a feature of the motility disorders due to decreased oral intake and fear of dysphagia and chest pain (9). Patients may also develop esophageal dysfunction secondary to other conditions, most notably scleroderma.

Achalasia is a motility disorder with deficient peristalsis and poor relaxation of the lower esophageal sphincter. Chest pain is the most common symptom in about half of patients followed by dysphagia, notably to both liquids and solids. Symptoms generally begin intermittently but become more persistent. Warm drinks may improve symptoms, whereas cold carbonated beverages produce more symptoms (9,10). The site of obstruction is often correctly located by the patient in the xiphoid area. Patients with achalasia learn maneuvers to assist esophageal emptying, such as throwing the shoulders back, extending the neck, or performing a Valsalva maneuver (1). Patients may report regurgitation of undigested food. Regurgitation occurs most commonly at night because of the recumbent position, and vomitus may be noted on the pillow on awakening in the morning. Aspiration is a common complication of achalasia and may present as cough, pneumonia, or lung abscess.

Diffuse esophageal spasm and nutcracker esophagus are characterized by increased simultaneous esophageal spasm and increased esophageal pressures, respectively. Patients may present with dysphagia or with chest pain that is triggered by the ingestion of very hot or cold liquids.

Obstructive dysphagia may be due to structural lesions of the esophagus, including esophageal webs and rings, as well as tumors. Esophageal carcinoma is a very important cause of dysphagia and is important to recognize early in its course. The prognosis is dismal

by the time a patient presents with progressive dysphagia. Heavy alcohol intake and smoking significantly increase the likelihood of squamous cell carcinoma of the esophagus, and adenocarcinoma tends to occur in patients with a long history of GERD or Barrett's esophagus. Food impaction is further discussed in Chapter 114, but food obstruction may be the first indication or presentation of an obstructive lesion.

DIFFERENTIAL DIAGNOSIS

In addition to those listed above, the differential diagnosis includes oropharyngeal dysphagia, or difficulty passing food from the mouth to the esophagus. This is often secondary to a CVA or other neurologic condition. Other conditions to be considered include cardiac, respiratory, and vascular causes of chest pain, as well as esophageal foreign bodies, GERD, and gastritis.

ED EVALUATION

The evaluation of dysmotility should begin, as always, with attention to the airway, breathing, circulation, and particularly to hydration status. A cardiac cause of chest pain should first be considered before implicating the esophagus. A chest X-ray to evaluate for evidence of esophageal perforation should be performed; this may also offer clues to other causes of dysmotility such as visualization of a mass, or evidence of achalasia with the presence of an air–fluid level in the posterior mediastinum (caused by the dilated, fluid-filled esophagus), and the absence of a gastric air bubble (because swallowed air cannot get into the stomach).

KEY TESTING

- Chest X-ray to evaluate for evidence of esophageal perforation

ED MANAGEMENT

Patients who are adequately hydrated, are able to eat and drink, and who have been ruled out for life-threatening causes of their symptoms can be referred for further work up as outpatients. If

patients have a known history of achalasia they should be encouraged to maintain an upright position after eating for several hours. Drinking hot liquids may also be helpful.

CRITICAL INTERVENTIONS

- Carefully differentiate esophageal chest pain from that of cardiac origin.

DISPOSITION

If cardiac causes have been excluded and the patient tolerates oral intake, follow up with the primary care physician or gastroenterologist is appropriate. Outpatient work up of dysmotility disorders may include Barium swallow, esophagogastroduodenoscopy (EGD), and esophageal manometry. Endoscopy is indicated in all patients suffering from food impaction, whether the food bolus is eventually passed or not. Food impaction may be the first sign of an obstructive lesion.

GASTROESOPHAGEAL REFLUX DISEASE

Clinical Presentation

GERD is defined as reflux of the stomach contents into the esophagus causing troubling symptoms or complications (11). Symptomatic GERD is common. Prevalence is significantly higher in developed countries. About 40% of US adults have monthly heartburn symptoms, about 20% have weekly symptoms, and about 7% have daily symptoms (12).

Risk factors for GERD include advanced age, male sex, white race, smoking, obesity, high-fat diet, and intake of alcohol, chocolate, citrus drinks, soda and coffee. Medications such as theophylline, nitrates, calcium channel blockers, meperidine, nonsteroidal anti-inflammatory drugs, and oral contraceptives may aggravate GERD. Stress and exercise have also been found to exacerbate symptoms. GERD is associated with several medical conditions including pregnancy, diabetes, hiatal hernia, scleroderma, cerebral palsy, and

Down's syndrome. Procedure-related conditions such as nasogastric tube insertion and gastrostomy feedings may lead to GERD (12).

The most common presenting symptoms include heartburn or a retrosternal burning sensation rising from the stomach to the throat, regurgitation or bitter taste, and dysphagia. Nausea may also be present (13). Symptoms are usually worse after eating, at night, with exercise, or with bending or lying supine. There may be radiation of the discomfort to the back, neck, or left arm. The intensity is variable, and the duration may be minutes or hours. Symptoms may improve after taking antacids.

DIFFERENTIAL DIAGNOSIS

A cardiac etiology must always be excluded when a patient presents with burning substernal chest pain, and the differential is the same as that of cardiac ischemia. Chest pain of esophageal origin may be impossible to distinguish from angina by history or physical examination alone. Both cardiac causes of chest pain as well as GERD can respond to either antacid/ "GI cocktail" or nitroglycerin; thus response to these medications is not diagnostic (14).

Unfortunately, there are no characteristic features of chest pain that are pathognomonic of esophageal disorders, including response to medications. Other considerations include pancreatitis, gallbladder disease, peptic ulcer disease, esophagitis, and esophageal dysmotility disorders.

ED EVALUATION

The ED evaluation should focus on ruling out cardiac ischemia as well as aortic and pulmonary pathology as the origin of chest pain. If these causes can be excluded and the patient gives a history of heartburn without dysphagia, fever, weight loss, or GI bleeding, no further studies are required in the ED and referral to a gastroenterologist may be appropriate. The most useful tests for diagnosing reflux are barium swallow, endoscopy, and 24-hour gastric pH monitoring, all of which are performed on an outpatient basis.

KEY TESTING

- Chest X-ray to evaluate for evidence of esophageal perforation
- EKG to evaluate for cardiac ischemia
- Cardiac markers, D-dimer, and advanced imaging as appropriate depending on suspicion of other pathologies

ED MANAGEMENT

ED management should begin with symptom control, including antacids, "GI cocktail," H_2 blockers, or proton pump inhibitors (PPIs). Gaviscon is a viscous solution containing antacids that float above the gastric pool to mechanically block reflux fluid and has been used for immediate relief (12).

Long-term management is typically with H_2 receptor antagonists or PPIs. For mild or intermittent symptoms, a trial of H_2 receptor antagonists has been considered traditional therapy. H_2 receptor antagonists can be used as premedication by patients who are able to predict symptom recurrence, such as before a large meal. They may also be used to prevent nocturnal acid production.

For moderate to severe symptoms and for those in whom there has not been adequate improvement with H_2 blockers, a 6-week trial of empiric acid suppressive therapy is often attempted. A meta-analysis suggests that PPIs are more effective at treating GERD when compared to H_2 blockers. Complete relief of symptoms with PPIs occurs at a rate of 11.5% per week versus 6.4% with H_2 blockers (15,16). PPIs have become standard therapy for GERD because they result in healing of about 80% of moderate to severe reflux esophagitis (12). Symptoms usually improve in 1 to 2 weeks. If symptoms disappear with therapy, then reappear when the medication is discontinued, a presumptive diagnosis of GERD is made (sensitivity 75%, specificity 80%) (17). If the diagnosis of GERD is established and symptoms still persist, physicians may elect to try twice daily dosing or switching to a different PPI (17).

Education at time of discharge regarding lifestyle modifications including dietary changes, remaining upright for 3 hours after

meals, elevation of head of bed, and cessation of smoking and alcohol intake is an important adjunct to pharmacologic treatment (18).

Patients whose symptoms persist for more than 6 weeks should be referred for outpatient GI workup including EGD. EGD is highly sensitive and specific for diagnosing reflux esophagitis and GERD complications such as Barrett's esophagus, bleeding, and strictures because the mucosa is observed directly. Biopsies can be performed and cultures obtained. Patients who should undergo initial EGD before a therapeutic trial include all patients older than 55 years, young patients with severe comorbidities; patients with severe symptoms, involuntary weight loss, or GI bleeding; patients using nonsteroidal anti-inflammatory drugs or aspirin; and native Japanese patients (12).

CRITICAL INTERVENTIONS

- Carefully differentiate GERD symptoms from those of cardiac origin.

DISPOSITION

If other life-threatening causes of patient symptoms have been excluded the patient can be discharged and referred to the primary care physician. ED physicians may elect to initiate acid suppressive therapy with a H_2 blocker or PPI. For severe or resistant symptoms or suspected complications of reflux esophagitis, the patient may be referred to a gastroenterologist for further evaluation.

ESOPHAGEAL PERFORATION

Esophageal perforation can be spontaneous, traumatic, or iatrogenic, with iatrogenic being the most common (19). Esophageal perforations have a very high morbidity and mortality. Traumatic esophageal ruptures are discussed further in Chapter 27. Esophageal foreign bodies can contribute to esophageal perforation, these are discussed further in Chapter 115. Caustic ingestions can also cause severe damage to the esophagus and represents a true emergency.

CLINICAL PRESENTATION

Patients with spontaneous esophageal perforations or Boorhave's syndrome present with chest pain radiating to the back, often following prolonged vomiting or coughing. A history of previous ingested foreign body, eating disorders, alcoholism, history of peptic ulcer disease, or pregnancy with hyperemesis may be obtained. Patients with iatrogenic perforations present with history of recent EGD or other esophageal procedures such as esophageal dilation. Nonbloody emesis followed acutely by chest pain, often radiating to the back, dominates the clinical picture. Patients with perforations appear more toxic and may also present with dyspnea or shock and their condition can deteriorate rapidly (19).

DIFFERENTIAL DIAGNOSIS

Again differential diagnosis includes other causes of chest pain including cardiac, aortic dissection, pulmonary causes including pneumonia or pneumothorax, as well as sepsis.

ED EVALUATION

Initial evaluation should include evaluation of airway, breathing, and circulation. IV access should be obtained and IV fluids started as indicated by the patient's hemodynamic status. A chest X-ray should quickly be obtained. Chest X-ray will usually demonstrate mediastinal air or free air under the diaphragm giving you the diagnosis. Other findings may include pleural effusion, pneumothorax, or widened mediastinum. If diagnosis is unclear after chest X-ray a CT scan of the chest should be pursued. Esophagram can also be performed but has a false negative rate of as high as 10% (20). Gastrografin should be used rather than barium as if perforation is present. Barium extravasation into the mediastinum can cause further complications (21).

KEY TESTING

- Chest X-ray. If chest X-ray is nondiagnostic, proceed to CT of the chest.

ED MANAGEMENT

ED management should include broad spectrum antibiotics, aggressive supportive care, and consultation with a thoracic surgeon for likely surgical repair.

CRITICAL INTERVENTIONS

- Identify perforation with chest X-ray, CT scan, or esophagram
- Early broad-spectrum antibiotics
- Early consultation with a thoracic surgeon

DISPOSITION

Patients with esophageal perforation require admission to the hospital.

Common Pitfalls

- Mistakenly attributing pain on swallowing to pharyngitis. Severe and potentially life-threatening conditions including epiglottitis and retropharyngeal abscesses should be excluded.
- Failing to consider an immunosuppressed state and susceptibility to infectious esophagitis.
- Failing to consider esophageal foreign bodies and food impaction, especially in the elderly and the alcoholic. Pill esophagitis is likewise underappreciated.
- Mistakenly attributing chest pain caused by coronary artery disease as GI in origin, especially when substernal burning or atypical chest pain appears to be relieved by antacids or a "GI cocktail."
- Failing to evaluate and refer patients with mild dysphagia when a potentially treatable obstructive lesion may be the cause.

CHAPTER 99

Upper Gastrointestinal Bleeding

Michael A. Cole and Sukhjit S. Takhar

Gastrointestinal (GI) bleeding is a common emergency, with a prevalence of 170 cases per 100,000 adults per year in America. In the majority of cases, the source is the upper GI tract, and the mortality from upper GI bleeding (UGIB) has remained at approximately 6% to 8% for three decades (1). Patients with GI hemorrhage often have coexisting serious illnesses, making their care even more challenging. The site of bleeding is usually predictable from the history and physical examination and is often confirmed and treated by endoscopy. Although there have been many advances in care, the fundamental goals of resuscitation and hemostasis remain the same.

UGIB is defined as a source of bleeding originating between the upper esophageal sphincter and the ligament of Treitz. Although peptic ulcer disease is the cause of more than 60% of UGIB cases, the highest mortality rates are associated with variceal bleeding. Due to the potential severity and unique pathophysiology and treatment of variceal bleeding, it is useful to divide UGIB into variceal and nonvariceal bleeding (1,2).

Causes of UGIB are listed in Table 99.1. UGIB may occur at any age but has a higher incidence in patients older than 40 years. It is more common in males than females. Elderly patients have less ability to compensate for acute hemorrhage and the majority of deaths occur in this subgroup. Mortality is also higher in those with multiple comorbidities (3,4).

TABLE 99.1
Causes of Upper Gastrointestinal Tract Bleeding

Most Common	
Peptic ulcer	35–66%
Gastroduodenal erosions	8–15%
Esophagitis	8–15%
Varices (esophageal and gastric)	5–10%
Mallory–Weiss tear	5%
Less Common	
Epistaxis, hemoptysis	
Aortoenteric fistula	
Boerhaave syndrome	
Carcinoma	
Vascular anomalies	
Caustic ingestion	
Anastomotic ulcer	

CLINICAL PRESENTATION

Patients present with a variety of GI symptoms, such as nausea, vomiting, and abdominal pain, as well as symptoms of acute blood loss, such as lightheadedness or syncope. UGIB classically presents with hematemesis and melena. Bright-red emesis suggests fresh blood with significant, ongoing hemorrhage. Both coffee-ground emesis and melenic stools signify a more subacute to chronic UGIB. Experienced clinicians sometimes make a presumptive diagnosis of UGIB based on the unique odor of melenic stool. Hematochezia is usually a result of lower GI hemorrhage but may occur in those with a massive UGIB and rapid GI transit (2,5,6). Furthermore, some patients with melena may have a lower GI source for their bleeding (7).

UGIB can result in varying degrees of blood loss, ranging from trivial, occult bleeding to fatal exsanguination. Patients may have underlying comorbid conditions that can complicate the interpretation of the vital signs. Hypovolemic patients often complain of thirst, apprehension, weakness, or lightheadedness. When reflex mechanisms can no longer fully compensate for volume

loss, hypotension develops and organ perfusion is impaired. This can result in oliguria, altered mentation, metabolic acidosis, and dyspnea. Some patients may not recognize that a black stool is a sign of bleeding. Melena must also be differentiated from black stools due to iron or bismuth, which do not have the tarry consistency and are guaiac-negative.

DIFFERENTIAL DIAGNOSIS

If the clinician can appropriately categorize the bleeding as having an upper or lower source, the differential may be more focused. However, it is not always possible to establish the location of bleeding in the ED. The appearance of the stool is often helpful but is sometimes misleading. In one study, the ingestion of 1000 mL of blood led to hematochezia, demonstrating that an upper rather than lower source may be the cause of hematochezia (8). Conversely, melena may be produced by as little as 50 mL of blood from an upper GI source (9).

The most frequent cause of UGIB is *peptic ulcer disease.* Hemorrhage results from erosion into an underlying vascular structure. Predisposing factors for peptic ulcers include cigarette smoking, ingestion of alcohol, nonsteroidal anti-inflammatory (NSAID) use, hereditary factors, and colonization with *Helicobacter pylori* (10,11). The rate of hemorrhage from peptic ulcer disease appears to be decreasing in the United States, possibly due to increased use of proton pump inhibitors (PPIs) and treatment for *H. pylori* (11).

Erosive gastritis is also a common cause of UGIB. The resultant bleeding can range from minimal to life-threatening, and the clinical presentation is often indistinguishable from that of a peptic ulcer. The most common predisposing factor is the use of NSAIDs. Other risk factors include use of alcohol, prolonged corticosteroid use, age, major trauma, burns, or head injury.

Esophageal and gastric *varices* are two of the most dangerous causes of UGIB. Varices should be suspected in patients with a history of cirrhosis or with other stigmata of liver disease. The

presence of hepatic dysfunction and other comorbidities further worsens the prognosis. Bleeding can be sudden and massive and is associated with an acute mortality rate between 15% and 53%. Patients with variceal hemorrhage also have a poor long-term prognosis, with a projected 1-year mortality of 70% (12).

Mallory–Weiss tears are longitudinal, *nontransmural* tears that occur at the gastroesophageal junction and are usually caused by recurrent forceful vomiting or retching. The history of sudden vomiting of bright-red blood after retching is characteristic, but this history is present in only one-half of patients with Mallory–Weiss tears. Risk factors include alcohol abuse, hiatal hernia, and underlying esophagitis. Bleeding usually stops spontaneously, and intervention is rarely required. Mallory–Weiss tears are differentiated from Boerhaave syndrome, which is a *transmural* tear of the esophagus that typically presents as chest pain, odynophagia, and pneumomediastinum *without* GI bleeding.

Other, less common conditions account for the remaining 10% of episodes of UGIB (see Table 99.1). *Aortoenteric fistula* occurs when an aortic aneurysm or a synthetic graft erodes into the small intestine, producing massive hemorrhage. Aortoenteric fistulas can occur within weeks to many years after the initial aneurysm repair, with one study reporting an average of 2.8 years (13).

Patients with small intestinal angiodysplasias may present with melena. This diagnosis is usually made on a small bowel examination after upper and lower endoscopies are negative.

ED EVALUATION

The first priority should be to identify and treat patients who are hemodynamically unstable. This assessment should start with the initial triage or in the prehospital setting. The goal is to rapidly assess the severity and location of bleeding and to determine whether the patient may have variceal bleeding.

Medications and allergies should be noted, with an emphasis on NSAIDs, acetylsalicylic acid, and anticoagulants. Patients who are anticoagulated have more severe bleeding and a higher mortality

(3,11,14,15). Use of iron products or bismuth (Pepto-Bismol) should be noted, as their use may mimic melena. Severe abdominal pain is unusual, as many causes of UGIB are painless. The review of systems should include symptoms consistent with hypovolemia (e.g., chest pain, dyspnea, light-headedness, or syncope). Those with a history of cirrhosis or alcoholism should be assumed to have variceal bleeding (14,16).

The physical examination should focus on finding evidence of bleeding and attempting to localize and quantify the blood loss. Hypotension may not be present until 30% to 40% of the circulating blood volume has been lost, though orthostatic changes occur with more modest losses. In an adult, a supine systolic blood pressure of $<$100 mm Hg, or an orthostatic pulse increase of $>$20 to 30 beats per minute, suggests an acute blood loss of at least 1 L. However, orthostatic vital signs are not reliable, especially at the extremes of age. Although tachycardia is usually present after acute blood loss, it is not a reliable finding. Flat neck veins; cold, mottled extremities; altered mental status; or pallor are all suggestive of significant acute blood loss.

The nose and oropharynx should also be examined for potential bleeding sources. Stigmata of chronic liver disease (jaundice, ascites, and spider angiomata) are concerning for variceal bleeding. Ecchymosis, gingival bleeding, and epistaxis suggest a coagulopathy or platelet deficit.

Digital rectal examination and stool appearance are important parts of the early evaluation. The presence of gross blood should be noted. Not all black stool is melena, so it should be tested to confirm the presence of blood. Abdominal tenderness can be associated with perforated peptic ulcer or gastritis.

Initial laboratory evaluation should include a complete blood count, electrolyte panel, blood urea nitrogen (BUN), creatinine levels, liver function tests, and coagulation studies. Unless the bleeding seems minimal, patients should also have a type and screen or crossmatch for blood. An elevated BUN is often seen in the setting of a UGIB, and a BUN-to-creatinine ratio of $>$30 increases the likelihood of UGIB (17,18). The hemoglobin and hematocrit can

be normal immediately after massive blood loss. Elderly patients should be evaluated for myocardial ischemia. A chest radiograph is indicated if aspiration, esophageal rupture, or cardiopulmonary complications are suspected. Abdominal films may be helpful in the subset of patients with suspected perforation or bowel obstruction, but computed tomography scan is more definitive.

The placement of a nasogastric (NG) tube may be considered in select patients with UGIB; however, routine placement is controversial (1,11,19). NG tube placement has been reported to be one of the most painful procedures performed in the ED (20). More importantly, a negative aspirate does not rule out a significant source of bleeding. NG placement may provoke vomiting, and aspiration and a recent study demonstrates that NG tube placement does not decrease mortality or the length of stay in a hospital (17,21,22). The poor sensitivity and specificity of an NG tube aspirate has been well described (1). In patients with melena but no hematemesis, the finding of fresh blood may be useful, but this information comes at the expense of significant discomfort to the patient (19). The early use of endoscopy can provide much more information. NG aspiration also misses up to 25% of bleeding duodenal ulcers, because it does not reliably sample material past the pylorus. Thus, making disposition decisions based on a negative aspirate is risky. Of note, varices are not a contraindication to NG tube placement.

KEY TESTING

- CBC, platelets, coagulation studies, type, and screen
- Stool guaiac test

ED MANAGEMENT

Initial resuscitation efforts should be guided by the estimated severity of bleeding. Patients with significant bleeding should be placed on a cardiac monitor, receive supplemental oxygen, and have intravenous access established with two large-bore catheters. Close attention to airway, breathing, and circulation is paramount.

Critically ill patients, those with massive bleeding or altered mental status, usually need endotracheal intubation (2,5).

Intravenous fluid resuscitation to maintain blood pressure is essential. If the patient's condition has not substantially improved after IV fluids and ongoing hemorrhage is suspected, blood transfusion is indicated. Crossmatched blood is preferred, but those in extremis may require type-specific or type O blood. The appropriate transfusion thresholds and targets during emergency care have not been established, and in acute hemorrhage, hemoglobin values can be misleading since compensatory hemodilution may lag by several hours. A normal hemoglobin concentration thus does not exclude an acute massive hemorrhage. After admission, a restrictive approach involving blood transfusion below hemoglobin levels of 7 g per dL improves clinical outcomes, although this benefit has not been demonstrated in the emergency setting (23). The decision to transfuse should also take into account the patient's symptoms and hemodynamics, and the physician's estimate of ongoing blood loss. Warmed blood should be used in patients who require massive transfusion, and if a large number of packed red blood cells (PRBCs) have been transfused one may consider initiating a "massive transfusion protocol" involving administration of blood, platelets, and fresh frozen plasma (FFP) in a 1:1:1 ratio. Massive transfusion protocols may help prevent the dilutional coagulopathy that results from the administration of large quantities of packed red blood cells, although evidence for improved outcomes in UGIB is lacking.

Coagulopathy and thrombocytopenia should be corrected as needed. Current recommendations are to resuscitate with FFP until the patient reaches an INR < 2.7 and to maintain the platelet count above 50×10^9/L (24,25). Platelet transfusion may also be considered in the presence of qualitative platelet defects due to NSAID or aspirin use. There is no current evidence to justify the routine use of factor VII or tranexamic acid (TXA) in UGIB (25–27). In a *stable,* coagulopathic UGIB patient the decision to use plasma or vitamin K should be based on the medical cause of coagulopathy (e.g., warfarin for chronic atrial fibrillation versus cirrhosis) (28).

An ongoing assessment of vital signs, general clinical status, and urine output will help to guide resuscitative efforts. In patients with massive bleeding, early consultation with a gastroenterologist, an intensivist, and possibly a surgeon or an interventional radiologist should be arranged. Further treatment of UGIB depends on whether the bleeding is nonvariceal or variceal.

Nonvariceal Bleeding

Pharmacologic therapy in nonvariceal UGIB centers on acid suppression. Gastric acid impairs clot formation, and many common causes of UGIB (e.g., ulcers, gastritis, esophagitis, and duodenitis) respond well to PPIs. High-dose intravenous PPIs decrease the need for endoscopic therapy, and consensus guidelines recommend starting high-dose PPI therapy prior to endoscopy (1). Nevertheless, no current evidence demonstrates that PPIs decrease mortality, risk of rebleeding at 30 days, or risk of surgery in patients with UGIB (29). A commonly recommended regimen is omeprazole 80 mg as an IV bolus, followed by 8 mg/hr for 3 days (11). H_2 blockers have no role in the treatment of acute UGIB since they do not consistently raise the pH, and studies have failed to show any benefits (1).

Endoscopy is the most important diagnostic and therapeutic tool in UGIB. Endoscopy can identify the cause of bleeding, may provide prognostic information, and allows for the administration of endoscopic therapy (3,5,30,31). Patients with high-risk endoscopic findings such as active bleeding or a visible vessel require emergent endoscopic therapy (1), the main techniques being thermocoagulation and injection therapy. Patients with low-risk endoscopic findings (e.g., flat-based ulcer) do not require endoscopic treatment or high-dose PPI therapy but may benefit from standard oral PPI therapy as outpatients. Occasionally, endoscopy and pharmacologic therapy fail to stop the bleeding, and emergent surgery or angiography must then be considered (1,4). Angiographic therapy is gaining popularity for high-risk patients who cannot tolerate a major surgical procedure.

Variceal Bleeding

Variceal bleeding occurs mainly in patients with advanced cirrhosis and is associated with complications related to hepatic dysfunction such as coagulopathy, sepsis, renal failure, and hepatic encephalopathy. Overresuscitation is also a concern, as this increases portal pressure and may increase the risk of rebleeding.

Early endoscopy is critical in these high-risk patients since it may enable definitive therapy. However, endoscopy is often delayed due to logistical issues or patient instability. Pharmacologic therapy is utilized to decrease portal pressures. Octreotide, a synthetic analog of somatostatin, reduces portal hypertension. Although no mortality benefit has been established, octreotide improves endoscopic visualization and hemostasis (32,33). It has largely replaced vasopressin due to its better safety profile (32). The dose is 25 to 50 μg/hr by infusion.

Patients with variceal hemorrhage are also susceptible to bacteremia and infections such as pneumonia, spontaneous bacterial peritonitis, and urinary tract infection. Empiric treatment with a third-generation cephalosporin or a fluoroquinolone improves outcomes (34,35).

Endoscopic therapy for varices is divided into two types: sclerotherapy and band ligation. In the former, sclerosing agents are injected into the esophageal vessels, causing thrombosis and eventual necrosis. Band ligation involves endoscopic placement of a rubber band around the varix, inducing obstruction and eventual tissue necrosis that obliterates the varix. This is the preferred endoscopic approach, though it is technically more difficult (14,16). Gastric varices are deeper and more difficult to treat. The direct injection of tissue adhesive is becoming more widely used.

When endoscopy and pharmacologic therapy have been unsuccessful or unavailable, balloon tamponade can be a lifesaving measure. The *Sengstaken-Blakemore tube,* the *Minnesota tube,* and the *Linton tube* are specialized inflatable NG tubes that apply direct pressure to the bleeding varix. However, the use of these tubes is associated with a number of complications, including esophageal

rupture, pulmonary aspiration, and airway compromise. The tubes come with an explicit list of instructions that should be reviewed prior to their use, and they are best placed by an experienced practitioner. The Linton tube does not have an esophageal balloon, but it may be better at controlling gastric varices. Endotracheal intubation is recommended prior to placement (12,16).

More drastic measures are sometimes needed to reduce portal pressure. Transjugular intrahepatic portosystemic shunt is extremely effective at controlling refractory variceal bleeding. This involves the placement, by an interventional radiologist, of an expandable metal stent across a tract between a hepatic vein and a hepatic branch of the portal vein. Surgical treatment of variceal bleeding is much less common since the advent of transjugular intrahepatic portosystemic shunt and is now typically limited to portocaval shunts in patients with very-well-compensated stable liver disease. Orthotopic liver transplantation is considered in selected patients (12,14,16).

CRITICAL INTERVENTIONS

- Aggressively volume resuscitate patients with UGIB and clinical signs of shock.
- Consider early blood transfusion.
- Reverse coagulopathy as needed (platelets, FFP, and vitamin K).

DISPOSITION

Risk scores have been designed to predict rebleeding and mortality in UGIB. Commonly used scores include the Rockall score and the Glasgow–Blatchford Bleeding Score (GBS). The GBS has been more extensively used (Table 99.2). An advantage of the GBS is that it does not require NG aspirate or endoscopy (17). A GBS of 0 is seen in up to 22% of UGIB patients and predicts that emergent medical care is not required; outpatient evaluation may thus be considered (17,36,37). Most other risk stratification models rely on the endoscopic appearance of the culprit lesion, which typically cannot be obtained in the ED.

TABLE 99.2
Glasgow–Blatchford Score

	Score
Blood Urea	
6.5–7.9	2
8.0–9.9	3
10.0–24.9	4
≥25	6
Hemoglobin (g/L) for Men	
12–12.9	1
10–11.9	3
<10.0	6
Hemoglobin (g/L) for Women	
10–12	1
<10.0	6
Systolic Blood Pressure (mm Hg)	
100–109	1
90–99	2
<90	3
Other Markers	
Pulse ≥100 (per min)	1
Presence of melena	1
Syncope	2
Hepatic disease	2
Congestive heart failure	2

Nonvariceal Bleeding

Most patients with UGIB due to a nonvariceal source should be admitted to the hospital, but carefully selected, stable patients with minimal blood loss may be safely discharged from the ED with close follow-up (Table 99.2). Endoscopic criteria can help to identify patients who can be safely managed as outpatients, since the risk of rebleeding is associated with certain endoscopic findings (Table 99.3) (38). This approach has the potential to identify a large subset of patients who may be discharged. Candidates for outpatient management must have reliable access to close outpatient follow-up

and a demonstrated history of compliance with medical instructions. They should receive an oral PPI, should be told to avoid NSAIDs, and should be given clear instructions on reasons to return immediately for further medical attention.

TABLE 99.3
Endoscopic Appearance of Ulcers and Risk of Rebleeding (5)

Endoscopic Finding	Risk Stratification	Risk of Rebleed (%)
Clean base	Low risk	3
Flat spot	Low risk	7
Adherent clot	High risk	33
Visible vessel	High risk	50
Active bleeding	Highest risk	80

Patients who are unstable or have multiple adverse prognostic factors should be admitted to the ICU (Table 99.4). Although UGIB will stop spontaneously in many cases, up to 20% of patients may have continued or recurrent bleeding, with the risk of rebleeding being highest in the first 72 hours (1,38).

TABLE 99.4
Intensive Care Unit Admission Guidelines for Patients with Upper GI Bleed

Unstable vital signs in the ED
Persistent bleeding that does not clear with lavage
Advanced age (older than 75 years)
Presence of coagulopathy
Portal hypertension or ascites
Severe anemia (e.g., hematocrit <20%)
Large drop in hematocrit (>8%)
Unstable comorbid disease (e.g., unstable coronary artery disease, chronic obstructive pulmonary disease, renal insufficiency, peripheral vascular disease, cerebrovascular disease)
Endoscopic findings of a "visible vessel" or an "overlying clot" or a variceal source
Use of esophageal tamponade balloon

UGIB, upper gastrointestinal bleeding; ED, emergency department.

Variceal Bleeding

The prognosis of patients with variceal bleeding is usually related to the severity of associated liver disease, and all such patients should be admitted. These patients frequently require critical care services. Early consultation with a gastroenterologist is imperative (12,14,16).

If the necessary critical care and consultant services are not readily available, the UGIB patient should be transferred to a facility with the necessary resources.

Common Pitfalls

- Underestimation of blood loss. Some patients can lose up to 20% to 30% of their blood volume and yet maintain a relatively normal blood pressure in the supine position. Moreover, patients with significant bleeding can have a normal initial hematocrit.
- Overreliance on a negative NG aspirate.
- Failure to recognize aortoenteric fistula as a cause of sudden massive hematemesis.
- Failure to involve a surgeon and/or interventional radiology in cases of massive hemorrhage with failed endoscopy.
- Treatment of hypovolemic shock with vasopressors instead of volume resuscitation.

CHAPTER 100

Lower Gastrointestinal Bleeding

Kenny V. Banh

Lower gastrointestinal bleeding (LGIB) is a common complaint of patients who present to the emergency department (ED), but is less significantly less common than upper gastrointestinal bleeding (UGIB), with an estimated annual incidence of 20 to 27 cases per 100,000 adults, compared to 100 to 200 cases per 100,000 for UGIB (1). The mortality rate for LGIB ranges from 2% to 4% (1).

The spectrum of illness is clinically broad, ranging from minor anorectal disorders to severe and life-threatening bleeding that results in hypovolemic shock and death. Depending upon the volume and rate of bleeding, patients can rapidly deteriorate in the ED. Therefore the clinician and ED staff must remain vigilant in the monitoring and care of these patients.

CLINICAL PRESENTATION

LGIB is defined as arising distal to the ligament of Treitz, which is the suspensory muscle of the duodenum. This includes bleeding from the distal one-fourth of the duodenum and from the jejunum, ileum, colon, rectum, and anus.

The appearance of the stool may provide a suggestion as to the location of the bleed, but is not an absolute indicator of the anatomic origin of the bleed. The terms *melena* and *hematochezia* are common descriptors of gastrointestinal bleeding. Melena appears as black, tarry stool and usually reflects the presence of blood that has

remained in the gastrointestinal tract for longer than 8 hours. Melena is approximately four times more likely to reflect an UGIB (2). *Hematochezia,* described as bright red or maroon stool, usually indicates an LGIB. It is about six times more likely to be caused by a lower gastrointestinal source than an upper source (2). However, 10% to 15% of patients with UGIB present with bright red blood coming from the rectum, as may occur with brisk bleeding and rapid transit of blood (3). Small amounts of bright red blood may come from minor anorectal sources and may be noticed on the outside of the stool or toilet paper following a bowel movement. Drops of blood from an anorectal source, when diffused in the toilet water, may cause patients to overestimate the volume and severity of the bleeding (4).

Because patients are not always aware of GI bleeding, clinicians should consider this diagnosis in patients who present with other concerning symptoms and signs such as hypotension, tachycardia, angina, syncope, weakness, confusion, stroke, myocardial infarction (MI), shock, or cardiac arrest.

DIFFERENTIAL DIAGNOSIS

Hemorrhoids and anal fissures are common, but rarely result in massive hemorrhage. Hemorrhoids are associated with chronic constipation, straining, low-fiber diet, and pregnancy. Patients may describe small amounts of bright red blood, pruritus ani, a protruding mass, pain with defecation, or pain when sitting on a hard surface. Hemorrhoids are divided into two major types. External hemorrhoids are found below the dentate line in well-innervated squamous epithelium and present with pain. Internal hemorrhoids originate above the dentate line and are classically seen at 2, 5, and 9 o'clock on anoscopy. *Anal fissures* are usually associated with hard stools but may also be seen with diarrhea. They present with extremely painful defecation; 90% are located in the posterior midline (5).

Anorectal varices are caused by portal hypertension of chronic liver disease and appear as discrete, bluish-gray submucosal veins.

They are usually more compressible and serpiginous than internal hemorrhoids and extend below the dentate line (5). Anorectal varices may cause severe rectal bleeding.

Rectal foreign bodies that cause tears need immediate surgical consultation. Improper technique or delay in removal of a retained rectal foreign body may cause perforation with subsequent infection and bleeding. Broken glass and other sharp retained foreign bodies pose the greatest risk for rectal tears and bleeding (6).

Ulcerative colitis affects the colon and rectum and presents with bloody stools, crampy abdominal pain, and tenesmus. Lesions involve both the mucosa and the submucosa. Distal disease is usually more severe. *Crohn disease* has a bimodal distribution of age of onset with peaks occurring in the 20s and at around age 70. The disease involves all layers of the bowel wall and lymph nodes. Any section of the gastrointestinal tract is vulnerable, but the distal ileum is the most commonly affected site. When present, colonic involvement is usually patchy with rectal sparing (5). During flares, patients describe bloody diarrhea, abdominal pain, fever, and weight loss.

Pseudomembranous colitis usually presents after the patient has been taking broad-spectrum antibiotics and is caused by the subsequent overgrowth of *Clostridium difficile.* Patients present with fever, crampy abdominal pain, and watery or bloody diarrhea, usually 7 to 10 days after a course of antibiotics but sometimes more remote. Pseudomembranous colitis rarely causes severe bleeding. The diagnosis can be confirmed by sending stool for *C. difficile* toxin or by finding the characteristic pseudomembranes on colonoscopy (7).

Infectious diarrhea, most commonly bacterial, may be associated with a significant inflammatory response and blood and mucus in the stool ("dysentery"). There is typically an abrupt onset with cramping abdominal pain. *Human immunodeficiency virus* (HIV)–related causes of gastrointestinal bleeding include cytomegalovirus colitis, Kaposi sarcoma, and gastrointestinal lymphoma (7).

Radiation colitis or *proctitis* most commonly occurs after radiation for cervical or prostate cancer. The onset of bleeding usually occurs

between 9 and 15 months following radiotherapy, but it may occur as far out as 41 months (1). Acute radiation colitis presents with rectal pain, diarrhea, and rectal bleeding.

Diverticulosis is described as the most common cause of severe LGIB in adults. In adults, diverticulosis and angiodysplasia together account for nearly 80% of significant lower gastrointestinal bleeds (8). Patients usually present with painless bleeding, which may be of a large volume. Diverticula are sac-like herniations (2 to 5 mm in greatest dimension) of the colonic mucosa and are most common in the sigmoid colon. The diagnosis should be considered in all patients older than 40 years of age. The prevalence increases with each decade of life, and more than 50% of patients have diverticula by age 60 (5). Other risk factors include living in industrialized countries and a diet that is deficient in fiber, high in fat, and high in red meat.

Angiodysplasias often bleed chronically and may present with occult fecal blood or iron-deficiency anemia. Angiodysplasias may also present as acute bleeding with hematochezia. This disease is more common in the elderly, in patients with renal failure, and in those with hereditary hemorrhagic telangiectasia (*Osler–Weber–Rendu* syndrome) (7).

Mesenteric ischemia most commonly presents in patients older than 50 years of age, especially in those with underlying cardiovascular disease. It is an uncommon but dangerous cause of LGIB. Risk factors also include atrial fibrillation, coronary artery disease (CAD), congestive heart failure (CHF), recent MI, valvular heart disease, hypercoagulable states, and hypotension. Specific causes include arterial embolus, venous thrombosis, atherosclerosis, external compression of vessels, and low flow states. The sudden onset of abdominal pain that is out of proportion to examination findings, especially with heme-positive stools, is suggestive of mesenteric ischemia.

Colonic polyps may cause LGIB and can be diagnosed and removed at colonoscopy. Postpolypectomy bleeding, although not common (up to 0.4%) (9), may be quite severe. Early bleeding most likely occurs because there is inadequate hemostasis of the blood vessel in

the stalk of the polyp. Later bleeding (up to 15 days following the procedure) may occur as a result of sloughing of the clot (1).

Colon cancer accounts for approximately 10% of major intestinal bleeding and 20% of minor bleeding in the elderly (1). Advanced colon cancer presents with altered bowel patterns, abdominal pain, involuntary weight loss, rectal bleeding, and anemia. Distal colon or rectal cancer may also cause a change in the caliber of the stools.

Aortoenteric fistula must be considered in patients who have abdominal aortic grafts and develop gastrointestinal bleeding.

ED EVALUATION

The initial assessment should include the patient's general appearance, vital signs, and mental status. Relevant questions include a history of colonic polyps, cancer, inflammatory bowel disease, or recent travel with bloody diarrhea. Medication use is also important, because there is an association between aspirin or nonsteroidal anti-inflammatory drug (NSAID) use and LGIB (1).

Orthostatic vital signs may be helpful in patients with significant blood loss without overt hemodynamic instability, but they are neither sensitive nor specific. Blood loss estimates per patient history are frequently inaccurate. Other clues that may be helpful in establishing a diagnosis include skin lesions such as telangiectasia, bruises, or petechiae. Hyperpigmentation of the lower abdomen may suggest previous radiation therapy. Diverticulosis, angiodysplasia, and cancer are unusual before the age of 40. Likewise, Meckel diverticulum rarely presents after adolescence (2). Stigmata of liver disease (ascites, jaundice, spider angiomata, and caput medusae) suggest the possibility of anorectal varices.

Abdominal tenderness may indicate an inflammatory condition or ischemic colitis (10). The perianal region and rectum should be carefully examined, both externally and by digital rectal examination, to check for masses, strictures, hemorrhoids, and blood. Stool should be tested for the presence of occult blood using the guaiac test. False-positive results may be seen with ingestion of red fruits, meat, iron, and bismuth.

Laboratory testing may be helpful, including measurement of hemoglobin, hematocrit, platelets, prothrombin (international normalized ratio [INR]), and partial thromboplastin time (PTT). A routine type-and-screen is recommended unless blood loss is significant or ongoing, demonstrating the need to crossmatch blood. Other laboratory studies that may be useful include a liver profile, blood urea nitrogen (BUN), creatinine, and electrolytes. Lactate and anion gap should be measured if mesenteric ischemia is suspected, but these tests may be normal early in the course of the disease. Likewise, the initial hematocrit may not accurately reflect the amount of acute blood loss. Cardiac ischemia can occur in gastrointestinal bleeding because of decreased oxygen delivery; therefore, an electrocardiogram should be performed, and supplemental oxygen should be administered if ischemia is suspected.

It is important to determine whether the bleeding is a result of LGIB or UGIB. Aspiration of the gastric contents with a nasogastric tube may be helpful if the source is unclear, though the value of this procedure is controversial. Gastric lavage may be falsely positive if the nasogastric tube insertion was traumatic (causing nasal trauma). Conversely, lavage is often negative in the presence of an UGIB when the source is distal to the pylorus.

Anoscopy may reveal an anorectal source of bleeding or may show bleeding from above the reach of the anoscope, suggesting a more proximal cause of bleeding. To perform this examination, place the patient in the lateral decubitus or knee–chest position. Lubricate the anoscope, insert it (with obturator) until the flange rests at the anal verge, and remove the obturator. Shine a bright light (e.g., an otoscope, penlight, or flashlight) into the center of the anoscope and visualize the rectal mucosa and stool above the opening to look for bleeding coming from above the anoscope. Finally, withdraw the anoscope slowly to look for anorectal disorders such as bleeding hemorrhoids, proctitis, or fissures. Although the presence of blood proximal to the anoscope may be seen with retrograde passage of blood, it usually indicates a more proximal bleed and should be further investigated.

Abdominal x-rays are rarely indicated in LGIBs unless perforation or bowel obstruction is suspected. Multidetector computed tomography should only be considered for the evaluation for tumor, mesenteric ischemia, or perforation.

Radionuclide scintigraphy (i.e., technetium-labeled red cell scan) remains controversial and is rarely applicable to the ED setting. The test localizes bleeding, and it can detect bleeding rates as low as 0.05 to 0.1 mL/min, therefore appearing to be more sensitive than angiography. However, it has variable accuracy and often does not change management (11).

Colonoscopy, in addition to identifying anorectal disorders, can diagnose many causes of lower gastrointestinal hemorrhage, including diverticulosis and angiodysplasia. Unfortunately, in emergent cases, the bowel is not adequately prepared, and the presence of stool can obscure lesions. Emergency colonoscopy in acute LGIB can miss the diagnosis in 40% of cases, especially in small bowel bleeding below the ligament of Treitz (12). Whether the best initial diagnostic procedure is colonoscopy or angiography (discussed below) is controversial (13). These decisions are commonly dependent upon the institution and consultant preferences.

KEY TESTING

- Test stool for gross or occult blood
- Serum hemoglobin and basic laboratory studies
- Anoscopy may help identify a distal bleeding source

ED MANAGEMENT

Adherence to a systematic approach to LGIB will help the clinician to be adequately prepared for sudden clinical deterioration. With any suspicion of significant blood loss, the patient should be placed on a monitor, oxygen should be administered, and intravenous access should be obtained with two large-bore intravenous catheters. Crystalloid solutions should be administered, and the fluid status should be evaluated frequently. While a restrictive transfusion

strategy has recently been supported for UGIB, this practice is not well studied in LGIB (14). Of critical importance is the generous use of blood products including packed red blood cells, platelets, and fresh frozen plasma in symptomatic, hypotensive, or hemodynamically unstable patients.

Surgical consultation should be considered when the patient is persistently unstable despite treatment, when there has been massive bleeding or when perforation is strongly suspected. Older patients usually need more aggressive surgical management (15). Patients presenting with gastrointestinal bleeding who have abdominal aortic grafts should have urgent vascular surgery consultation because of the possibility of an aortoenteric fistula.

Angiography has both diagnostic and therapeutic value. It is more commonly used in the evaluation of LGIB than UGIB, but should be considered in consultation with a surgeon and an interventional radiologist. A fairly brisk bleeding rate of at least 1 mL/min is required for angiography to be diagnostic (16). Although angiography rarely identifies the specific cause of the bleeding, it can help to identify the location, which can facilitate limited bowel resection during surgery (12). Available catheter-based interventional angiography techniques include intra-arterial infusion of vasopressin and arterial embolization. Unfortunately, when the infusion is stopped, the vasoconstrictive effects of vasopressin dissipate rapidly, so a stable clot must be formed and retained to prevent rebleeding. Recurrent hemorrhage is common occurring in 36% to 43% (17).

Arterial embolization used to be reserved for UGIB, because bowel infarction was a frequent complication of embolization in LGIB. However, with modern embolization techniques, clinically significant bowel ischemia has become an uncommon complication (17). Angiography is associated with a combined complication rate of 2% to 9%. These include hematomas, arterial dissection, renal failure, contrast allergy, and bowel ischemia and infarction.

Colonoscopy, besides its diagnostic value, may also be used therapeutically to ablate bleeding sites, but it fails to stop the bleeding in about 20% of cases (12).

Thrombosed external hemorrhoids can be excised under local anesthesia if pain is severe. Hemorrhoids and anal fissures are best treated with stool softeners, increased fiber, sitz baths, and external analgesics (see Chapter 114).

Treatment for ulcerative colitis and Crohn disease include analgesia, corticosteroids, sulfasalazine, and metronidazole (see Chapter 111). Pseudomembranous colitis is treated with oral vancomycin or metronidazole. Infectious diarrhea is treated with appropriate antibiotics to which the pathogen is sensitive (see Chapter 112).

CRITICAL INTERVENTIONS

- Initiate aggressive resuscitation in hypovolemic patients with LGIB, using crystalloid and blood as needed.
- Obtain emergent surgical consultation for unstable patients.

DISPOSITION

Optimizing the management of patients with gastrointestinal bleeding involves stratification of the risk of rebleeding and mortality. Evaluating these criteria can help the clinician to make management decisions such as (i) hospitalization versus outpatient treatment; (ii) admission to an unmonitored bed, a monitored bed, or an intensive care unit bed; (iii) emergency versus elective endoscopy; (iv) timing and number of packed red blood cell transfusions; and (v) diagnostic angiography versus conservative therapy (18).

Factors predicting rebleeding and mortality include age older than 60 years, comorbidity (particularly liver disease, renal disease, pulmonary disease, encephalopathy, cancer, recent major surgery, trauma, or coexisting disease in three-organ systems), low hematocrit, melena, hematochezia, or prolonged PT. Other factors include requiring more than 5 U of packed red blood cells, tachycardia, hypotension, shock, elevated serum transaminases, and elevated serum creatinine (18). Mortality in elderly patients has been shown to be 16% to 25% higher than in younger patients.

Mortality increases by 25% to 70% in patients who require transfusion of more than 5 U of packed red blood cells. Patients with high-risk criteria should be admitted to the intensive care unit. Patients who are at low risk can be admitted to the floor and have arrangements made for colonoscopy.

If the cause of LGIB is determined to be hemorrhoids, proctitis, or fissures and there is no evidence of portal hypertension, the stable patient may be discharged home with treatment and follow-up.

Common Pitfalls

- Failure to appreciate the significance and volume of LGIB or to anticipate the possibility of rapid clinical deterioration.
- Failure to adequately resuscitate the patient with crystalloid fluids and blood.
- Failure to consider gastrointestinal bleeding in patients who present with other seemingly unrelated complaints such as syncope, angina, MI, weakness, dyspnea, altered mental status, or shock.

CHAPTER 101 Peptic Ulcer

Dale S. Birenbaum and Justin D. Britton

Peptic ulcer disease (PUD) affects almost 1 in 10 Americans. There are approximately 500 000 new cases of PUD and four million recurrent cases in the United States each year (1). Over the past three decades the incidence and prevalence of PUD has been on the decline (2). The decline is largely due to the discovery and treatment of *Helicobacter pylori* (*H. pylori*) in the 1980s. Despite this great advance in PUD management, it still remains a significant problem with the increasing use of nonsteroidal anti-inflammatory drugs (NSAIDs) and Aspirin in the aging population with coronary artery disease and arthropathy.

The estimated annual cost of PUD is about $10 billion in direct and indirect costs (1). The management of PUD has significantly changed over the last half century. Initially, PUD was thought to be due to stress and diet, but in the 1950s, it was found that gastric acid plays an important role in the development of an ulcer. Treatment of PUD evolved from dietary modifications, vagotomy, and acid suppression with H2 receptor antagonist to more potent proton pump inhibitors (PPIs) in the late 1980s. Elective peptic ulcer surgery declined between 80% and 97% in the 1980s with the development of acid-suppressive therapy (3). The discovery of *H. pylori*'s role in PUD has reshaped modern management and changed PUD from a chronic reoccurring disease to a potentially curable one. Antimicrobial therapy has since been tailored to *H. pylori* eradication and has thus decreased hospitalization, complication rates, and ulcer recurrences (4).

PATHOPHYSIOLOGY

The mechanisms leading to gastric and duodenal ulcers are due to an imbalance between the mucosal protective barrier and destructive acidic environment. Healthy gastric or duodenal mucosa provides an impressive barrier to the diffusion of hydrogen ions and can maintain a gradient of 3 million to 1 between the lumen and blood. It also secretes bicarbonate and mucus, which form a buffering gel over the mucosa. Mucosal gel thickness is increased by the E-prostaglandins and diminished by Aspirin and NSAIDs.

H. pylori is a small microaerophilic gram-negative spiral bacterium which was associated with up to 90% of duodenal and 80% of gastric ulcers in the 1980s, but more recent studies have shown that the prevalence has declined (5). *H. pylori* is uniquely adapted to survive in the acidic environment of the stomach. It does so by producing a large amount of urease, an enzyme that catalyzes the breakdown of urea to alkaline ammonia and carbon dioxide, which allows the bacteria to be protected in this alkaline milieu (6). *H. pylori* induces chronic inflammation, abnormal acid output, decreased bicarbonate secretion, and causes gastric metaplasia which all contribute to ulcer formation. Eradication of *H. pylori* has been shown to greatly reduce the incidence of ulcer recurrence from 67% to 6% in duodenal ulcers and 59% to 4% in gastric ulcers (7). Its eradication from the gastrointestinal (GI) tract on first detection has been routinely advocated; this treatment strategy has been associated with accelerated ulcer healing, a reduced rate of ulcer recurrence, and cure of the disease (8).

Several factors have a role in the pathogenesis of stress-related mucosal disease (SRMD), including mechanical ventilation longer than 48 hours, burns, coagulopathy, moderate to severe trauma, head or spinal cord injury, liver failure, and organ transplantation. Endoscopic signs of SRMD include multiple subepithelial petechiae progressing to superficial erosions and in some cases discrete ulceration in the gastric fundus. Because of their diffuse nature these ulcers are generally not amendable to endoscopic therapy (9). H2

blockers, PPIs, and early enteral nutrition have all been shown to decrease the risk of obtaining a SRMD (10).

Many factors predispose to the development of ulcers (Table 101.1).

TABLE 101.1
Risk Factors for Peptic Ulcer Disease

Helicobacter pylori
Nonsteroidal anti-inflammatory drugs
Aspirin
Acid hypersecretory conditions (Zollinger–Ellison)
Family history
History of prior ulcers
Associated disease (COPD, cirrhosis, chronic renal failure)
Male gender
Advanced age
Smoking

COMPLICATIONS

In the United States, hemorrhage is the most common complication and accounts for 73%, followed by perforation 9% and obstruction 3% (11). The demographics of *H. pylori* prevalence and PUD complications have been shifting toward the later years of life, and there has been a significant decrease in the hospitalization rate over the last decade (11).

Hemorrhage occurs in 10% to 20% of patients. The bleeding from peptic ulcers is usually self-limited, but occasionally massive and life-threatening with mortality between 5% and 10%.

Perforation continues to occur in peptic ulcer patients despite the availability of reasonably effective medical treatment (12). Perforation can present with sudden or gradual symptoms, but either way this is a surgical emergency.

Gastric outlet obstruction is usually the result of fibrous tissue from chronic scarring or edema from an active ulcer, and is more common in duodenal ulcer. Massive distention of the stomach can

occur; volume depletion and electrolyte disturbances may be dramatic. However, almost 70% of cases resolve without surgery.

Penetration is similar to perforation, but rather than the ulcer eroding into the peritoneal cavity, it erodes into an adjacent organ. Penetration can occur into the pancreas, omentum, biliary tract, liver, colon, and vascular structures.

Malignancy can be characterized by a chronic nonhealing ulcer that continues to give problems despite acid-suppressive therapy or *H. pylori* eradication. *H. pylori*-positive patients are at a higher risk of gastric carcinoma, and *H. pylori* is considered to be a carcinogen.

CLINICAL PRESENTATION

PUD has a classic symptomatology, but these features are not always specific in ulcer localization. Gastric ulcers cause pain shortly after eating when acid production is high. This has led to anorexia and weight loss in up to 50% of patients with gastric ulcers. Duodenal ulcers are painful 2 to 5 hours after a meal or between 2 and 3 AM when there is no bicarbonate or food to buffer the ulcer from the acid. Symptoms are often relieved with antacids, thus many patients do not seek medical attention.

Most patients present to the emergency department (ED) because of constant burning, gnawing, or aching pain. The pain of PUD is primarily epigastric, but it can be localized anywhere in the upper abdomen.

Asymptomatic peptic ulcers are not uncommon and abdominal pain may be absent in up to 30% of elderly patients (13). Uncomplicated PUD does not produce remarkable physical findings. Epigastric tenderness may be noted, but guarding and rebound are not present. Bowel sounds are usually normal, and there is no organomegaly. Rectal examination may show guaiac-positive stool if there has been unrecognized bleeding.

Guarding, rebound, and a tense abdomen signal perforation of an ulcer. Patients with perforation usually lie perfectly still, because the slightest movement produces intense peritoneal pain. In the

elderly, findings may be minimal or absent, which tends to delay the diagnosis.

Hemorrhage from PUD may cause surprisingly few physical findings on examination. A history of melenic stools should be sought, and orthostatic vital signs may help uncover clinically important but nonobvious bleeding. Many patients present with hematemesis, but nearly a third with ulcer perforation and a fifth of those with upper GI hemorrhage have no previous symptoms of ulcer disease.

Gastric outlet obstruction usually produces some degree of nausea, vomiting, and a distended abdomen. The patient may get some relief with vomiting or nasogastric suctioning.

DIFFERENTIAL DIAGNOSIS

Cardiac disease is one of the more serious diagnoses to consider in a patient with pain anywhere from the chest to epigastrium. Acute coronary syndrome may present atypically with epigastric pain, nausea, bloating, and burning sensation similar to those of PUD. A careful history and electrocardiographic (ECG) examination can help differentiate heart disease.

Many medical conditions of the GI track can present with pain or burning in the epigastrium: functional dyspepsia, gastroesophageal reflux disease (GERD), gastritis, gastric carcinoma, biliary tract disease, and acute pancreatitis. History, physical examination, laboratory test, and imaging when indicated can help rule out many of these disorders.

ED EVALUATION

PUD is a clinical diagnosis based on adequate history and physical examination. The diagnosis is confirmed by direct visualization through endoscopy, which is not typically performed in the ED. Management in the ED focuses on ruling out life-threatening problems and complications. Specific studies to diagnose *H. pylori* take time and therefore are not routinely ordered in the ED.

Bleeding is a common complication of PUD; so a complete blood count is typically used to assess for significant blood loss. Type and screen is also necessary if the patient will need blood products. Red cell indices may indicate a more chronic source. The white cell count is usually normal in uncomplicated PUD but can rise with any stressful event like perforation. Serum lipase is helpful if pancreatitis is in the differential. Electrolytes, blood urea nitrogen, and serum creatinine are useful if the patient is critically ill, has significant vomiting, or has a gastric outlet obstruction. Liver function tests, including alkaline phosphatase and bilirubin levels, may be useful to delineate hepatobiliary disease.

A nasogastric tube should be placed in the presence of gastric outlet obstruction. The need for a nasogastric tube for upper GI bleeding has questionable value. Aspiration of bloody fluid through a nasogastric tube that does not clear with gastric irrigation may help the gastroenterologist decide whether emergent endoscopy is needed. Tests for the presence of occult gastric blood are available, but their value is questionable because clinically insignificant iatrogenic bleeding often accompanies nasogastric tube insertion.

Chest X-rays are a useful adjunct for detecting free air under the diaphragm giving suspicion for perforation. Unfortunately, pneumoperitoneum is only seen in 50% of patients with perforation, and the absence of this finding is often associated with delayed diagnosis and increased mortality. In cases where there is still a high clinical suspicion for perforation, CT scan is more sensitive and specific for detecting the perforation.

With *H. pylori* being the most common cause of PUD, testing has become standard (Table 101.2). Patients usually have these tests performed on an outpatient basis for uncomplicated PUD. Noninvasive testing is usually recommended for those under 55 years without alarming signs, and endoscopy is usually recommended for any alarming symptoms or patients over 55 years.

TABLE 101.2
***Helicobacter Pylori* Testing (Outpatient Workup)**

Noninvasive
- Urea breath test
- Stool antigen test
- ELISA for *H. Pylori* (only for initial diagnosis)

Invasive (endoscopy)
- Biopsy and culture
- Histological stain of tissue sample
- Rapid urease test on biopsy specimen

KEY TESTING

- Laboratory studies: complete blood count, electrolytes, blood urea nitrogen, creatinine, liver function test, lipase, coagulation studies, type and Screen (if transfusion considered)
- EKG
- CXR and/or CT scan (if perforation or obstruction suspected)

ED MANAGEMENT

Uncomplicated Peptic Ulcer Disease

Most patients that present with PUD have normal vital signs and only have mild abdominal discomfort. ED management usually focuses on symptomatic relief with antacids. These patients are usually discharged from the ED with instruction for primary care physician follow-up for further workup and acid-suppressive therapy with a H2 blocker or PPI. If they take salicylates or NSAIDs they are discouraged from using them unless necessary for another medical condition like coronary artery disease.

All patients with suspected PUD need to be tested for *H. pylori.* If *H. pylori* testing results come back negative, then therapy focuses on acid-suppressive therapy and risk-factor modifications. If results are positive, treatment for *H. pylori* eradication is initiated, consisting of antimicrobials and acid-suppressive therapy (see Table 101.3).

TABLE 101.3
***Helicobacter Pylori* Eradication Regimens**

	Regimens	Duration (d)	Indications
First-line therapy	Amoxicillin 1000 mg bid, Clarithromycin 500 mg bid, and PPI[a]	10–14	Standard regimen
	Metronidazole 500 mg bid, Clarithromycin 500 mg bid, and PPI[a]	10–14	Penicillin allergy
	Bismuth subsalicylate 525 mg qid, Metronidazole 500 mg qid, Tetracycline 500 mg qid, and PPI[a]	10–14	High clarithromycin resistance area or penicillin allergy
	Days 1–5 Amoxicillin 1000 mg bid and PPI[a] Days 6–10 Clarithromycin 500 mg bid, Tinidazole 500 mg bid, and PPI[a]	10	
2nd line therapy	Bismuth subsalicylate 525 mg qid, Metronidazole 500 mg qid, Tetracycline 500 mg qid, and PPI[a]	14	1st line treatment failure
	Levofloxacin 250 mg bid, Amoxicillin 1000 mg bid, and PPI[a]	10–14	
	Rifabutin 150 mg bid, Amoxicillin 1000 mg bid, and PPI[a]	14	

[a]PPI at standard bid dosing; esomeprazole can be dosed once daily.
Adapted from Feldman M, Friedman L, Brandt LJ, et al. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*. 9th ed. Philadelphia, PA: Saunder; 2010.

- H2-receptor antagonists inhibit the action of histamine on H2 receptors located in gastric parietal cells resulting in reduced acid secretion. They are generally safe and effective.
- PPIs, such as omeprazole, effectively reduce gastric acid secretion and are effective in the treatment of PUD (7). The use of a PPI is relatively safe, but is not without risk. Patients on PPIs have an increased risk of pneumonia and *Clostridium difficile* colitis.

- Sucralfate is an aluminum salt of sucrose that forms a polymer in the acid environment of the stomach. This polymer adheres selectively to the ulcer, forming a barrier between the acid environment and the damaged mucosa.
- Prostaglandins, such as misoprostol, increase the cytoprotective properties of the gastric mucosa; they stimulate mucus production, bicarbonate production, and stimulate vascular blood flow to gastric mucosa.
- Bismuth, aka Pepto-Bismol, coats ulcer craters and has ulcer-healing properties. It increases mucosal prostaglandins, bicarbonate secretion, and has some antimicrobial properties against *H. pylori.*

Hemorrhage

Prompt assessment, resuscitation, and hemostasis are essential. Hemostasis is generally attempted through endoscopic management with injection of vasopressor agents at bleeding site, ablative therapy, or placing a clip. Early intravenous PPI therapy has been shown to decrease risk of rebleeding and need for surgical intervention (14). Upper GI bleeding from PUD will resolve spontaneously in up to 80% of patients. Inability to control bleeding or recurrent bleeding despite endoscopy attempts is an indication for surgery; radiologic intervention with embolization may be an alternative to surgery.

Penetration/Perforation

Rapid diagnosis and resuscitation prior to surgical repair are essential. Resuscitation with IV fluids, sometimes blood, pain medication, and broad-spectrum antibiotics are indicated in this circumstance. Resection of the ulcer along with simple closure and patch repair with open versus endoscopic surgery, and sometimes bowel resection, are the treatment alternatives for this condition (6,15).

Gastric Outlet Obstruction

Patients with gastric outlet obstructions are often markedly dehydrated and require urgent fluid resuscitation along with a nasogastric tube set to suction for decompression. The majority of these patients will improve with these measures; when combined with endoscopic balloon dilation, they produce a nice result in patients with acute inflammatory edema versus those with chronic scarring and fibrosis (6,15).

CRITICAL INTERVENTIONS

- Aggressive resuscitation for patients with serious complications of PUD
  - Hemorrhage: IV fluids (up to 2 L), blood products (if indicated), PPI, GI and/or surgical consultation
  - Penetration/perforation: IV fluids and surgical consultation
  - Gastric outlet obstruction: nasogastric tube, IV fluids, GI and/or surgical consultation.
- Rule out acute coronary syndrome when patients come with epigastric pain with symptoms similar to PUD.

DISPOSITION

Patients who are stable with no signs of PUD complications or abnormal laboratory work can be discharged home with a H2 blocker or PPI. The patient will need follow up with a primary care provider or GI physician for further evaluation and possible endoscopy.

Patients that are unstable or showing symptoms of a possible complication from PUD required immediate resuscitation, stabilization, specialist consultation, and admission.

Common Pitfalls

- Failure to consider other life-threatening etiologies for epigastric pain, such as, acute myocardial infarction or abdominal aortic aneurysm
- Failure to recognize signs and symptoms of a serious PUD complication

- Failure to place a nasogastric tube for a gastric outlet obstruction
- Failure to refer the patient to an appropriate specialist for further evaluation and management

CHAPTER 102
Jaundice

Gus M. Garmel and Tobias D. Barker

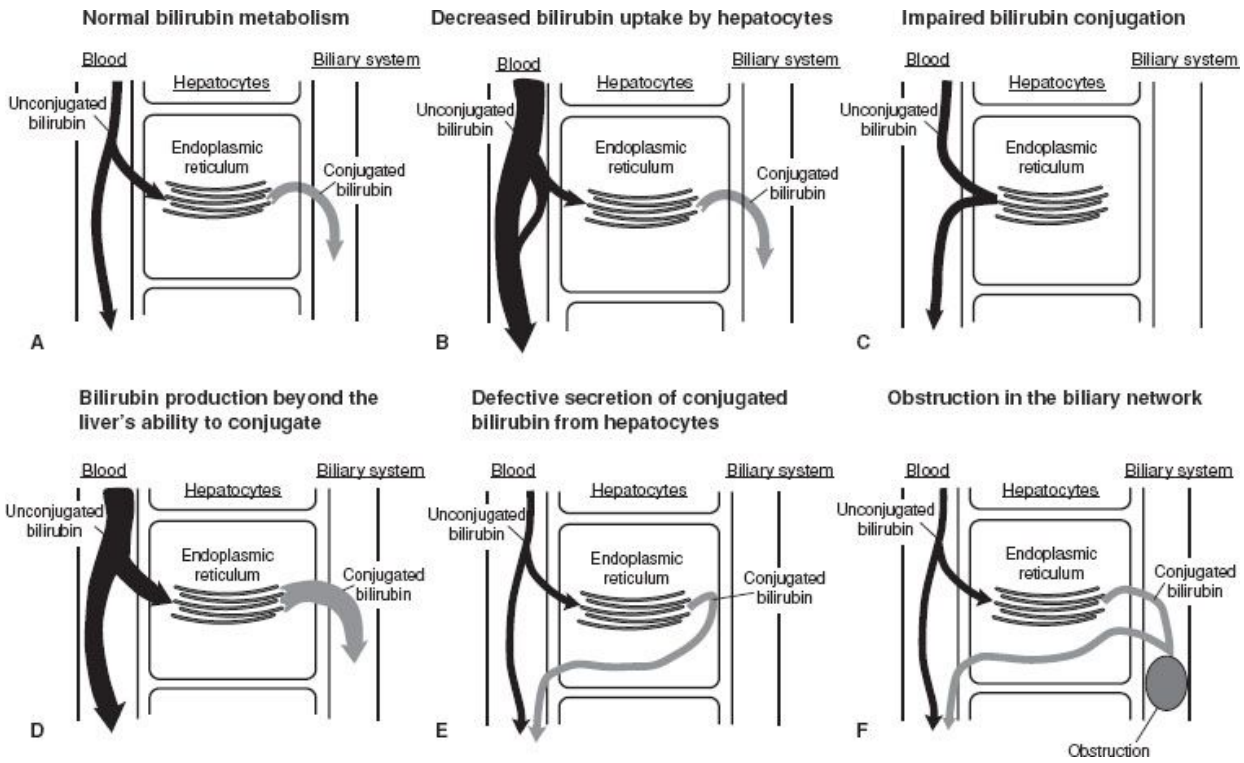
JAUNDICE, APPROACH TO JAUNDICE, ICTERUS, BILIRUBIN METABOLISM, BILIRUBIN CONJUGATION

Jaundice may be defined as the yellowing of skin, sclera, and other tissues owing to deposition of excess circulating bilirubin. The clinical challenge is not the identification of jaundice but with the workup to delineate the responsible pathologic process, typically liver disease or a hemolytic condition. This chapter describes an approach to the jaundiced patient, with particular attention to understanding bilirubin metabolism. It includes historical, physical examination, laboratory, and imaging findings that should help clinicians establish an etiology. This chapter also discusses diagnostic and management strategies based on findings associated with the presentation of jaundice.

BILIRUBIN METABOLISM

Bilirubin is an end product of heme metabolism. Approximately 75% of bilirubin is derived from the hemoglobin of senescent red blood cells; the remainder comes from myoglobin, cytochromes, and respiratory enzymes with structures similar to that of heme (1,2). Initially, bilirubin produced in the body is unconjugated. Physiological jaundice in newborns is due to the relatively low activity of glucuronosyltransferase, an enzyme responsible for the conversion of unconjugated bilirubin to conjugated bilirubin. Unconjugated bilirubin is able to cross the placenta, which prevents fetal accumulation. Unconjugated bilirubin is actively transported from albumin into liver cells. Here, bilirubin is combined with

glucuronic acid in the smooth endoplasmic reticulum, where it becomes conjugated. Conjugated bilirubin is then excreted from the hepatocyte to the biliary tract, where it eventually reaches the intestines and is excreted from the body (eFig. 102.1A).



eFIGURE 102.1 Mechanisms of hyperbilirubinemia. A: Normal bilirubin metabolism. B: Gilbert disease and certain drugs: defective bilirubin uptake from the blood, resulting in unconjugated hyperbilirubinemia. C: Physiologic jaundice of the newborn and Crigler–Najjar syndrome, inability to conjugate bilirubin. D: Hemolytic anemia, the capacity of the hepatocytes is overwhelmed, resulting in unconjugated hyperbilirubinemia. E: Dubin–Johnson syndrome: Hepatocytes are unable to secrete conjugated bilirubin into the biliary system. F: Obstruction in the biliary outflow tract (e.g., gallstones, tumor, mass) results in backup and reabsorption of conjugated bilirubin. (Baggott J, Dennis SE. Diseases associated with hyperbilirubinemia. Available at: http://library.med.utah.edu/NetBiochem/hi7d.htm. Accessed 9 June, 2014. Modified and used with permission.)

CLINICAL PRESENTATION

Sir William Osler stated, “Jaundice is the disease your friends diagnose” (3). Regardless of who identifies the color changes associated with jaundice (also known as *icterus*), patients are likely to be concerned about the underlying cause. Skin color changes may occur in isolation or with nausea, vomiting, abdominal pain, pruritus, and/or fever. Patients may notice darkening or discoloration of their urine (often described as “tea” or “cola” in color). Although rarely a true medical emergency in itself, physicians must quickly assess for and begin treating any concomitant life-threatening conditions, such as hypotension, sepsis, or alterations in mental status.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of jaundice is extensive. Jaundice has many possible etiologies, including biliary obstruction, hepatocellular dysfunction, hemolysis, and hereditary disorders of bilirubin metabolism. Certain epidemiologic factors may provide clues to the cause of a patient’s jaundice. In general, younger patients are more likely to have parenchymal liver disease, whereas older patients are more likely to have biliary stones or malignancy. Jaundice in the newborn (neonatal jaundice) is discussed in Chapter 221. Worldwide, the most common cause of hepatocellular disease-causing jaundice is viral hepatitis, whereas in the developed world, alcoholic hepatitis is increasingly prevalent. Liver injury may be the result of sepsis or ischemia (4), in addition to toxic effects of drugs, alcohol, or pathogens. Zoonotic infections have been reported as a rare cause of jaundice (5). Table 102.1 suggests common causes of jaundice grouped by age.

TABLE 102.1
Common Causes of Jaundice According to Age

Neonates
Physiologic jaundice
Biliary atresia
Infections (TORCHES)
Metabolic
Adolescents
Gilbert syndrome
Viral hepatitis
Pregnant patients
Hyperemesis gravidarum
Intrahepatic cholestasis of pregnancy
Adults
Viral hepatitis
Biliary tract disease
Alcoholic liver disease
Ischemic liver disease
Sepsis
Drug-induced liver disease
Elderly
Malignant disease
Biliary tract disease
Sepsis
Ischemic liver disease
Drug toxicity

TORCHES: *toxoplasma gondii*, rubella, cytomegalovirus, herpes simplex, syphilis.

Causes of yellow skin in the absence of hyperbilirubinemia include carotenemia (carotenoderma), quinacrine ingestion, and occupational exposure to phenols (6). One feature that differentiates jaundice from other causes of yellow skin is that bilirubin stains the sclera. Other areas where jaundice may be identified are those regions relatively free of melanin, such as the palms, soles, and the undersurface of the tongue.

ED EVALUATION

The underlying pathology behind a patient's jaundice can often be discovered after a thorough history, physical examination, selected laboratory tests, and focused imaging studies. The cause of jaundice was successfully identified as either obstructive or nonobstructive in

75% of cases in one study (7). A diagnostic approach to the jaundiced patient is provided in Figure 102.1 (8).

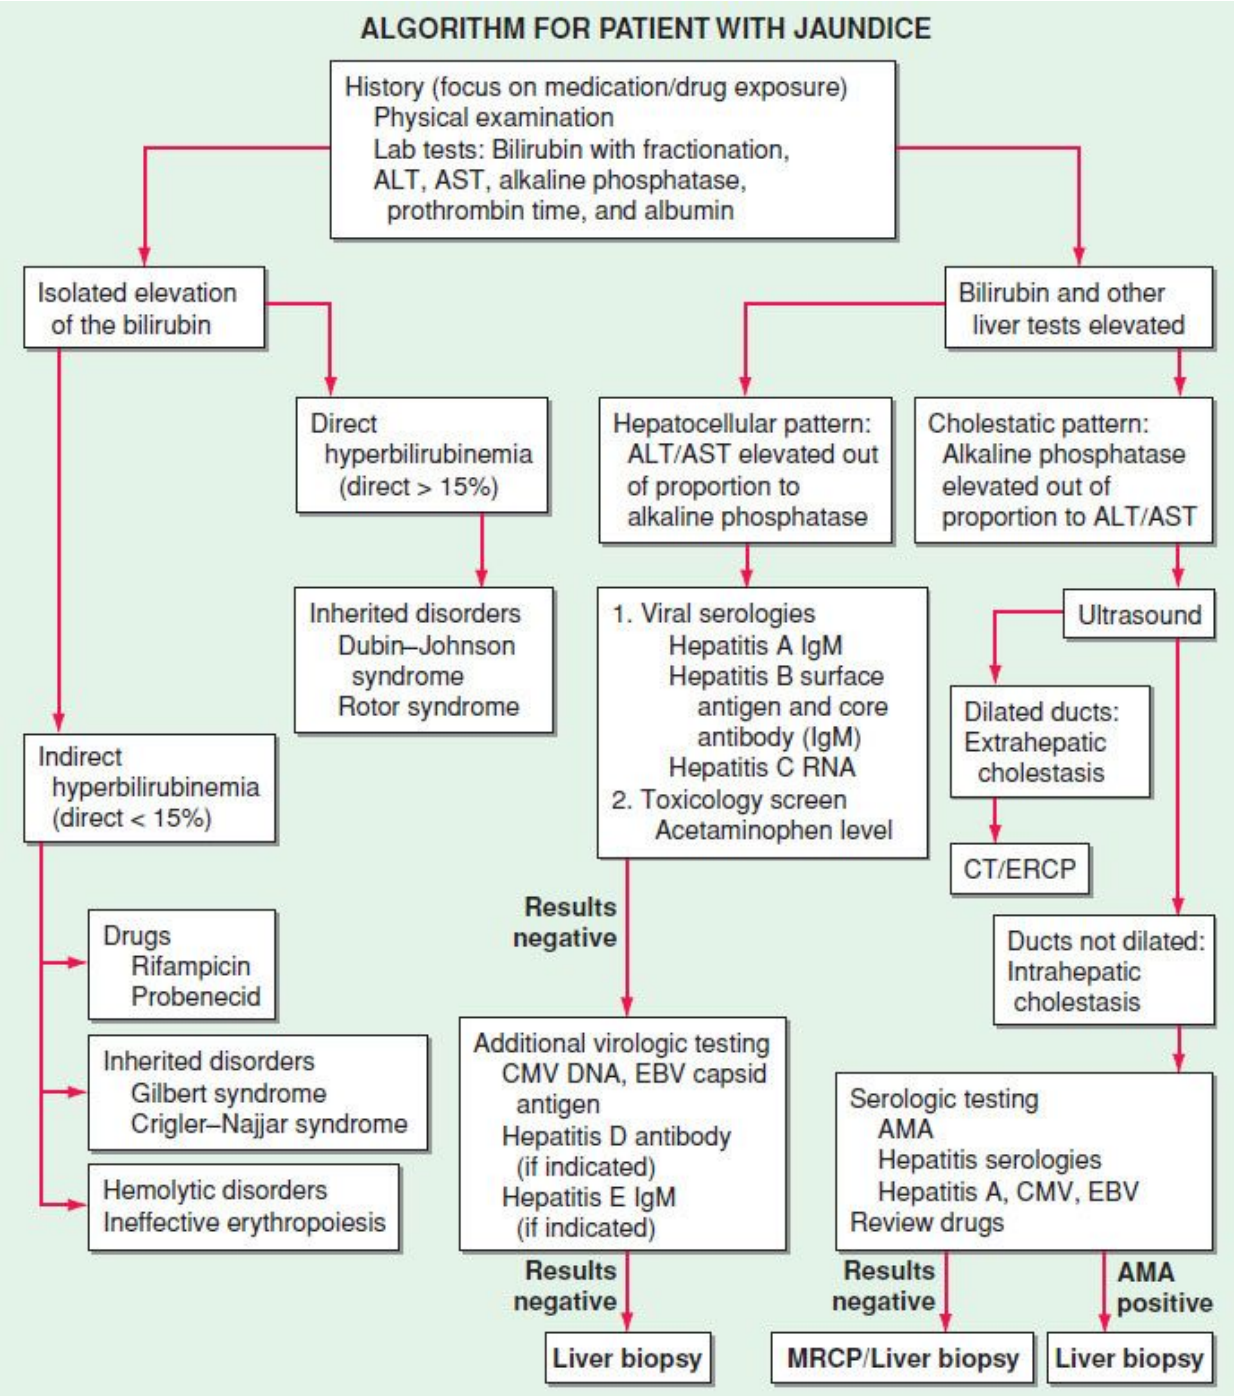


FIGURE 102.1 Algorithm for patient with jaundice (8). (Modified from Pratt DS, Kaplan MM. Jaundice. In: Longo DL, Fauci AS, Kasper DL, et al., eds. *Access Medicine, Harrison's Principles of Internal*

Medicine, Harrison's Online. 18th ed. McGraw Hill Professional; 2011). Accessed June 9, 2014 through www.AccessMed.com. Used with permission.)

History

As always, a good history can help delineate possible etiologies responsible for any patient's presentation. Important historical points in a jaundiced patient include the following:

New-onset dark urine indicates conjugated hyperbilirubinemia, as unconjugated bilirubin is bound to albumin in the serum and is not filtered into the urine. Patients often notice dark urine before skin discoloration, which may be the first indication of hyperbilirubinemia.

Clay-colored stool indicates that bilirubin is not leaving the biliary ducts due to an obstruction, resulting in conjugated hyperbilirubinemia.

Medications, alcohol, and *environmental hepatotoxins* (such as phosphorus, petrochemicals, organic solvents, or toxic mushrooms) may result in jaundice. Medications such as acetaminophen, anabolic steroids, and sulfonamides can cause jaundice through direct cellular damage or by interfering with biliary secretion. Idiosyncratic drug-induced liver injury may result in jaundice (9).

Nausea and vomiting preceding jaundice most often indicate acute hepatitis or obstruction of the common biliary duct by a gallstone. Abdominal pain, fever, chills, or rigors favor the latter. Recent flu-like symptoms and aspirin use raise the possibility of Reye syndrome in younger patients. Anorexia and malaise, especially long-standing, suggest alcoholic liver disease, chronic hepatitis, or pancreatic cancer.

Infectious exposures, intravenous drug use, or blood transfusions increase the possibility of viral hepatitis.

Pregnancy suggests benign recurrent cholestasis or acute fatty liver of pregnancy.

Family history of jaundice or liver disease increases the likelihood of a hereditary cause of hyperbilirubinemia, such as Gilbert, Crigler–

Najjar, Dubin–Johnson, or Rotor syndrome.

Physical Examination

Jaundice is best seen in natural light and is usually detectable when serum bilirubin exceeds 2.5 mg/dL (about twice the upper limit of normal) (10). The identification of jaundice may be more difficult in artificial light, especially in the fluorescent lights found in many emergency departments (EDs). Jaundice may also be more difficult to identify depending on the patient's skin color, age, or hydration status. The greater the bilirubin level, the more easily jaundice is recognized. One study calculated the clinical sensitivity of diagnosing jaundice in patients with a bilirubin level >3.0 mg/dL at 78.4%, reaching a sensitivity of 100% with a bilirubin level >15 mg/dL (11).

Other useful physical examination findings include the following:

Signs of cirrhosis include ascites (serous fluid accumulation in the abdominal cavity resulting from salt and water retention in patients with cirrhosis); spider hemangiomas (red tufts of fine blood vessels which blanch with pressure, oriented in a spider-like pattern on the trunk, face, forearms and hands, thought to be a result of increased levels of circulating estrogens); or caput medusae (dilated veins in the abdominal wall, radiating from the umbilicus, which develop as portosystemic collateral vessels secondary to portal hypertension).

Right upper quadrant (RUQ) *tenderness* and inspiratory arrest on palpation of the gallbladder (Murphy sign) suggest cholecystitis. *Charcot triad* (RUQ pain, jaundice, and fever) and *Reynold pentad* (RUQ pain, jaundice, fever, hypotension, and mental status changes) are indicative of cholangitis.

Fetor hepaticus (a musty, sweetish breath odor) may develop in patients with advanced liver disease or hepatic encephalopathy.

Diffuse lymphadenopathy is suggestive of infectious mononucleosis in acute jaundice, and lymphoma or leukemia in chronic illness with jaundice. Specific lymph node enlargement, such as an enlarged left supraclavicular (Virchow) node or periumbilical (Sister Mary Joseph) node, increases the likelihood of abdominal malignancy.

Hepatosplenomegaly without other signs of chronic liver disease may be the result of an infiltrative disorder, such as lymphoma or amyloidosis. Nodularity or a small liver may suggest cirrhosis. A palpable mass suggests an abscess or malignancy.

Temporal and proximal muscle wasting suggest long-standing diseases, such as cirrhosis or malignancy.

Asterixis and altered mentation are ominous findings that indicate fulminant hepatic failure.

Kayser–Fleischer rings are seen in Wilson disease (a rare, progressive, autosomal recessive disease due to a defect in copper metabolism), which may result in cirrhosis.

Skin pigmentation (often bronze in nature) is seen in hemochromatosis, a condition resulting in liver dysfunction due to abnormal deposits of hemosiderin in the liver.

Laboratory Evaluation

Laboratory testing is important in the evaluation of a patient with jaundice, as the results may identify a specific etiology or assist in the next stage of the evaluation, such as imaging or consultation. The minimum laboratory tests needed in these patients include bilirubin level with fractionation, aminotransferases (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]), alkaline phosphatase, prothrombin time, and complete blood count. The first step in the decision analysis is to determine whether hyperbilirubinemia is isolated or associated with liver function abnormalities (see Fig. 102.1).

Hyperbilirubinemia Without Other Laboratory Abnormalities

In a patient with isolated hyperbilirubinemia, it is important to determine whether the bilirubin is unconjugated or conjugated. Isolated *unconjugated (indirect) hyperbilirubinemia* is due to either a hemolytic process or impaired hepatic function. Therefore, isolated unconjugated (indirect) hyperbilirubinemia is caused either by decreased uptake (see eFig. 102.1B), decreased conjugation (see eFig. 102.1C), or overproduction of bilirubin (see eFig. 102.1D). The drugs rifampin, probenecid, and ribavirin can decrease bilirubin uptake

into the hepatocyte. *Gilbert syndrome* is a hereditary disorder resulting in abnormal bilirubin metabolism, in part through decreased bilirubin uptake (12,13). It is the most common hereditary cause of isolated unconjugated hyperbilirubinemia, occurring in approximately 9% of Caucasians (14). This benign condition is usually noted as an incidental laboratory finding and is not responsible for liver damage or hematologic abnormalities.

Decreased bilirubin conjugation may be the result of decreased levels or inactivity of UDP-glucuronosyltransferase (UGT), the enzyme necessary for the formation of conjugated bilirubin. *Crigler–Najjar syndrome* is a more serious condition than Gilbert syndrome and has varying degrees of jaundice directly related to the degree of UGT available. In type I Crigler–Najjar syndrome, UGT is absent; these patients often die in the neonatal period. In type II disease, there is reduced but variable UGT activity, so the diagnosis may not be established until later in childhood. These patients may have a normal life expectancy and usually take phenobarbital, which increases UGT activity. *Physiologic jaundice of the newborn* is thought to be secondary to decreased conjugation as a result of delayed expression of UGT during the newborn period (see Chapter 221).

Disorders resulting in overproduction of bilirubin cause jaundice by overwhelming the capacity of hepatocytes to conjugate bilirubin (eFig. 102.1D). One cause is *hemolysis,* which may occur from mechanical shearing (disseminated intravascular coagulation, artificial valves). Other causes include hereditary red cell fragility (G6PD deficiency, sickle cell anemia, paroxysmal nocturnal hemoglobinuria), environmental stressors (heat, envenomation), or reactions following blood transfusion. Hemolysis due to vitamin B12 deficiency from pernicious anemia has been reported as an underlying cause of jaundice (15). Increased bilirubin that occurs from the resorption of hematoma following trauma is a more benign cause. A complete blood count in these patients may reveal anemia or an abnormal red blood cell morphology implicating an underlying pathologic cause for the anemia.

Isolated *conjugated (direct) hyperbilirubinemia* is usually caused by one of two inherited disorders. *Dubin–Johnson syndrome* (rare except

in Jews of Middle Eastern descent) and *Rotor syndrome* both have fairly benign clinical courses. These are the result of an inability to secrete conjugated bilirubin through the canalicular membrane into the biliary system (eFig. 102.1E).

ED imaging is not generally required in the primary diagnosis of isolated hyperbilirubinemia. However, one may find secondary signs of the underlying pathology responsible for the hyperbilirubinemia (paravertebral masses seen in extramedullary hematopoiesis, avascular necrosis of the femoral head seen in sickle cell disease). In such cases, focused imaging directed at a potential etiology is appropriate, although this may occur in the outpatient setting based on the patient's medical condition and the availability of follow-up care.

Hyperbilirubinemia With Other Laboratory Abnormalities

In patients with jaundice due to hyperbilirubinemia and other laboratory abnormalities, it is important to determine whether a hepatocellular condition or cholestasis is responsible. This can be determined by identifying which laboratory abnormalities predominate—elevated transaminases or an elevated alkaline phosphatase.

If **elevated transaminases predominate,** direct hepatocellular damage in *hepatitis* is likely (16,17). There are two common transaminase enzymes: AST (found primarily in the liver, although it is also in several other tissues) and ALT (found predominantly in hepatocytes). AST activity is increased in alcoholics; therefore, an AST:ALT ratio $>2:1$ suggests alcohol toxicity (18,19). AST levels >400 IU/mL indicate hepatocellular injury, whereas higher levels may be associated with liver ischemia, viral infection, or toxins. Imaging for these intrahepatic causes of jaundice often reveal no specific findings. The liver parenchyma often has diffuse interstitial edema and infiltration of inflammatory cells that causes diffuse decreased parenchymal echogenicity on ultrasound. This gives rise to the "starry sky" appearance of the relatively bright portal triads against the background of dark parenchyma (20).

If **elevated alkaline phosphatase predominates,** clinicians must be concerned about *biliary obstruction.* Whether the cause of obstruction is intrahepatic or extrahepatic, the synthesis and release of alkaline phosphatase into the serum is increased (eFig. 102.1F). However, extrahepatic tissues also synthesize and release alkaline phosphatase. To confirm the hepatic origin for the elevated alkaline phosphatase, enzymes such as γ-glutamyl transferase may be tested. In a jaundiced patient, however, an increased alkaline phosphatase with normal transaminases strongly suggests biliary tract obstruction. Patients in this category should have their gallbladder and liver evaluated with abdominal ultrasound. This test is noninvasive and has a sensitivity of 77% and a specificity of 83% to 95% for bile duct obstruction (21).

The goal of imaging jaundiced patients is to identify which patients have an obstructive (and therefore perhaps correctable) cause of their jaundice. Ultrasound is particularly suited to this purpose because of its ability to visualize the intra- and extrahepatic biliary tree in detail. If dilated ducts are present, one must determine whether sonographic signs consistent with *cholecystitis* or *cholangitis* are present. Ultrasound findings consistent with cholecystitis include the sonographic Murphy sign, calculi in the gallbladder, gallbladder wall thickening of >3 mm, distention of the gallbladder, and pericholecystic fluid. Any of these findings warrant antibiotics and surgical consultation. A gastroenterology consultation to discuss whether a computed tomography (CT) scan or endoscopic retrograde cholangiopancreatography (ERCP) is prudent if these findings are absent should occur in a patient with dilated ducts, as extrinsic compression of the bile duct must be excluded. Magnetic resonance cholangiopancreatography (MRCP) is gaining favor among specialists as a diagnostic examination for a jaundiced patient without or with borderline common biliary duct dilatation if choledocholithiasis is a possible etiology. If available, MRCP has fewer risks than ERCP, although it does not provide the option for therapeutic maneuvers. Endoscopic ultrasound may serve as the standard for identifying gallbladder and bile duct stones in some institutions (22). If dilated ducts are not seen on ultrasound, further workup should focus on

sources of intrahepatic cholestasis, such as viral infection (hepatitis, Epstein–Barr virus, cytomegalovirus), toxin damage (alcohol, steroids), or disorders such as primary biliary cirrhosis and primary sclerosing cholangitis. This workup can generally be performed on an outpatient basis if the patient does not appear ill, can tolerate oral intake, and has reliable follow-up.

KEY TESTING

- Bilirubin (fractionated), transaminases, alkaline phosphatase, CBC, PT
- Biliary ultrasound if laboratory tests suggest biliary obstruction

ED MANAGEMENT

When evaluating a patient with jaundice, emergency physicians must quickly determine whether a life-threatening condition is present. During assessment of the airway, breathing, and circulation (ABCs), history, and physical examination, patients should be given oxygen, placed on a cardiac monitor, and intravenous access should be obtained. Caution is advised during invasive procedures, as hepatitis transmission through occupational exposures is a concern. Patients may require aggressive intravenous fluid resuscitation, as they may be dehydrated, hypotensive, or in shock due to decreased oral intake, vomiting, infection, sepsis, or third-space losses (such as occurs with ascites). Antiemetics should be given as needed. Patients with ascending cholangitis are often critically ill and require aggressive resuscitation. Airway intervention, cardiovascular support (including pressors after aggressive fluid resuscitation), early antibiotics, and emergent surgical consultation are all important measures in reducing morbidity and mortality.

Depending on the cause of jaundice and the toxicity of the patient, surgical, gastroenterologic, or radiologic intervention may be necessary to relieve an obstruction or address the cause of underlying infection. A general surgeon may need to perform an open or laparoscopic cholecystectomy depending on the patient's condition, the underlying pathology, and their skill set. A

gastroenterologist (or a surgeon at some institutions) may do an ERCP to stent an obstruction, to remove an obstructing gallstone from the common bile duct, or to perform a sphincterotomy. An interventional radiologist may execute a percutaneous transhepatic cholangiogram (PTC), a diagnostic and therapeutic procedure that may allow drainage of an obstructed bile duct with or without cholangitis. Further information about the evaluation and management of ascending cholangitis may be found in Chapter 103.

Fortunately, most patients with jaundice are not acutely ill. Pruritus may be their most troublesome symptom. Drugs such as cholestyramine (4 g PO qd-tid) and rifampin (300 to 450 mg PO qd) improve pruritus in patients with cholestasis, although these do not act immediately. Of note, long-term administration of rifampin for refractory pruritus has been associated with occasional hepatotoxicity (23). Oral naltrexone (50 mg qd) has also been shown to significantly decrease symptoms in patients with pruritus (24). Antihistamines should be used with caution, as they may precipitate hepatic encephalopathy. Additional treatment options depend on the underlying pathology.

CRITICAL INTERVENTIONS

- When a serious infection is likely, aggressive fluid administration, broad-spectrum parenteral antibiotics, and emergent consultation are mandatory.
- Aggressive fluid resuscitation and blood transfusion may be necessary in patients presenting in acute hemolytic crisis. Administration of folic acid is useful because hemolysis depletes folate.
- Patients with jaundice presenting in fulminant liver failure and confusion may require emergent airway management. Fluids, broad-spectrum antibiotics, and lactulose and/or neomycin should be administered, and any critical electrolyte abnormalities should be aggressively corrected.

DISPOSITION

Acute hemolysis must be ruled out in patients with *isolated unconjugated hyperbilirubinemia.* If hemolysis is present, the patient should be admitted and a diligent search for the underlying cause (either inherited or acquired) must occur in consultation with hematology. If hemolysis or resorption of a hematoma do not appear to be the cause of the unconjugated hyperbilirubinemia, hereditary problems of bilirubin metabolism are likely. Affected patients may be candidates for outpatient follow-up with gastroenterology consultation.

In patients with *isolated conjugated hyperbilirubinemia,* hereditary metabolic problems are most likely. These patients may need gastroenterology consultation, although they can usually be followed on an outpatient basis as long as critical laboratory abnormalities do not exist, reliable follow-up arrangements can be made, and symptoms are controlled.

Patients with *hyperbilirubinemia and elevated transaminases* to a degree greater than the alkaline phosphatase require medical evaluation for causes of hepatocellular injury, often in the inpatient setting if these are not known to be chronic. Treatment may include cessation of offending toxins (e.g., alcohol, acetaminophen, isoniazid, other drugs), antiviral treatment for hepatitis, or treatment for autoimmune or metabolic causes (e.g., Wilson disease, hemochromatosis).

Patients with *hyperbilirubinemia and an elevated alkaline phosphatase* to an extent greater than the transaminases require urgent abdominal ultrasound to search for obstructive causes. Those patients *with dilated ducts* and fever, leukocytosis, bandemia, or toxic appearance should be aggressively hydrated, started on broad-spectrum antibiotics in the ED, and admitted to the hospital. It is prudent to keep these patients nil per os, provide analgesia and antiemetics as needed, as well as antipyretics if fever is present and no signs of acute hepatotoxicity exist. Prompt consultation with surgery (for possible laparotomy or laparoscopy, depending on the condition of the patient and the skills of the surgeon) or gastroenterology (for possible ERCP) is essential. Further workup of these patients is discussed in Chapter 103. Afebrile patients with dilated ducts who

are less acutely ill may have extrinsic compression of the biliary tree from such sources as pancreatic cancer, nearby arterial aneurysms, or other abdominal masses. These patients may benefit from abdominal CT scan, MRCP, or PTC. Patients *without dilated ducts* require a medical workup for causes of intrahepatic jaundice, such as infiltrative disorders, drugs or toxins, primary biliary cirrhosis, primary sclerosing cholangitis, or complications of pregnancy. The disposition of these patients depends on their clinical status and degree of laboratory abnormalities. Patients with chronic alcoholism who present with jaundice, especially of new onset, should be carefully managed and observed prior to release from the ED. This is extremely important for those who are unreliable, have uncertain follow-up care, or live in suboptimal conditions.

Common Pitfalls

- Delayed fluid intervention, broad-spectrum antibiotic administration, and emergent consultation in an acutely ill patient with jaundice and signs of cholangitis, such as Charcot triad (RUQ pain, jaundice, fever) or Reynold pentad (RUQ pain, jaundice, fever, hypotension, mental status changes).
- Failure to recognize signs and symptoms of fulminant liver failure (e.g., confusion, asterixis, abnormal vital signs), as well as predict associated problems related to the airway, cardiovascular status, glucose, and electrolytes.
- Failure to order appropriate imaging studies for patients with hyperbilirubinemia and an elevated alkaline phosphatase, suggestive of biliary obstruction requiring intervention.
- Failure to arrange or ensure reliable follow-up care for patients with unclear etiologies of their jaundice, as these patients will likely require serial evaluations and repeat testing before a diagnosis is confirmed.

ACKNOWLEDGMENTS

Drs. Garmel and Barker would like to thank Elaine Barnes from the Kaiser Santa Clara Health Sciences Library for her research assistance

and Dr. Timothy Steck from the Department of Gastroenterology at Kaiser Santa Clara Medical Center for his thoughtful review.

CHAPTER 103

Acute Diseases of the Biliary Tract

Boris Garber and Lance D. Wilson

Biliary disease is a common problem in emergency department patients, primarily because of the high prevalence of gallstones, which are present in as many as 25% of women and 15% of men over the age of 50. In the United States, over 120,000 cholecystectomies are performed yearly for acute cholecystitis, contributing to the $6.3 billion annual cost of gallbladder disease (1). Emergency physicians are confronted with a wide range of biliary pathology and must be familiar with the natural history of biliary disease to understand the variable presentations of acute disease and acute complications of chronic disease.

PATHOPHYSIOLOGY

The gallbladder is a reservoir off the common bile duct (CBD) that receives, concentrates, and secretes bile to assist in intestinal absorption of fat and fat-soluble vitamins. Gallstones form when cholesterol is supersaturated in the bile, leaves solution, and crystallizes on a matrix of calcium and other bile constituents. In Western countries, 75% to 80% of gallstones are cholesterol or mixed cholesterol stones (2). Once formed, gallstones may dissolve, remain unchanged, or grow larger.

Risk factors for gallstones are features that predispose to increased concentrations of cholesterol in the bile, including increased age, obesity, female sex, ethnicity, and hyperlipidemia. Family history is increasingly recognized as an important risk factor for biliary disease

(3). Crohn disease, ileal resection, total parenteral nutrition, and rapid weight loss, particularly in the setting of bariatric surgery, also predispose patients to gallstone formation (3). Approximately 10% to 20% of gallstones are formed of calcium bilirubinate (pigment stones); these are associated with hemolytic anemias, cirrhosis, biliary tract anomalies, and biliary infections.

Although gallbladder pathology is secondary to gallstones, as much as 10% of acute cholecystitis is acalculous. Acalculous cholecystitis classically occurs in patients after major surgery, burns, trauma, or sepsis, where after a major insult, bile stasis and low arterial inflow lead to gallbladder inflammation, infection, and eventually necrosis (4); however, patients clearly present to the emergency department with acalculous cholecystitis. These patients are typically elderly men with significant atherosclerotic disease; however, other risk factors include diabetes, abdominal vasculitis, renal failure, congestive heart failure (CHF), and resuscitation from shock or arrest. Importantly, acalculous cholecystitis represents 50% to 70% of all acute cholecystitis in children (5). Acalculous cholecystitis must be considered in patients with acquired immunodeficiency syndrome (AIDS), who may present with cholecystitis and cholangitis secondary to cytomegalovirus and *Cryptosporidium* infection; however, the incidence of these infections is decreasing with highly active antiretroviral treatment (5). Gangrene or perforation of the gallbladder complicate a significant percentage of acalculous cholecystitis cases. Diagnosis is challenging as clinical and laboratory findings are nonspecific, so a high index of suspicion and imaging studies are necessary though the imaging criteria are complex. Definite therapy is cholecystectomy; rarely gallbladder drainage can be used (4). Acute acalculous cholecystitis is associated with a mortality rate of greater than 30% (5).

Gallbladder cancer also must be considered in the approach to patients with presumed biliary disease. It is the most common biliary tract tumor, is highly lethal, and early on lacks any specific symptoms or signs. When localized, surgery offers the hope for cure, so early diagnosis is crucial. Chronically inflamed gallbladders can become calcified, thereby leading to the radiographic finding of a

porcelain gallbladder. These patients have as much as a 21% risk of developing gallbladder cancer, which normally occurs in less than 1% of patients with chronic cholelithiasis (6). Additional risk factors are asymptomatic gall stones 3 cm in diameter or larger (although surgery for asymptomatic gall stones is controversial) (6) and gallbladder polyps larger than 10 mm in diameter. Therefore, when these are discovered incidently during abdominal imaging, this mandates a discussion with the patient and a referral. Differentiating between benign and malignant gallbladder lesions based on imaging is difficult. Color Doppler study of polyps has been proposed to distinguish benign from malignant lesions (7).

CLINICAL PRESENTATION

It is helpful to view cholelithiasis in three categories: asymptomatic, symptomatic, and complicated. Clinical features of biliary emergencies are summarized in Table 103.1 (3,5,8–10).

TABLE 103.1
Diagnostic Features in Diseases of the Gallbladder

Cholelithiasis	Acute Cholecystitis	Choledocholithiasis	Cholangitis	Acalculous Cholecystitis
Presentation				
Usually asymptomatic, if not: biliary pain either RUQ or epigastric, persistent, associated nausea and vomiting, classically associated with meals	Pain in RUQ (sensitivity 81%, specificity 67%), severe, nausea, vomiting most common symptom in children (60%)	May be asymptomatic; usually persistent pain in RUQ	Usually elderly patients with biliary tract disease; recent biliary instrumentation, intermittent RUQ pain, typically more mild, fever, chills	Suspected in patients with recent critical illness or other risk factors who have unexplained sepsis, abdominal pain, jaundice, fever
Physical Examination				
Asymptomatic—normal examination, biliary colic—tenderness (RUQ and/or epigastrium)	Fever (sensitivity 35%, specificity 80%), tachycardia, tenderness in RUQ (sensitivity 77%, specificity 54%) + Murphy sign (sensitivity 65%, specificity 89%); palpable mass in RUQ + 1/3 of patients; clinical jaundice: unusual, although most common symptom in children younger than 1 yr (90%)	May have normal examination, or if common duct obstruction; clinical jaundice, RUQ tenderness	RUQ tenderness, clinical jaundice (mild); fever, sometimes shock, and sepsis; typical clinical picture in only 50%	Similar to calculous cholecystitis, but may be unreliable
Laboratory				
Typically normal	Leukocytosis (sensitivity 63%, specificity 57%); liver chemistries—typically slight elevation total bilirubin, AST, alkaline phosphatase (sensitivity 34%, specificity 80% for all three, for any one sensitivity 70%, specificity 42%)	If CBD obstruction; elevated bilirubin, alkaline phosphatase, LFTs, pancreatitis	Leukocytosis with left shift; hyperbilirubinemia elevated alkaline phosphatase level	Leukocytosis and hyperbilirubinemia common
Diagnostic Imaging				
Ultrasonography → gallstones (sensitivity 88%; specificity, 99%, both >95% for stones >3 mm)	Ultrasonography—(sensitivity 88%; specificity 80%) for cholecystitis. Tc99-HIDA scans somewhat better test characteristics but more inconvenient	Ultrasonography—stones in CBD (sensitivity 25–68%, specificity 97–100%), dilation of CBD (75%)	Similar ultrasound findings to those with choledocholithiasis	Ultrasonography—sensitivity 80%; specificity 98% for gallbladder wall thickness >5 mm, although controversial. Tc-HIDA scans 98% accuracy, but high false-negative rates reported
Differential Diagnosis				
Gastric/duodenal ulcer, pancreatitis, hepatitis, renal colic, gastroesophageal reflux, angina, hiatal hernia	Appendicitis, pancreatitis, hepatitis, RLL pneumonia, gastric/duodenal ulcer, renal colic, cardiac pain, hiatal hernia	Other causes of obstructive jaundice: Mirizzi syndrome, tumor in CBD, hepatic duct, head of pancreas	Nonsuppurative cholangitis; amoebic/pyogenic hepatic abscess, choledocholithiasis, cholangiocarcinoma, biliary stricture or fistula, extrinsic bile-duct obstruction, primary sclerosing cholangitis	Similar to calculous cholecystitis, other causes of sepsis

RUQ, right upper quadrant; LFT, liver function test; AST, aspartate aminotransferase; CBD, common bile duct; RLL, right lower lobe.

Asymptomatic Cholelithiasis

Most people with asymptomatic gallstones remain asymptomatic with only about 1% to 4% developing symptoms every year (1). When patients become symptomatic, nearly all initially develop pain, rather than cholecystitis or other acute complications, so they can be managed expectantly. The incidental discovery of gall stones when using ultrasound (US) or other imaging can be problematic and care should be taken not to attribute all the presenting symptoms to potentially incidental gallstones (6).

Symptomatic Cholelithiasis

Many people present to the emergency department with symptomatic gallstones. Pain is caused by distention of the gallbladder as it contracts against stones obstructing the gallbladder neck or cystic duct. Typically, biliary pain is a vague epigastric or right upper quadrant (RUQ) discomfort, usually associated with nausea. The term *biliary colic* is a misnomer, as biliary pain is constant, typically lasting longer than 30 minutes but less than 4 to 6 hours. Pain typically occurs in the evening and is usually postprandial (10). The vague nature and nonspecific location of the discomfort makes it easily mistaken for gastritis, reflux disease, or other benign abdominal pathologies. If the process continues, pain may become more severe, become localized to the epigastrium or the RUQ, radiates to the back or scapula, and may be associated with vomiting.

Complicated Cholelithiasis

Complicated cholelithiasis includes conditions such as acute cholecystitis and its complications, choledocholithiasis (stones in the CBD), cholangitis, and the acute complications of chronic gallstones. All are potentially life-threatening and require prompt recognition and treatment.

Acute Cholecystitis

In acute cholecystitis, the gallbladder neck or cystic duct is obstructed, and persistently increased intraluminal pressure along with irritation from bile and stones leads to mucosal damage, inflammation of the gallbladder wall, and eventually ischemia. Bacterial suprainfection (usually enteric gram-negative bacteria and occasionally anaerobes) plays a role in majority of the cases (1). In acute cholecystitis, pain is typically more severe and more often localized to the RUQ, with variable radiation to the epigastrium or back. Nausea and vomiting are common. Low-grade fever and tachycardia are typically present. *Murphy's sign* (inspiratory arrest during palpation of the RUQ) or localized peritonitis may be elicited.

In up to one-third of cases, a swollen, tender gallbladder is palpated. Typically, a leukocytosis with left shift is present, and mild increases in liver function tests, alkaline phosphatase, and bilirubin are seen in 30% to 40% of patients. Laboratory tests are frequently normal and fever can be absent, especially in the diabetic or chronically debilitated patient and must not be relied on to make the diagnosis. In acute cholecystitis, patients are rarely septic. If sepsis is present, consider more complicated conditions, particularly ascending cholangitis.

Complications of Acute Cholecystitis

Gallbladder perforation usually occurs in the setting of acute or chronic cholecystitis, typically in the elderly, debilitated, or diabetic patients. The gallbladder becomes gangrenous, perforates, and normally walls off to form an empyema, but occasionally a bile leak occurs, leading to bile peritonitis. Gallbladder wall gangrene may lead to diminishing pain and tenderness and absence of Murphy sign as nerve endings necrose (11). Rarely, acute cholecystitis is complicated by infection with a gas-forming organism, leading to *emphysematous cholecystitis*. This typically occurs in diabetics and elderly men with vascular disease. Emphysematous cholecystitis is a disease with mortality much higher than uncomplicated acute cholecystitis (11).

Choledocholithiasis

Gallstones in the CBD are termed *choledocholithiasis*. Stones usually form in the gallbladder and migrate from the cystic duct, but they can form primarily in the biliary tree. Presentation is usually similar to that of acute cholecystitis but can be variable and more subtle. Patients may have jaundice (3). Choledocholithiasis usually causes an elevation in alkaline phosphatase and conjugated bilirubin, consistent with extrahepatic obstruction. Increases in amylase and lipase are variable. A small proportion of patients with gallstones develop acute *gallstone pancreatitis*. *Mirizzi syndrome* is caused by extrinsic compression of the common hepatic duct by a gallstone

impacted in the cystic duct or neck of gallbladder and presents in similar fashion to choledocholithiasis (3).

Ascending Cholangitis

Ascending cholangitis must be considered in any septic patient who presents with signs and symptoms of acute biliary tract disease, especially if the patient is diabetic, elderly, or debilitated. Ascending cholangitis is a bacterial infection of the biliary system, most frequently associated with CBD stones and obstruction from any cause. Various bacteria have been isolated from bile in patients with cholangitis; polymicrobial isolation is not unusual and blood cultures are positive in approximately 50% of patients. Endoscopic retrograde cholangiopancreatography (ERCP) in patients with biliary obstruction is the most common iatrogenic way of introducing bacteria into the biliary system, and cholangitis after biliary manipulation has a poor prognosis (12). Classically, it presents with *Charcot triad* of RUQ pain, jaundice, and fever; if mental status changes and shock occurs, this is considered *Reynold pentad.* Ascending cholangitis seldom presents classically, so it must be considered in any septic patient without a source. Mortality approaches 40%. To investigate the etiology of cholangitis, endoscopic ultrasonography is the most sensitive study to detect small stones, but ERCP is the only method which may also be therapeutic. Computed tomography (CT) and MRCP are also useful diagnostically. Tokyo criteria defines mild, moderate, and severe diseases. Treatment requires aggressive supportive measures, admission to ICU for patients with severe disease, intravenous antibiotics as soon as the diagnosis is suspected, followed by prompt biliary drainage. The more severe the presentation, the more urgently biliary decompression should be performed. A landmark study (13) showed that endoscopic therapy results in much lower mortality when compared to surgery. ERCP can be done at bedside, but it should be recognized that if contrast injection increases intrabiliary pressure, the patient may acutely decompensate from worsening septicemia (12).

Complications of Chronic Cholelithiasis

In chronic and occasionally in acute cholecystitis, gallbladder–enteric fistulas may form, causing pain, aerobilia, or infection. Rarely, a gallstone may pass through a fistula into the small bowel and lodge in the ileocecal valve, causing a small bowel obstruction (*gallstone ileus*) (3). Fistulas between the gallbladder and the duodenum, stomach, colon, pleura, and other organs have also been described. Presentation for gallstone ileus is typically abdominal distention, pain, vomiting, usually in an elderly patient with multiple medical problems. Patients will appear acutely ill and dehydrated, and have signs of intestinal obstruction, but clinical jaundice is unusual. Abdominal films are useful for showing evidence of mechanical bowel obstruction, pneumobilia, or a stone in the gastrointestinal tract.

DIFFERENTIAL DIAGNOSIS

When patients present with complaints attributable to gallbladder disease, a wide range of both intra-abdominal and extra-abdominal processes must be considered (Table 103.2). Failing to consider biliary tract pathology in the differential diagnosis of nonspecific abdominal pain, fever, or sepsis in special populations can be problematic. The elderly can have very subtle presentations with only food intolerance or altered mental status (14). Elderly, diabetic, or debilitated patients are often difficult to assess and require ancillary studies to rule out life-threatening disease. Because pregnancy is associated with increased incidence of biliary sludge and cholesterol stone formation (14), biliary disease must be considered in the differential diagnosis of the pregnant patient with abdominal pain. Signs and symptoms of acute cholecystitis in pregnant and nonpregnant patients are similar. Although advancing age is a primary risk factor for gallstones, gallbladder disease and cholecystectomies are increasing among children, potentially related to increasing obesity (15). Acquired gall bladder pathology in infants is associated with prematurity, total parenteral nutrition status, and generalized severe illness, particularly in neonates, dehydration, and

sepsis (16). Children with cholelithiasis typically have underlying risk factors for the development of stones and biliary disease, such as sickle cell disease or other hemolytic anemias. Hispanic race and female gender appear to be important risk factors (15).

TABLE 103.2
Differential Diagnosis of Acute Diseases of the Gallbladder

Complications of gallstones
Acute cholecystitis
Hepatitis
Pancreatitis
Peptic ulcer disease
Esophageal disease, with or without perforation
Appendicitis
Bowel obstruction
Colonic pathology
Pelvic inflammatory disease
Fitz–Hugh–Curtis syndrome/perihepatitis
Renal colic
Pyelonephritis
Pneumonia
Pulmonary embolism
Acute myocardial infarction
Aortic dissection
HELLP syndrome

HELLP, hemolytic anemia, elevated liver enzymes, low platelet count.

ED EVALUATION

Despite the diversity in acute gallbladder pathology, evaluation should follow a relatively straightforward sequence based on the patient's clinical status (Table 103.1). The emergency physician's goal is to rule out life-threatening problems and if gallbladder pathology is suspected, acute cholecystitis and other complicated acute biliary diseases should be ruled out. If the patient presents with symptoms attributable to gallstones without complications, referral for outpatient ultrasound and follow-up is appropriate. No further emergency department workup is necessary. In the patient with more

severe symptoms or dehydration, further workup is indicated, including a complete blood count, electrolytes, liver function tests, bilirubin, amylase, lipase, urinalysis, and possibly diagnostic imaging. A summary of the clinical features and test characteristics in acute biliary diseases are shown in Table 103.2 (5,8,10,16). As no single clinical or laboratory finding is sufficient for diagnosing acute cholecystitis or acute biliary pathology, the physician's overall impression of the likelihood of the disease determines whether the diagnosis is pursed and diagnostic imaging is initiated (10).

Diagnostic Imaging

Plain radiographs are helpful only for diagnosing associated bowel obstruction or ileus, although gallstones are visible on plain radiographs in approximately 10% of cases. US and cholescintigraphy (commonly referred to as HIDA scans) both have excellent positive and negative predictive values when done appropriately; HIDA is considered to have higher accuracy, but because of its accessibility and ease of use, US is typically the initial study of choice. Sonographic evaluation for gallstones and acute cholecystitis by emergency physicians is now an accepted part of routine practice, reduces length of stay, and has test characteristics similar to US performed in the radiology department (7,17). However, as with other radiographic studies, ED physicians must use caution when interpreting bed-side US and avoid premature diagnostic closure. Gallstones alone do not establish the diagnosis of acute cholecystitis. To establish US diagnosis of cholecystitis secondary signs such as pericholecystic fluid, sonographic Murphy sign, and thickened Gallbladder wall need to be present in addition to gall stones. Presence of stones together with either positive sonographic Murphy sign or Gallbladder wall thickening of 5 mm or greater has positive predictive value of greater than 90%, alternatively absence of the above results in negative predictive value of 95% (1). Gallbladder wall thickening is nonspecific and can occur in chronic cholecystitis, CHF, cirrhosis, hepatitis, and other conditions (9). Other relevant findings include sludge in the gallbladder, gallbladder distention, and pericholecystic fluid. US is

also helpful in making the diagnosis of complications of acute cholecystitis where free fluid suggests gallbladder perforation.

CT scanning is reserved for patients with atypical presentations in whom other intra-abdominal pathology is a consideration and where a wide differential diagnosis persists (18). Ultrasound is superior to CT in ruling out acute cholecystitis and a CT diagnosis of cholecystitis should usually be confirmed with US. Only ~2/3 of gall stones will be visible on CT. Normal CT examination of gallbladder makes acute cholecystitis unlikely but if high suspicion persists US should still be done. CT is most useful in evaluating complications such as gallbladder perforation, pericholecystic abscess, and gangrenous and emphysematous cholecystitis (9). Intraluminal gas, membranes, or irregular or absent wall on CT or US are indicative of gangrenous cholecystitis (11).

A dilated CBD or intraluminal stone is diagnostic of choledocholithiasis. However, these findings are not present in all cases, and if CBD stones are suspected, they may be evaluated by ERCP or MRI with cholangiography. Ultrasound can also assess other extrabiliary causes of RUQ pain involving liver, kidney, or pancreas. HIDA scans test the patency of the cystic duct. Failure to visualize the gallbladder is highly sensitive for acute cholecystitis. The main indication for HIDA is a high suspicion for acute cholecystitis, with an equivocal or negative ultrasound examination, particularly if acalculous cholecystitis is suspected (1).

KEY TESTING

- Although laboratory testing lacks sensitivity and specificity, liver function tests and lipase may be useful in identifying patients with biliary obstruction.
- Ultrasound is the most useful initial imaging study.

ED MANAGEMENT

Emergency department management of symptomatic cholelithiasis includes hydration, antiemetics, and analgesia. These patients can usually be sent home with appropriate follow-up. If acute

cholecystitis or another complicated presentation of gallbladder disease is suspected, prompt consultation with a general surgeon is mandatory. Attention to the patient's volume and electrolyte status, antiemetics, and analgesia, typically with nonsteroidal anti-inflammatory drugs or narcotics, is appropriate (3). For acute cholecystitis, antibiotics are indicated and should be discussed with the consultant. The patient who is septic or suspected of having ascending cholangitis, perforation, or emphysematous cholecystitis should be given antibiotics promptly. Typical biliary pathogens include enteric gram-negative bacteria and gram-positive species such as *enterococcus* or *streptococci.* Anaerobic species, particularly *Clostridium* and *Bacteroides fragilis,* occur in approximately 10% to 15% of cases, usually in the elderly or in patients with biliary obstruction. Appropriate coverage includes a parenteral antipseudomonal penicillin such as ticarcillin/clavulanate 3.1 g q6 h or piperacillin/tazobactam 3.375 g q6 h. Alternative regimens, especially if anaerobes are suspected, include a second- or third-generation cephalosporin or a quinolone plus clindamycin or metronidazole (1).

Treatment for symptomatic gallstones is surgical, almost exclusively with laparoscopic cholecystectomy (1,19). In acute cholecystitis, urgent cholecystectomy, optimally performed within 48 to 96 hours of presentation, is preferred over delayed surgery for mild disease as defined by Tokyo criteria (1,19,20). Patients with moderate disease can have either early or delayed surgical intervention while those with severe disease should be stabilized in the ICU first (1). Early cholecystectomy is safe and appropriate in elderly patients as well (21). In patients who present with pain, fever, or jaundice after laparoscopic cholecystectomy, one must consider the recognized complications of the procedure, including biliary injury and fistulas, wound infections, and intra-abdominal abscesses, which may present weeks to months after surgery (19). Newer techniques, such as endoscopic surgery through natural orifices, which do not require a skin incision and routine open cholecystectomies via minilaparotomies are currently being tested (3). Percutaneous urgent cholecystostomy followed by elective

cholecystectomy is an option for patients with significant comorbidities who are at high operative risk (1,19). Oral dissolution therapy for gallstones, occasionally in conjunction with extracorporeal shock-wave lithotripsy, is used in patients who are substantial surgical risks or do not want surgery.

In patients with CBD stones, endoscopic sphincterotomy or dilatation to relieve obstruction followed by elective cholecystectomy is typically performed, rather than open cholecystectomy with CBD exploration. Almost all patients with ascending cholangitis require urgent biliary decompression. Typically this is performed by using endoscopic sphincterotomy rather than surgical approaches (12). All patients with gallbladder perforation, emphysematous cholecystitis, or gallbladder empyema need emergent surgery. Pregnant patients with biliary colic should be admitted and if symptoms persist more than 12 hours, antibiotics should be administered. Whether early surgical intervention is warranted in pregnancy is still a controversy (14). Children with biliary colic should also be admitted.

CRITICAL INTERVENTIONS

- Surgical consultation in all cases of acute cholecystitis or acute biliary disease
- Early surgical or gastroenterology consultation for ERCP when prompt biliary decompression is indicated
- Antibiotics in suspected acute cholecystitis or cholangitis

DISPOSITION

Most patients with symptomatic cholelithiasis may be managed as outpatients, with analgesics, antiemetics, and follow-up with a general surgeon. Those with more severe symptoms refractory to emergency department treatment should be admitted. Patients with acute cholecystitis, choledocholithiasis, gallstone pancreatitis, ascending cholangitis, or complications of chronic cholelithiasis such as gallstone ileus must be admitted to the hospital for antibiotics and/or surgical care.

Common Pitfalls

- Acute complications of gallstone disease must be considered and recognized, particularly in the elderly and debilitated who typically have subtle presentations.
- Remember to consider cholecystitis or cholangitis in the elderly, diabetic, or debilitated patient who presents with fever of unknown origin, change in mental status, or other nonspecific complaints.
- Symptomatic gallstones should be considered in patients with mild or atypical presentations, such as nausea, dyspepsia, or vague abdominal pain.
- Always consider acute gallbladder disease in pregnant women and children with abdominal pain.
- Always obtain timely surgical consultation when complications of gallstone disease are considered and arrange for urgent biliary decompression in cases of cholangitis.

CHAPTER 104
Hepatitis

Mark J. Ault and Joel M. Geiderman

Viruses are responsible for the majority of cases of acute hepatitis. The primary hepatotropic viruses include hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus, also called the delta agent (HDV), hepatitis E virus (HEV), and the non-A through E hepatitis viruses. In addition, Epstein–Barr virus (EBV), cytomegalovirus (CMV), and other viruses are known to cause hepatitis as part of a systemic infection, as are a variety of bacteria, rickettsiae, and protozoal organisms (Table 104.1). A similar clinical and histopathologic picture can result from a variety of toxic and metabolic processes.

TABLE 104.1
Infectious Agents Known to Cause Hepatitis

- Primary hepatitis viruses
  - Hepatitis A (HAV)
  - Hepatitis B (HBV)
  - Hepatitis C (HCV)
  - Hepatitis D (HDV)
  - Hepatitis E (HEV)
  - Non-A through E
- Secondary hepatitis viruses
  - Epstein–Barr
  - Cytomegalovirus
  - Herpes simplex
  - Varicella-zoster
  - Rubella
  - Rubeola
  - Mumps
  - Adenovirus
  - Coxsackievirus B
  - Yellow fever
- Nonviral infectious agents
  - Brucellosis
  - Ehrlichiosis
  - Gram-negative sepsis
  - Gram-positive toxic shock syndromes
  - Legionellosis
  - Leptospirosis
  - Malaria
  - Mycoplasma disease
  - Plague
  - Q fever
  - Salmonellosis
  - Syphilis
  - Toxoplasmosis
  - Tularemia
  - Tuberculosis

CLINICAL PRESENTATION

The clinical manifestations of hepatitis, regardless of cause, are protean and vary from individual to individual with respect to the severity of symptoms, duration of illness, and outcome. The ultimate

course of the illness is thought to depend on the nature of the etiologic agent, the extent of pre-existing or underlying liver disease, and, with infectious causes, the interaction between host factors, and the pathogen.

In its classic presentation, viral hepatitis has a highly characteristic clinical picture that is easily recognizable in its various stages. After a variable incubation period, a *prodromal phase* of illness occurs, with symptoms such as anorexia, low-grade fever, malaise, and lassitude. Often characterized as flu-like symptoms, they are nonspecific constitutional complaints typical of a variety of viral illnesses. Gastrointestinal symptoms may predominate, particularly in the adult patient, and abdominal discomfort representing hepatic, and occasionally splenic, enlargement may be reported. Within days to weeks after the onset of symptoms, the patient who enters the *icteric phase* of the illness first notes discoloration of the urine, representing the early rise of direct-reacting bilirubin and the spillage of bilirubin pigment into the urine. Subsequently, light (clay-colored) stools develop, scleral icterus may be noted, and clinical jaundice may become evident both to the patient and to the clinician as the serum bilirubin level exceeds 3 to 4 mg/dL. At this point, particularly in hepatitis A, symptoms may begin to resolve, heralding the *convalescent phase* of the illness.

Physical findings are highly variable in that the examination findings may be completely normal or may reveal frank jaundice and evidence of hepatic dysfunction. Liver enlargement and tenderness are common, and splenomegaly and lymphadenopathy may be present in 15% to 20% of cases.

Hepatitis may not be recognized when it does not present as the classic textbook picture because the history may be nonspecific or even misleading. This may occur, for example, when surreptitious toxin ingestion is involved or when the patient is reluctant to reveal specific risk factors for viral hepatitis.

If the patient is frankly jaundiced, hepatitis is usually readily considered. Recognition of more subtle findings such as scleral

discoloration, sublingual yellowing, or excoriations, which may only be evident on careful examination, may also be informative.

When frank jaundice is absent, a higher index of suspicion is necessary. Constitutional symptoms alone are not at all specific for hepatitis but nonetheless are usually a sensitive trigger for initial laboratory screening which may reveal viral hepatitis.

Extrahepatic manifestations are particularly prevalent in hepatitis B and are generally considered to result from the deposition of immune complexes in various extrahepatic sites. They include urticaria and morbilliform rashes, arthralgias and frank arthritis, hematuria and proteinuria, and, less commonly, vasculitis of the mixed cryoglobulinemia or polyarteritis nodosa types (7). Other extrahepatic manifestations are not believed to be immunologically mediated. Pancreatitis, pneumonitis, and myocarditis are thought to be caused by direct viral involvement.

Occasionally, a patient presents with advanced hepatic failure and no history of hepatitis. This may occur in the context of progressive chronic hepatitis, a toxic insult, or acute-on-chronic hepatitis. Unexplained encephalopathy, personality change, coagulopathy, hypoglycemia, or respiratory alkalosis should prompt consideration of hepatic disease, including hepatitis. The following is a discussion of the myriad causes of hepatitis.

Viral Hepatitis

During the incubation period, there are no clinical manifestations of disease, but viral replication is occurring and serologic and chemical markers of this activity and the host response to it can be detected. Clinical manifestations appear only if and when enough hepatocytes are invaded. The etiologic agent causing hepatitis cannot be determined from the clinical presentation. Therefore, in evaluating the patient with presumed viral hepatitis, one must be familiar with the serologic markers associated with the various types.

HAV is spread primarily by the fecal–oral route, although the virus can be found in the blood as well as in the liver, bile, and stool during the latter part of the incubation period. The 2-week period

before the onset of jaundice is the time of greatest infectivity; viremia, fecal shedding in the stool, and infectivity diminishes markedly by the time the icteric phase begins (Fig. 104.1). Source outbreaks are usually the result of fecal contamination of water supplies (e.g., with poor sanitation or during disasters) or food contamination, or occasionally by oral–anal contact. The incubation period is short: 2 to 7 weeks. The *preicteric* phase of hepatitis A usually lasts 4 to 14 days, presenting with nonspecific weakness, malaise, anorexia, nausea, and vomiting. There may be pain in the right upper quadrant and a characteristic loss of taste for cigarettes. Rash, urticaria, and joint pain occur infrequently, but the diagnosis of acute hepatitis should be considered in patients with these complaints. The term *preicteric* is presumptive (and often retrospective), because not all patients infected at this stage go on to have clinically evident jaundice. Children with hepatitis A typically manifest with gastroenteritis and commonly do not develop jaundice.

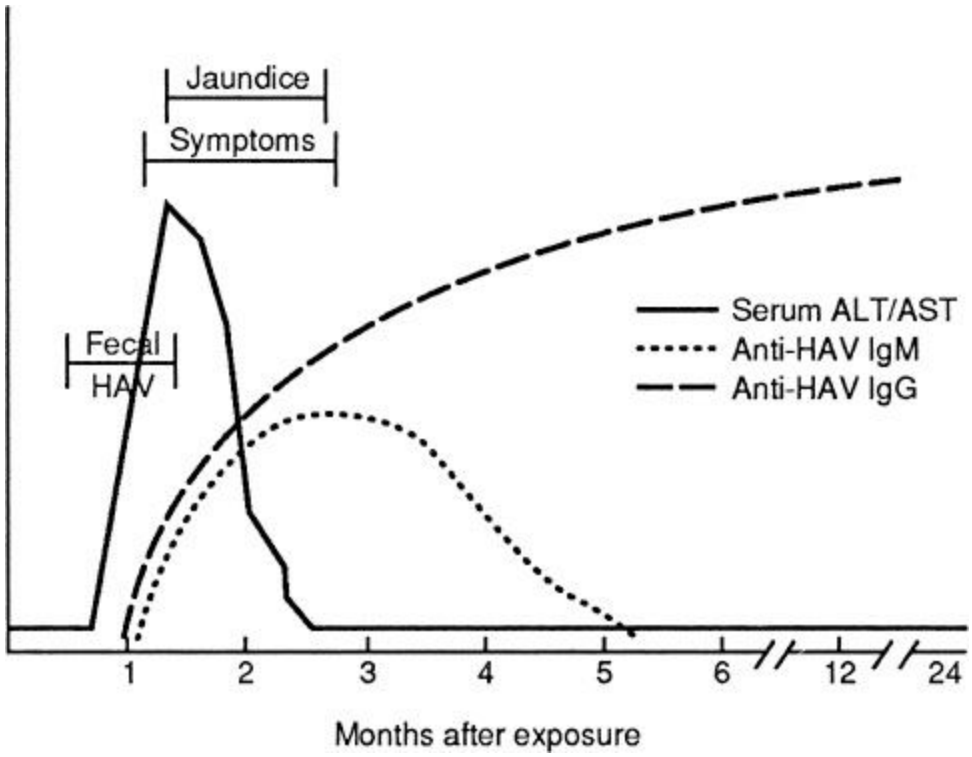

FIGURE 104.1 Serologic course of viral hepatitis A. Children usually have only mild symptoms with no jaundice. Adults more

often develop jaundice. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatology update/portal hypertension: viral hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med.* 1988;6:26.)

The presence of dark urine frequently heralds the onset of the icteric phase and is often what prompts the patient to seek medical attention. Most of the other symptoms, with the exception of malaise, resolve shortly after the appearance of jaundice, which may persist for up to a month. However, jaundice appears in the minority of patients infected with HAV. The convalescent period is variable; weakness and malaise may last for months. The onset of hepatitis A is usually more abrupt than that of the other types of viral hepatitis, but this observation is not useful in the individual case. Figure 104.1 depicts the usual serologic and biochemical course of hepatitis A. The alanine aminotransferase (ALT) level begins to rise late in the incubation phase, just before the onset of symptoms. Fecal shedding has peaked before this time and is abating. During the symptomatic period, about 4 to 5 weeks after exposure, immunoglobulin M (IgM) antibodies to HAV (anti-HAV IgM) begin to rise. Because this antibody usually becomes undetectable after 4 to 5 months, its presence implies recent infection. IgG antibodies rise later and remain detectable for life. The presence of such antibodies in the serum of at least 50% of adults reflects the high incidence of asymptomatic or unrecognized prior infection.

HBV is spread by exposure to blood, contaminated needles, infected secretions, sexual contact, and perinatal contact. Its prevalence is high among homosexual men, intravenous drug abusers, dialysis patients, patients and staff of institutions for the mentally retarded, and in certain endemic regions of the world. HBV has an incubation period of 45 to 160 days, during which the virus is actively replicating and is present not only in the hepatocyte but in virtually all body fluids. Patients are contagious during this

asymptomatic period, and diagnostic serologic markers become positive. Immunoprophylaxis given before the onset of symptoms may prevent or attenuate the disease.

The acute clinical course of hepatitis B is similar to that of hepatitis A. Jaundice is more likely to occur in hepatitis B than A but still occurs in a minority of cases. About 85% of cases resolve completely, leaving the patient immune to hepatitis B; 1% to 3% of cases evolve into fulminant hepatitis, which has a mortality rate of 90%, and the remainder develop chronic hepatitis.

The serologic and biochemical courses of acute hepatitis B are depicted in Figure 104.2. The first marker to appear in the serum is the hepatitis B surface antigen (HBsAg), indicating infection with hepatitis B. Next, DNA polymerase, HBV DNA, and the hepatitis B e antigen (HBeAg) appear in the serum. These reflect active HBV replication and infectivity and appear well before the onset of biochemical damage to the liver. Of this group, only HBeAg can be measured easily; the presence of antibody to the HBeAg (anti-HBe) suggests low infectivity. In patients who become symptomatic, the ALT level rises and, in some, jaundice appears. It is important to understand the significance of the next immunologic event—the appearance of antibodies to the hepatitis B core antigen (anti-HBc), initially IgM, then IgG. This rise precedes the appearance of antibodies to the surface antigen (anti-HBs). In Figure 104.2, the gap between *HBsAg* and the rise of *anti-HBs* is called the “window,” when the sole specific marker of recent infection with HBV is the presence of anti-HBc IgM.

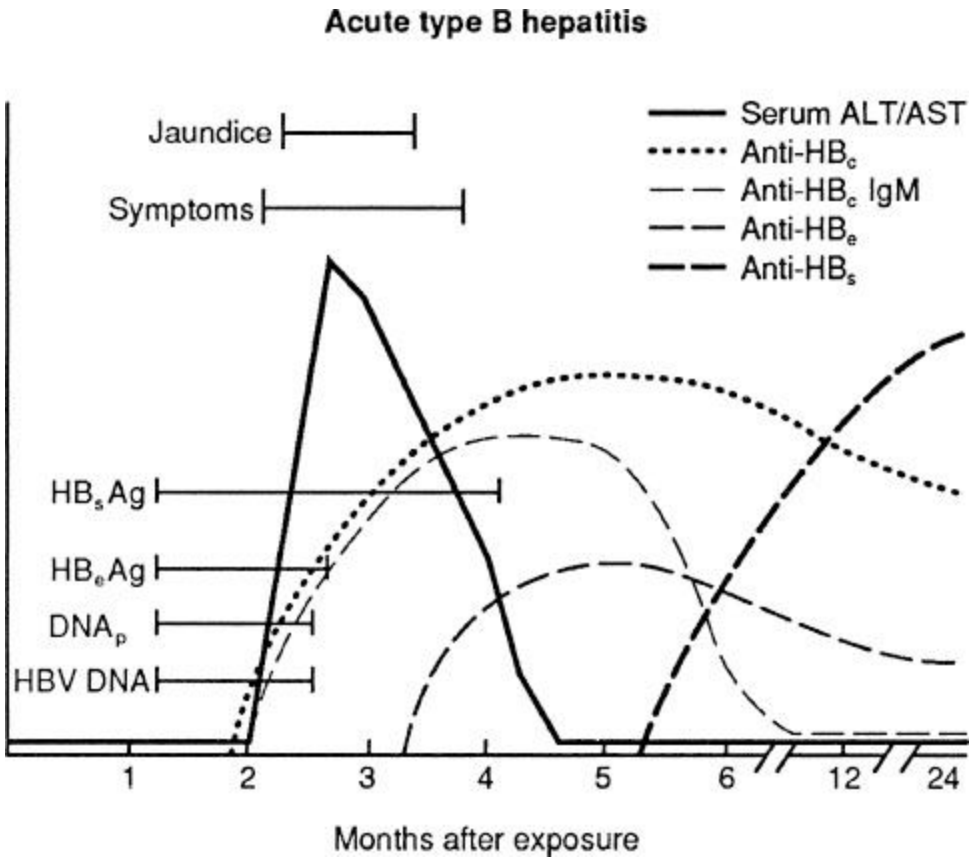

FIGURE 104.2 Serologic course of acute hepatitis B. This is more likely to cause jaundice than type A or non-A/non-B types. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatology update/portal hypertension: viral hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med.* 1988;6:33.)

The rise of anti-HBsAg signifies immunity to HBV and corresponds to the abatement of symptoms and the return of ALT to normal levels. When hepatitis B fails to resolve, a chronic carrier state occurs. This is characterized by the persistence of HBsAg for a period exceeding 6 months and may be associated with the presence of either HBeAg or the antibodies to HBeAg. The carriage rate in United States is only 0.1% to 0.5% but may be as high as 5% to 20% in some demographic groups. Figure 104.3 depicts the typical serologic course of chronic HBV disease. Note that the HBsAg remains positive, anti-HBs is lacking, and the patient remains

susceptible to further liver damage or to superinfection with hepatitis D.

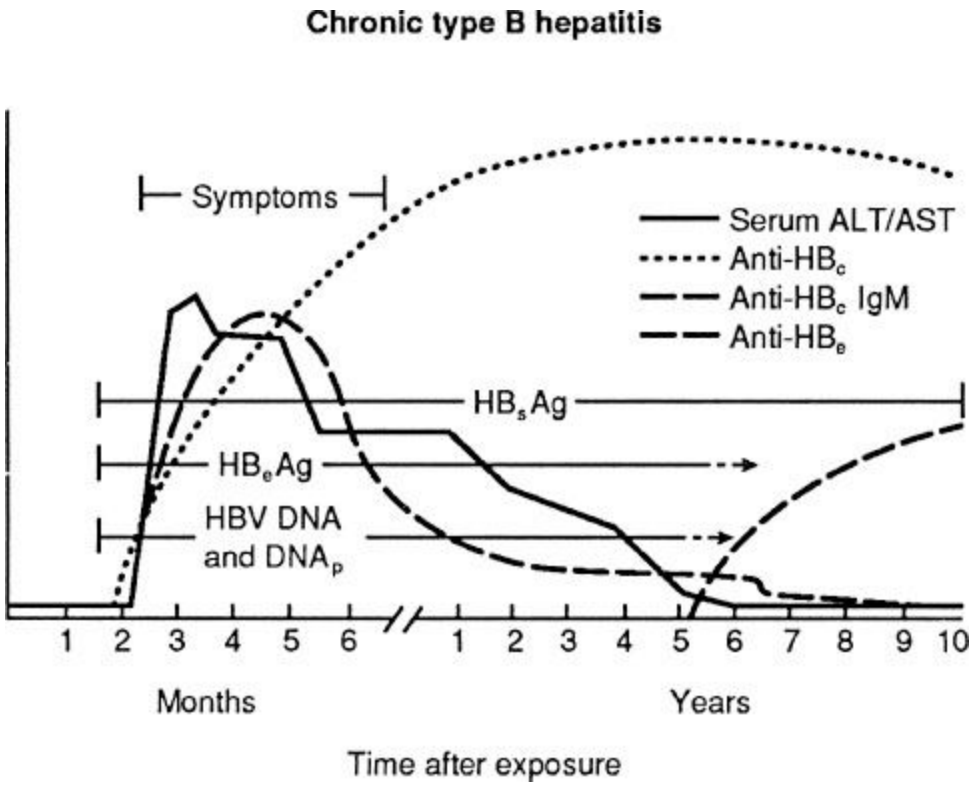

FIGURE 104.3 Serologic course of chronic hepatitis B virus (HBV) disease. (Adapted from Hoofnagle JH. Serologic diagnosis of acute and chronic hepatitis. In: Hepatology update/portal hypertension: viral hepatitis [postgraduate course of the American Association for the Study of Liver Diseases]. *Hosp Med.* 1988;6:33.)

HCV is an RNA virus of the Flaviviridae family. After the introduction of donor screening for HBV infection, posttransfusion hepatitis continued to be a significant problem. This led to the conclusion that most of the posttransfusion hepatitis was caused by another blood-borne pathogen, which was designated non-A, non-B (NANB) hepatitis. After the discovery of HCV in 1989 and the routine screening of the blood supply in the United States since 1990, it became clear that 80% to 90% of parenterally transmitted NANB hepatitis was caused by HCV. Currently, since the advent of genomic testing, the risk of transfusion-related hepatitis C is in the

range of 1 in 1,000,000 units transfused. Aside from blood transfusion, other parenteral sources of HCV infection include intravenous drug use, hemodialysis, organ transplantation, and occupational exposure. Low levels of transmission occur in sexual and household contacts and perinatally (i.e., vertical transmission) (1). There is no evidence that breast feeding transmits HCV from mother to baby. Sporadic cases also occur.

Hepatitis C viral RNA can be detected in blood within 1 to 3 weeks of exposure. Anti-HCV can be detected in 50% to 70% of patients at the onset of symptoms and in approximately 90% of patients 3 months after the onset of infection. However, the majority of infected patients are asymptomatic and anicteric. The symptoms of HCV—malaise, weakness, and anorexia—are similar to those seen with other types of hepatitis. However, compared with hepatitis B, the acute disease is usually milder. Acute HCV infection rarely causes fulminant disease.

Chronic disease, with persistent although sometimes intermittent viremia, occurs in 85% of infected patients (10). Most patients with chronic disease are clinically well (12). Unfortunately, although the natural history of HCV infection is somewhat unclear, most researchers would agree that the disease ultimately causes progression to clinically significant liver disease in a large portion of infected patients. Important factors leading to more accelerated progression of hepatic fibrosis include coinfection with HIV, infection with other hepatotropic viruses, alcohol use, and young age of acquisition. Hepatitis C is the leading reason for liver transplantation in the United States, owing to the high prevalence rate, estimated to be approximately 4 million (3).

Chronic HCV infection also leads to hepatocellular carcinoma in up to 5% of patients after 20 years. Once cirrhosis develops, the rate of acquiring hepatocellular carcinoma rises to 1% to 4% per year.

There are several different tests for hepatitis C, including anti-HCV by enzyme immunoassay (EIA), recombinant immunoblot assay (RIBA), HCV-RNA, viral load, and genotyping. Anti-HCV is positive in approximately 90% of infected patients, usually within 5 to 6 weeks after the onset of clinical hepatitis. However, it does not

distinguish among acute, chronic, and past infection, and positive tests are frequently falsely positive in populations with a low prevalence of infection. The HCV-RNA test identifies the presence of the virus in the blood. A reasonable testing strategy would be to order an anti-HCV and HCV-RNA. If both are negative, it is unlikely that the patient has acute hepatitis C. A positive anti-HCV and negative HCV-RNA generally represents remote infection. If both tests are positive, it may represent acute hepatitis C or an acute exacerbation of chronic hepatitis C. Finally, a positive HCV-RNA and negative anti-HCV is strongly suggestive of acute hepatitis C infection.

It appears that passive immunization with immune serum globulin derived from patients with previous HCV infection is unlikely to prevent disease, and no active vaccine is presently on the horizon. The Centre for Disease Control (CDC) recommends no postexposure prophylaxis. Until recently, treatment of chronic function has included combination therapy with recombinant α-interferon and ribavirin with the possible addition of boceprevir or telapravir, both protease inhibitors, for HCV genotype 1 infection (14). This resulted in a two- to threefold improvement in virologic response rates over the prior α-interferon monotherapy regimens. It is not known whether combination treatment can prevent the development of cirrhosis and hepatocellular carcinoma. Side effects of therapy are frequent and may prompt emergency department evaluation. Side effects of interferon include fever, nausea, irritability, and depression. Hemolytic anemia with subsequent decrease in the hematocrit is a common side effect of ribavirin and may require dose reduction.

In late 2013, the Food and Drug Administration approved 2 new direct acting antiviral agents, Sovaldi and Simeprivir, both oral agents, that can be effective in treating certain patients with chronic HCV infection. Treatment is tailored depending on viral genotype (14). A full discussion of the treatment of chronic HCV disease is beyond the scope of this text.

Hepatitis D, or delta hepatitis, is caused by a defective virus, the replication of which is dependent on the presence of HBsAg

synthesis. The virus consists of the delta-antigen–bearing core encapsulated by an HBsAg coat. It should not be surprising that a virus that requires HBV for its replication follows a similar transmission pattern. The clinical course of HDV infection depends on whether the virus is acquired at the same time as HBV (coinfection) or whether HDV infects a patient with chronic HBV infection (superinfection).

In coinfection, the fate of HDV parallels that of HBV. The clinical course is similar to that described for hepatitis B, although it is often more severe. Because patients with HDV superinfection, by definition, have not been able to mount an immunologic response sufficient to clear their HBV infection, these individuals are prone to unchecked HDV replication and fulminant hepatitis.

Hepatitis E, formerly called *enterically transmitted NANB hepatitis,* is responsible for more than 50% of acute viral hepatitis occurring in some developing countries (5). Caused by an RNA virus of the genus *Hepevirus,* this organism was originally discovered during electron microscopy of feces contaminated with enteric NANB hepatitis. More recently, isolation and sequencing of the hepatitis E viral genome has revealed four genotypes that fall into two major groups. Genotypes 1 and 2 cause epidemic hepatitis. Genotypes 3 and 4 cause a sporadic (autochthonous) form of hepatitis. These two variants have distinct clinical and epidemiologic characteristics.

The epidemic form, as its name implies, can have a fairly widespread distribution particularly in developing countries. Large outbreaks have occurred in Sudan and Iraq. It is generally of little concern in the United States, although imported cases have occurred in patients who have traveled to endemic areas such as India, Nepal, Pakistan, and parts of the former Soviet Union and Mexico. Clinically, the presentation is very similar to hepatitis A. Transmission is largely by the fecal–oral route and can result from contamination of the water supply, with human feces a frequent source of epidemic outbreaks. Secondary spread is uncommon. The clinical course is very similar to that of hepatitis A, with an incubation period of 2 to 9 weeks and an anicteric phase lasting 3 to 8 weeks. As in hepatitis A, nausea, vomiting, and diarrhea are

frequent and usually resolve with the onset of jaundice. Overall, the case fatality rate is approximately 5% but can be as high as 20% for pregnant women. No chronic hepatitis has been described for these genotypes.

While genotypically similar, autochthonous hepatitis E has a distinct clinical presentation from the more common epidemic form. Acquisition is generally attributed to food exposure, particularly undercooked pork and sausage. Autochthonous hepatitis E tends to present in an older age group. The disease is usually subclinical and mild, with icterus occurring in only 20% of cases. On the other hand, autochthonous hepatitis E is also associated with a striking spectrum of unique and serious extrahepatic complications which include acute-on-chronic liver failure, neurologic disorders, and chronic hepatitis. Patients with mild or unsuspected hepatitis from other etiologies may experience a fairly rapid appearance of ascites, encephalopathy, or overt liver failure, with secondary infection by hepatitis E. The extrahepatic manifestations may be striking and may be the predominant presentation. Neurologic symptomatology in particular, such as Guillain–Barré syndrome, Bell palsy, ataxia, confusion, or peripheral neuropathy, may be so striking as to obscure the primary diagnosis of hepatitis. Nonneurologic extrahepatic manifestations such as aplastic anemia, pancreatitis, or arthritis can present a similarly distracting clinical picture. While not common, autochthonous hepatitis E has been associated with chronic infection, predominantly in immunocompromised individuals. Liver transplantation patients, HIV-infected patients, and cancer patients receiving chemotherapy seem to be particularly susceptible. Although hepatitis E is not commonly diagnosed in the United States, exposure to the virus may be fairly common. Studies have found that up to 21% of adults in United States had anti-HEV antibodies, making it more common than hepatitis B (5.7%) or C (2%), and only slightly less common than hepatitis A (38.3%). Tests for anti-hepatitis E antibody are available commercially, but their sensitivity and specificity vary widely and at present do not have Food and Drug Administration approval. As with other forms of the viral hepatitis, treatment options are generally limited to supportive

care. Limited reports describing the use of ribavirin and peginterferon suggest a potential for viral clearance and a sustained response with treatment of chronic hepatitis E. This combination therapy has also been used in the treatment of severe, acute hepatitis E, although neither agent has been approved for this use. Hepatitis E infection is potentially preventable by vaccination, though at present this is more applicable to endemic areas. The most effective form of prevention at this time is for travelers to endemic areas to use strict enteric precautions, avoid exposure to raw shellfish, and ensure that pork has been cooked at 260˚F for at least 20 minutes.

Non-A through E hepatitis refers to the small population of patients with clinical hepatitis in whom all serologic studies on both the donor and the recipient patients are negative. With the discovery of new viruses and the development of new serologic tests, these patients will undoubtedly be further differentiated. One of these, independently discovered and named hepatitis G virus and hepatitis Gallbladder virus C, is an RNA virus of the Flaviviridae family (2). It appears to be blood-borne and has been found in as many as 10% of patients with non-A through E hepatitis. Its role has been questioned, and its definition as a true hepatotropic cause of acute or chronic hepatitis is yet to be determined (6). Similarly, hepatitis F virus has been isolated from the stool of a patient with hepatitis and transmitted to primates. As with hepatitis G, the role of this virus as a significant cause of non-A through E hepatitis is unclear.

Infectious, Nonviral Hepatitis

Although uncommon, hepatitis can accompany a wide variety of bacterial, rickettsial, and protozoal diseases. Included in this list are legionellosis, salmonellosis, tularemia, leptospirosis, brucellosis, plague, syphilis, gram-negative sepsis, gram-positive toxic shock syndromes, Q fever, mycoplasmal disease, tuberculosis, toxoplasmosis, ehrlichiosis, and malaria (see Table 104.1).

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic inflammatory liver disorder of uncertain etiology. A standardized definition and diagnostic criteria have been developed (8). The diagnosis relies heavily on the exclusion of viral etiologies, lack of exposure to alcohol and other hepatotoxic agents, and hypergammaglobulinemia with gamma globulin levels >1.5 times the upper limits of normal. A scoring system for the quantitative diagnosis of autoimmune hepatitis has been proposed by the International Autoimmune Hepatitis Group. With a sensitivity of 97% to 100% and a specificity of 66% to 92%, it has utility in clinical practice especially for atypical or overlapping cases. Liver biopsy remains essential to the diagnosis and evaluation of disease severity in patients with autoimmune hepatitis. Compounding the diagnostic clarity of this illness is the recognition that the overlap syndrome, the simultaneous presence of autoimmune hepatitis and another liver disease, seems to occur more frequently than expected (9).

Clinically, the presentation may be extremely variable and difficult to differentiate from viral hepatitis. Two types have been described based on the presence of circulating autoantibodies. Type I (classic) autoimmune hepatitis has been associated with antinuclear and anti–smooth-muscle antibodies, and type II has been characterized by the presence of autoantibodies against liver–kidney microsome type I (anti-L K M-1). Both types are more prevalent in young females, and appropriate diagnosis is crucial, as they may be treated with prednisone and immunosuppressive therapy.

Toxic Hepatitis

Liver injury may result from direct hepatocellular toxicity or from idiosyncratic injury caused by a hypersensitivity-type reaction (10). Toxic exposures also may manifest as cholestasis, in which elevations of alkaline phosphatase and bilirubin levels predominate. Pharmacologic and chemical agents produce a diverse spectrum of hepatic insults, including both acute and chronic liver disease (Table 104.2). Drug-induced hepatic injury is the most frequent reason cited for withdrawal a drug approved by the U.S. Food and Drug

Administration (FDA) from the market, and it accounts for more than 50% of cases of acute liver failure in the United States. Although any evidence of hepatic dysfunction should prompt a diligent search for both intentional and inadvertent exposure to any of a number of chemical agents, several agents deserve specific mention because of the inherent likelihood of hepatocellular injury, because of their widespread use, or because of their particular relevance to the practice of emergency medicine.

TABLE 104.2
Drug-Induced Hepatitis

Clinical/Morphologic Presentation	Examples
Hepatitis (acute)	α-Methyldopa
	Isoniazid
	Phenytoin
	Chlorothiazide
	Nonsteroidal anti-inflammatory agents
	Statins
Cholestasis	Anabolic steroids
	Flutamide
	Oral contraceptive agents
	Erythromycin estolate
	Methimazole
	Chlorpropamide
	Chlorpromazine
Hepatic necrosis	Carbon tetrachloride
	Amanita phalloides mushrooms
	Acetaminophen
	Yellow phosphorus
Hepatitis (chronic)	α-Methyldopa
	Arsenic
	Isoniazid
	Halothane

Acetaminophen is one of the most common agents encountered in the acute setting that is responsible for striking liver enzyme elevations (see Chapter 285). Toxicity is dose-dependent, but several factors have been shown to contribute in a synergistic way to toxicity at even relatively low doses. These include concomitant alcohol ingestion, chronic phenobarbital use, or chronic exposure to moderately large doses of acetaminophen.

Hepatitis caused by *isoniazid* clinically resembles acute viral hepatitis and may occur in as many as 20% of patients taking the drug, with the risk and severity of injury increasing with the age of the patient. Clinical toxicity generally occurs in the first few months of therapy, but transaminase elevations greater than two to three times normal at any time must be considered potentially serious, because progression to fulminant hepatitis may occur.

Statins are generally well tolerated but have been associated with severe hepatocellular injury. Moreover, there is concern that concomitant use of nicotinic acid for the treatment of hypercholesterolemia may promote additional toxicity.

Although overt hepatotoxicity to *phenytoin* is unusual, use of the drug is particularly common, and prevention of serious toxicity requires an awareness of the nature and mechanisms of injury. Hepatic injury is believed to be caused by toxic metabolites; current evidence has implicated a heritable metabolic defect that may predispose to a viral hepatitis-like hypersensitivity reaction within weeks of starting therapy at usual therapeutic doses. Like the other toxic exposures, early detection and interruption of therapy can result in complete resolution and the avoidance of serious hepatic injury.

Troglitazone (Rezulin) was the first of a new class of oral agents used for the treatment of type II diabetes. The agent was originally approved by the FDA in 1997, and the recognition of significant hepatotoxicity appeared to outweigh the benefits of therapy, thereby leading to the withdrawal of *troglitazone* from the market. Two new agents of the same class have been available since 1999, *rosiglitazone (Avandia)* and *pioglitazone (Actos)*. They do not appear to have the same degree of hepatic toxicity, although liver injury

has been reported. Recognition of potential severe liver injury, monitoring of liver enzymes, and early discontinuation of therapy are important to maintain the safety of these agents (11).

Flutamide is an antiandrogen drug used in the treatment of metastatic prostate cancer. Well-documented cases of serious hepatotoxicity have been reported. Although the toxicity appeared to be reversible, several patients have died of massive hepatic necrosis, emphasizing the need for prompt consideration and diagnosis.

Hepatitis has been reported to be associated with the use of several of the *nonsteroidal anti-inflammatory drugs* (NSAIDs). Because of the frequency with which NSAIDs are used, emergency physicians should be aware of their potential for causing hepatic toxicity. *Sulindac* has received special attention because it has been well established as a cause of hepatitis, including fatal hepatic necrosis. Similarly, *bromfenac* was introduced for short-term use for the treatment of orthopedic pain. Reports of severe liver injury led to withdrawal of this agent.

In the past, the inhalational anesthetics *halothane* and *methoxyflurane* were well-known causes of fulminant hepatitis. Halothane has been superseded by newer agents, and methoxyflurane is no longer marketed in the United States.

Recently, reports have implicated *clopidogrel* as a cause of mixed hepatocellular and cholestatic liver damage. The true incidence of this complication is unknown, but *clopidogrel* is virtually universally used for patients undergoing percutaneous coronary intervention and in those with acute coronary syndromes. Additionally, treatment courses are generally protracted, thus resulting in more prolonged exposure. Routine liver enzyme testing is not currently recommended; however, given the wide use of this drug, clinical suspicion is reasonable in appropriate clinical settings.

A careful medication history should include an inventory of complementary and alternative medications. Studies have demonstrated that use of these modalities is common but volunteer reporting of their use to the physician is limited. Often referred to as simply “Chinese herbs,” specific compounds of interest include

germander, chaparral leaf, and weight loss preparations containing usnic acid.

It is worth mentioning that alcohol is probably the most common chemical to result in liver injury; this is covered in depth in Chapter 281 on Ethanol and its complications.

Metabolic Causes of Hepatitis

Although the metabolic causes of liver disease are numerous, several are notable for the potential for acute presentations. *Wilson disease* is a disorder of copper excretion. Patients generally present in adolescence when copper has had sufficient time to accumulate in excess. Liver involvement is common but, occasionally in younger patients, the illness will present as fulminant hepatitis. Prompt recognition and treatment are necessary to limit end-organ damage (13).

Acute fatty liver of pregnancy is a life-threatening condition that occurs late in pregnancy. Histologically, it is described as microvesicular fatty liver and is believed to be caused by disordered metabolism of fatty acids. Pregnant patients, usually in the 35th week or later, present with jaundice and hepatic failure frequently accompanied by disseminated vascular coagulation. The condition resolves with termination of pregnancy, although the mother must first be stabilized.

Reye's syndrome presents almost exclusively in children younger than 15 years. Though an association with salicylate use has been noted, it can occur in the absence of salicylates. It is generally seen after upper-respiratory illness, especially influenza and chickenpox, and is characterized by hepatic injury, hypoglycemia, and encephalopathy. Care is supportive, and chronic liver disease has not been reported when recovery occurs.

Another cause of elevated transaminase levels (transaminitis) that should be considered in the differential diagnosis is *hepatobiliary disease.* Elevated ALT and aspartate amino transferase (AST) levels should not lead one on a fruitless search for infection or toxic causes of hepatitis when the chemistry patterns suggest hepatobiliary

obstruction (i.e., elevated serum bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase levels [GGTP]).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for the patient with right upper quadrant abdominal pain is extensive and includes hepatitis, biliary colic, cholecystitis, peptic ulcer disease, pyelonephritis, renal colic, cardiac ischemia, and right lower lobe pneumonia. The differential diagnosis for jaundice includes many other possibilities, and is discussed further in Chapter 101. Once the differential has been narrowed to hepatitis, the next task is to determine the specific etiologic agent, whether infectious, toxic, metabolic, or autoimmune. Eliciting a history of risk factors, medications, exposures, and clinical course as described previously, combined with laboratory testing, will help in determining the specific cause.

ED EVALUATION

Evaluation of suspected hepatitis may be divided into several steps. The first step is to make the diagnosis, which, in light of the previous discussion, may not be entirely straightforward. Clearly, a reasonable index of suspicion is necessary in most cases, and the physician must consider the relative likelihood of illness in each patient compared with the risk of excessive testing in the many patients with nonspecific symptomatology.

If the likelihood of hepatitis is present but low, a reasonable approach initially is to order a serum AST level as a preliminary screen. Although nonspecific, this is a sensitive screen, and a normal AST value virtually excludes hepatocellular disease.

In patients in whom hepatic disease is believed to be more likely or who has an abnormal AST level on the preliminary screen, more extensive laboratory testing is necessary. This should consist of indices of necrosis (AST and ALT) as well as indices of cholestasis (alkaline phosphatase, total bilirubin, or GGTP). Although these values lack diagnostic specificity, certain patterns may be helpful in limiting the differential diagnosis and in directing further

evaluation. For instance, a transaminase elevation >10 times normal strongly suggests acute viral or toxic injury and essentially excludes chronic hepatitis. Elevation of alkaline phosphatase and bilirubin values suggests intrahepatic or extrahepatic obstruction. Transaminase elevations of two to three times normal, with the AST higher than the ALT, suggest alcoholic injury.

In the second step of the evaluation, specific tests of hepatic synthetic function are necessary. Serum protein, albumin, and glucose levels should be used in conjunction with the serum bilirubin level to assess the extent of hepatocellular dysfunction. If there is indication of central nervous system involvement, with lethargy or confusion, a serum ammonia level may serve as a useful baseline for serial evaluations.

Further evaluation should focus on defining the specific cause of the illness. If hepatocellular necrosis is the dominant picture, detailed serologic studies (anti-HAV IgM, HBsAg, anti-HBs, anti-HBc, anti-HCV by enzyme immunoassay (EIA), HCV-RNA and Monospot test) are warranted, as well as a diligent historical search for foreign travel to HEV-endemic regions and for drug or toxic exposures. If cholestasis is the dominant picture, ultrasound examination should be performed to exclude mechanical obstruction.

KEY TESTING

- Consider the diagnosis of hepatitis and the risk profile. If risk is low, consider screening with an AST. If high, test more extensively for hepatic necrosis and obstructive etiologies.
- If hepatitis is confirmed, stage the severity of disease and seek evidence of clinically significant hepatic dysfunction: serum protein, albumin, glucose, and bilirubin, and ammonia levels if altered mental status is noted.
- Begin a search for a definitive diagnosis. Send acute hepatitis serologies and consider drug exposures (especially acetaminophen and alcohol) and travel history.

ED MANAGEMENT

Patients with acute viral hepatitis may present to the emergency department because of signs and symptoms typical of a viral syndrome that may include prostration, nausea, vomiting, and dehydration. Treatment for these patients is symptomatic and is usually limited to intravenous fluids, acetaminophen, and antiemetics. Metoclopramide (Reglan) or ondansetron (Zofran) are the antiemetic agents of choice, because phenothiazines can impair hepatic excretory function and may produce cholestasis. Patients who present without symptoms or present because they have noticed jaundice require no specific therapy.

For patients with diagnosed viral hepatitis, there is no specific therapy indicated beyond supportive care and symptomatic treatment. If the prothrombin time is prolonged, the patient should receive vitamin K. Immune globulin is of no use for the patient who has already contracted hepatitis. Corticosteroids are probably harmful rather than beneficial.

Patients who present because they have been exposed, or think they have been exposed, to hepatitis present a different management problem (see Chapter 194). Immunoprophylaxis is highly effective if given under the proper circumstances. Because this treatment should be guided in part by serologic studies, it is often not initiated in the emergency department.

If results of serologic testing are not available in a timely fashion, therapy must be empiric. The discussion that follows and Table 104.3 should help guide immunoprophylactic therapy.

TABLE 104.3
Immunoprophylaxis of Viral Hepatitis

Type	Persons at Risk	Immunoprophylaxis
A	Household and sexual contacts[a] Staff and attendees of daycare centers Staff and residents of custodial institutions	Immune globulin, 0.02 mL/kg IM
B	Sexual contacts	Hepatitis B immune globulin, 0.06 mg/kg IM
	Percutaneous or transmucosal exposure	Begin active immunization (Heptavax or Recombivax)
C	Intravenous drug abusers, intranasal cocaine abusers, homosexuals, multiple sexual partners, perinatal exposure, household contacts	None
D	Same as B	Protection against hepatitis B
E	Travelers to endemic areas	None in serum pooled from US donors
Non-A through E	Percutaneous exposure to blood or certain products of patients with no serologic evidence or HAV, HBV, or HCV	None

HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus.
[a]Residents of dormitories and barracks are frequently included in this group.

Patients considered at risk for contracting hepatitis A include household and sexual contacts of persons with hepatitis A, staff and attendees at daycare centers, and staff and residents in close contact at custodial care institutions. Immune globulin, which is derived from pooled human serum but treated so as not to be capable of transmitting HIV infection or other diseases, is given as a single intramuscular dose of 0.02 mL/kg as soon as possible within the first 2 weeks after exposure. Casual contacts need not be treated.

Postexposure prophylaxis for hepatitis B is indicated for sexual contacts of persons with hepatitis B or after percutaneous or transmucosal exposure to HBsAg-positive blood. For nonimmunized patients, treatment is with hepatitis B immune globulin, 0.06 mL/kg intramuscularly. Active immunization should be started at the same time. If information about the source patient is unknown but can be

obtained within 5 to 7 days, it is reasonable to wait. If not, one must make a decision based on risk factors such as sexual contacts and intravenous drug use. See Chapter 191 for more information on postexposure prophylaxis.

Immunoprophylaxis has not proven useful in patients who have been exposed to hepatitis C or in those suspected of being exposed to non-A through E hepatitis.

CRITICAL INTERVENTIONS

- Hospitalize patients with evidence of fulminant hepatitis (e.g., significantly impaired synthetic function, encephalopathy).

DISPOSITION

Most patients with hepatitis do not require hospital admission, but it is recommended in circumstances such as intractable nausea and vomiting, dehydration, or severe electrolyte imbalance or for signs of hepatic deterioration, as evidenced by changes in sensorium or increased international normalized ratio. Patients with signs or symptoms suggesting a fulminant course of hepatic failure require admission. The absolute levels of serum transaminase values should not be a criterion for admission.

Patients with acute viral hepatitis who are discharged should be prescribed antiemetic agents and instructed to ensure adequate caloric intake. It is best to allow patients to eat small meals of their choice rather than insist they follow some of the high-calorie or high-protein dietary regimens that have been proposed. Prolonged bed rest, once a staple of care, has been shown to be of no value and has its own risks (6). Alcohol consumption should be avoided during the acute illness. After recovery, alcohol consumption has not been shown to be any more harmful for these patients than for the general population (4). Estrogen-based oral contraceptives may be continued during hepatitis.

Patients with acute hepatitis should be seen by an internist or gastroenterologist for follow-up within a few days, after the results of serologic tests. Patients with any prolongation of the prothrombin

time are often admitted to the hospital, but others should probably be seen the next day. Instructions should include an admonition to return if food and fluids cannot be kept down or if there is any change in sensorium.

Finally, it is the duty of the emergency physician in many locales to notify public health authorities of cases of acute hepatitis. Patients and their close contacts should be counseled with regard to preventing the spread of hepatitis.

Common Pitfalls

- Missed toxic ingestion or exposure, with continued exposure.
- Failure to recognize hepatitis B or hepatitis C by performing serologic tests during "window periods" between infection and seroconversion.
- Missed hepatobiliary disease, with failure to diagnose surgically correctable lesions.
- Failure to recognize the distinction between liver tests and liver function (e.g., patients with cirrhosis may have nearly normal enzyme levels; patients with "sky high" transaminase levels may have reasonably intact synthetic capability).
- Inappropriate admission of patients with uncomplicated hepatitis and markedly elevated ALT or AST levels without consideration of synthetic factors or clinical status.
- Inappropriate discharge of patients with early evidence of synthetic failure.
- Failure to follow-up contacts for recommended prophylaxis.
- Inappropriate restrictions: Patients with hepatitis need not be excluded from school or work; education regarding precautions is indicated.
- Failure to consider the effects of hepatitis on drugs with hepatic clearance, resulting in high serum levels or long duration of action.

CHAPTER 105 Hepatic Failure and Cirrhosis

Stacie Zelman

Acute hepatic failure (AHF) differs clinically, therapeutically, and prognostically from hepatic cirrhosis, but priorities for the management of both entities have similar features. AHF is relatively rare with approximately 2,000 cases per year in the United States but is associated with a high mortality rate (1). The majority of cases are due to acetaminophen overdose and drug reactions, followed by viral illness (2). Hepatic cirrhosis is a more common condition in the United States and also has a high mortality rate accounting for approximately 25,000 deaths in 2000 (3). Cirrhosis is most commonly caused by alcoholism or hepatitis C. The presence of ascites in combination with cirrhosis has an association with poor long-term survival (3).

CLINICAL PRESENTATION

The presentation of AHF is, to some degree, dependent on the specific etiologic agent, but the basic definition is altered mental status (encephalopathy) with coagulopathy (INR >1.5) in a patient without previously known liver pathology (1,4). Other symptoms that may be present are jaundice, motor dysfunction, and fetor hepaticus (a sweetish, musty, or pungent odor on the breath). In severe cases, a patient may present with signs indistinguishable from septic shock including tachycardia, hypotension, and multiorgan failure (5).

The manifestations of hepatic encephalopathy in both AHF and cirrhosis are similar, but the onset is generally slower with cirrhosis. Encephalopathy may present anywhere on a continuum of mild confusion to frank coma. Encephalopathic patients with cirrhosis commonly present with euphoria, depression, or muscular incoordination or may demonstrate more obvious mental status changes. Symptoms such as malaise, lethargy, fluid retention, loss of libido, and pruritus are common, and typical physical findings include hepatomegaly, spider angioma, ascites, and jaundice (Fig. 105.1). Asterixis, a flapping tremor best seen with the patient's arms outstretched and wrists hyperextended, is a classic symptom that is absent in many cases. The factors most commonly precipitating hepatic encephalopathy in patients with cirrhosis are infection, gastrointestinal bleeding, use of tranquilizing drugs or alcohol, and overuse of diuretics.

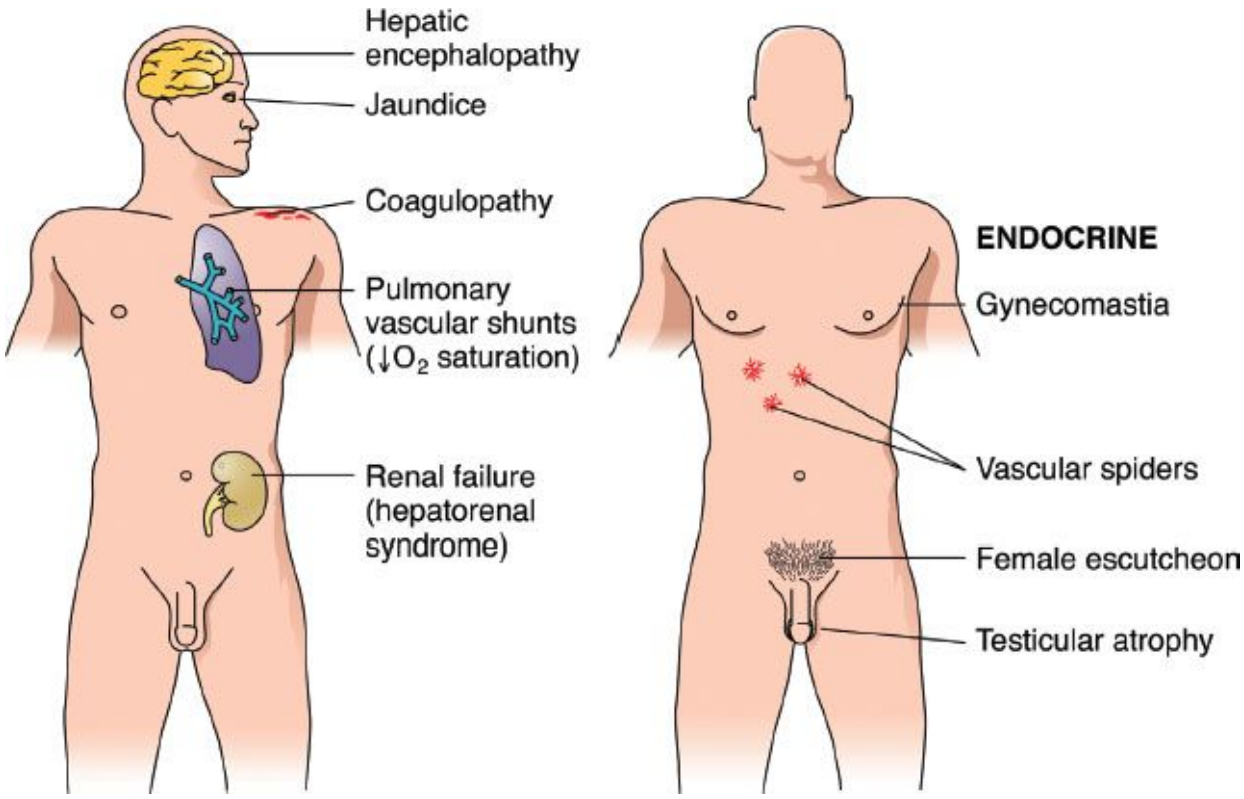

FIGURE 105.1 Complications of hepatic failure. (Image from Rubin E, Farber JL. *Pathology.* 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Most patients with hepatic disease are, at baseline, immunocompromised. Thus, any infection, such as spontaneous bacterial peritonitis (SBP), pneumonia, urinary tract infection, and systemic inflammatory response syndrome (SIRS), are serious complications. Infection is a prominent precipitant of acute chronic liver failure and can advance to multisystem organ failure (6,17). Febrile patients with cirrhosis, ascites, and abdominal pain should be considered to have SBP until proven otherwise, as SBP complicates up to 33% of these patients (7,8). Patients admitted with SBP and septic shock have a mortality rate greater than 70% (9). While typical signs of infection may not always be apparent in this population, rapid treatment at first suspicion should be a priority.

Because of portal hypertension and secondary esophageal varices, death from gastrointestinal bleeding is more common with cirrhosis than with AHF. In the later stages of cirrhosis, ascites may become markedly symptomatic with abdominal pain and shortness of breath (3). The hepatorenal syndrome, or functional renal failure, occurs in advanced cirrhosis and is commonly fatal.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cirrhosis and AHF varies, depending on presenting symptoms and precipitating causes. The differential diagnosis of cirrhosis presenting with jaundice includes hemolysis, biliary tract obstruction, viral hepatitis, hepatotoxic ingestions, septicemia, and numerous minor causes. The association of mental status changes with jaundice should alert the emergency physician to the possibility of hepatic encephalopathy. In the patient without known chronic liver disease, the differential diagnosis of hepatic encephalopathy includes viral hepatitis, fatty degeneration of pregnancy, Reye syndrome, and hepatotoxic ingestions such as acetaminophen, isoniazid, rifampin, *Amanita phalloides* mushrooms, carbon tetrachloride, or ecstasy. Historical information, such as preillness activity, previous suicidal behavior, and the presence of fever or malaise, may help to differentiate among potential causes.

Patients with hepatic cirrhosis may have chronic jaundice and may sustain acute mental status changes for reasons other than hepatic

encephalopathy. Because alcoholic patients are at greater risk for bleeding after a traumatic event, subdural hematoma or other form of ICH must be considered in cirrhotic patients with altered sensorium. Patients with renal failure also may present with features suggestive of severe liver disease—altered sensorium, fluid retention, and coagulopathy. Alcoholics may develop pancreatitis or alcoholic hepatitis, with severe dehydration and associated mental status changes that may mimic hepatic encephalopathy.

ED EVALUATION

Current and past medical information should be sought from the patient, prehospital personnel, family, previous medical records, and the patient's private physician to differentiate acute from chronic abnormalities. ABCs need to be addressed before secondary evaluation may begin.

Key points of the physical examination include the following:

- Examination of the conjunctiva and skin for the presence of jaundice (Fig. 105.2)

FIGURE 105.2 Jaundice. A patient in hepatic failure displays a yellow sclera. (Image from Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

- Abdominal examination for the presence of ascites and liver size
- Rectal examination for evidence of gastrointestinal bleeding
- Careful neurologic examination with attention to subtle changes in mental status. Asterixis, alterations in motor tone, or abnormal posturing should be noted.

Appropriate laboratory testing includes blood counts and electrolytes, as well as serum ammonia, coagulation studies (PT/INR), and in some cases toxicologic studies or acetaminophen level. It is important to keep in mind that encephalopathy may precede an elevated ammonia level. Chest radiography may be indicated if pulmonary edema or pleural effusion is suspected. Abdominal imaging with CT or ultrasound may be useful in the evaluation of abdominal pain, excluding biliary tract disease, or localizing ascites. If SBP is suspected or ascites is excessive, paracentesis is indicated, with subsequent laboratory evaluation for cell counts, Gram stain, and culture. The diagnosis of SPB is determined on the basis of positive culture or ascitic fluid with a absolute neutrophil count >250 cells/mL (3).

KEY TESTING

- **Lab Studies:** complete blood count (CBC), electrolytes, ammonia, INR, and acetaminophen level
- **Imaging:** chest x-ray (CXR), abdominal ultrasound, and CT of abdomen/pelvis
- **Paracentesis**

ED MANAGEMENT

The treatment of hepatic encephalopathy in patients with AHF requires a more aggressive approach than in those with an exacerbation of chronic liver disease. Hepatic encephalopathy in AHF develops rapidly and is almost always complicated by cerebral edema, with possible central herniation of the brain (5).

Immediate attention should be given to securing a patent airway and initiating artificial ventilation if the patient is comatose or lacks an active gag reflex. Supplemental oxygen should be given, even in

the absence of pulmonary edema. Fluid resuscitation should be aggressive in hypotensive or bleeding patients and should be undertaken despite the possibility of pulmonary edema (5,10). Persistent hypotension signals the need for vasopressors with the preferred drug of choice being norepinephrine (10).

Patients should be placed on a cardiac monitor and quickly assessed for dysrhythmias. Blood glucose should be monitored closely, as impaired glucogenesis and reduced glycogen stores predispose these patients to hypoglycemia (11). Patients who demonstrate clinical signs of significant, increased intracranial pressure, such as abnormal posturing or unreactive pupils, should receive mannitol 0.5 g/kg intravenously over 10 minutes (after head CT) (12). Fresh-frozen plasma (2 to 4 U) should be given when the prothrombin time is >1.5 times normal and there is evidence of active bleeding (12). Platelet infusions (5 to 10 U) are recommended when thrombocytopenia is severe ($<10{,}000$ or $<50{,}000$ in the presence of active bleeding) (12). Severe variceal bleeding when present should be treated with blood, antibiotics (a quinolone or third-generation cephalosporin), endoscopy within 12 hours, and vasoactive therapy (such as octreotide 25 to 50 μg/hr) (13).

Proven or suspected infection should be treated promptly. Cultures may be used to modify therapy, but if SIRS or septic shock is evident, empiric antibiotics should be started immediately. Responsible organisms are both gram-positive and gram-negative, but gram-negative organisms may have an increased association with worsening encephalopathy (14). Empiric broad-spectrum coverage such as piperacillin–tazobactam (3.375 g intravenously) or cefotaxime (1 to 2 g intravenously) is recommended. Care should be taken not to use nephrotoxic or hepatotoxic antibiotics unless there is a favorable risk/benefit ratio. In addition, aspiration pneumonia should be considered in these patients, and if suspected, it should be treated with pulmonary toilet, ventilatory support, and broad-spectrum antibiotics. Prophylactic antibiotics in AHF are controversial.

Lactulose may decrease the severity of hepatic encephalopathy in cirrhosis, but its benefits in AHF are unproven (5). *N*-acetylcysteine

improves survival from acetaminophen overdose, even late in its course (12).

Decisions concerning potential transplantation for AHF should be made early by a gastroenterologist (12,15). In many cases of severe AHF, transplantation is the only means of increasing the chance of survival (15). Survival after transplantation is nearly 70% (15). Artificial liver support is helpful for acute-on-chronic liver failure (16), but in general is not recommended outside clinical trials (12).

For the management of symptomatic recurrent ascites in cirrhotic patients, large-volume paracentesis is recommended as having fewer side effects than diuretics and a comparable rate of fluid reaccumulation (3,16). Hypovolemia may occur 3 to 6 hours later when volumes of >5 L are removed. Administration of albumin, 8 g/L of ascites removed, is recommended in some cases. Other plasma volume expanders are available, but albumin is thought to have greater circulatory protection (7). Ultrasound-guided paracentesis may lower needle-related intra-abdominal complications.

When patients with hepatic cirrhosis present to the emergency department with nonlife-threatening conditions, care must be taken to avoid interventions (e.g., medications) that may cause clinical deterioration. Sedatives may trigger clinical hepatic encephalopathy. Nonsteroidal anti-inflammatory drugs may induce renal failure in cirrhotic patients and should be used with caution and at appropriate doses.

CRITICAL INTERVENTIONS

- Airway control for obtunded liver failure patients
- Fluid resuscitation and pressor support as indicated for patients in shock
- Fresh-frozen plasma and platelets in patients with bleeding or undergoing invasive procedures
- Appropriate cultures and intravenous antibiotics for suspected or proven infection
- Oral or rectal lactulose for patients with cirrhosis and hepatic encephalopathy

DISPOSITION

Patients with gastrointestinal bleeding, SBP, and hepatic encephalopathy should be admitted to the hospital. Those with severe presentations often require an intensive care setting, and immediate consultation with a gastroenterologist is indicated. For severe cases, consideration should be given to transporting the patient to a facility capable of critical care and liver transplantation (15).

Because patients with chronic liver disease commonly respond poorly to illness or other stresses, indications for admission to the hospital are generally less stringent than for other patients. Thus admission for intravenous antibiotic treatment should be considered for most infections.

Common Pitfalls

- Failure to consider a hepatotoxic drug as the cause of the patient's symptoms. Patients who have ingested a hepatotoxic drug may be unwilling to give an adequate history and may present early in the course of their illness, before there is obvious clinical evidence of hepatic failure.
- Ruling out the diagnosis of hepatic encephalopathy on the basis of a normal serum ammonia level.
- Failure to adequately treat hypoglycemia. One bolus of 50% dextrose may not be adequate therapy because of depleted glycogen stores; in this case, maintenance infusions of D_{10} or D_{20} should be administered.
- Failure to identify causes of coma other than hepatic encephalopathy in patients with cirrhosis. In particular, subdural hematoma/Intracerebral hemorrhage, drug overdose, and meningitis/encephalitis should be ruled out.

CHAPTER 106 The Liver Transplant Patient

Douglas W. Lowery-North and Scott R. Votey

Since the first human orthotopic liver transplant (OLT) in 1963, more than 120,000 transplants have been performed in the United States. Three-year survival rates for both patients and grafts of nearly 70% to 80% are the result of utilization of multidisciplinary care teams, increased availability of organs, improved organ allocation systems, newer operative techniques, safer immunosuppressive regimens, and improved management of postoperative complications (1–3). More than 120 US centers perform approximately 6000 OLT operations each year. As of 2011, more than 62,000 liver transplant recipients were living in the United States, and the number of OLT recipients presenting to the emergency department (ED) continues to rise. To provide effective care, ED physicians must be aware of the particular OLT-related problems these patients may experience.

TRANSPLANT SURGERY

Surgical innovations have resulted in several transplant technique variants. A whole cadaveric liver can be transplanted, or the organ can be surgically split to provide two transplantable segments, or reduced for transplant into a single smaller recipient. Alternately, a portion of the liver, usually the right lobe, can be transplanted from an adult living donor into a child or an adult (2,4–6). Regardless of the technique used, the liver is transplanted without a gallbladder.

Transplantation of the donor organ into the recipient has three major phases. First, the recipient undergoes hepatectomy. Typically, a bilateral subcostal incision is made, which is extended cephalad in the midline. The recipient may be placed on femoral to axillary venovenous bypass, and the recipient portal vein and inferior vena cava (IVC) are clamped. After vascular clamping, hepatectomy is performed. In the second phase the donor graft is inserted, and the vascular anastomoses are performed, beginning with the suprahepatic and infrahepatic IVC, followed by the portal vein, and finally the hepatic artery. Vascular clamps are released, and reperfusion of the graft occurs. In the third phase, the biliary anastomosis is performed. Most adult recipients have an end-to-end re-anastomosis (choledochocholedochostomy) with or without T-tube placement. T-tube placement affords direct monitoring of bile production as well as access for evaluation of the biliary system by T-tube cholangiography. Despite these advantages, T-tube use has declined owing to a high rate of postoperative complications (7,8). Alternately, a Roux-en-Y loop with a choledochojejunostomy can be performed. This technique is used in patients having intrinsic biliary system disease, such as biliary atresia or primary sclerosing cholangitis, or who are undergoing repeat transplantation. Pneumobilia is a normal result of choledochojejunostomy.

Typical Posttransplant Course

After surgery, OLT recipients spend several days in an intensive care unit (ICU), during which time their liver function indices are closely monitored. Recipients continue on an aggressive immunosuppressive regimen, begun intraoperatively, designed to minimize immune-mediated graft rejection. Immunosuppressive regimens continue to evolve and vary between institutions, but currently the most common initial “tolerance-friendly” regimen consists of three drugs: tacrolimus (TAC), mycophenolate (MMF/MPA), and prednisone (9,10). Alternate regimens include two drug regimens consisting of TAC combined with MMF/MPA, and TAC combined with prednisone.

Early postoperative complications of transplantation include bleeding and primary nonfunction (PNF) of the graft. Systemic coagulopathy, thrombocytopenia, and portal hypertension-induced abdominal venous collaterals render OLT candidates susceptible to bleeding complications. Postoperative bleeding is usually the result of dehiscence of a vascular anastomosis, and patients present with intraperitoneal hemorrhage before discharge from the hospital (11). Emergency physicians are much more likely to encounter OLT patients with upper gastrointestinal tract bleeding from peptic ulcer disease. Upper and lower gastrointestinal tract bleeding in OLT patients is managed in the standard fashion.

PNF occurs in 4% to 10% of adult OLT recipients. The pathophysiology is multifactorial. Graft harvest technique, ischemia time, reperfusion injury, and graft size all influence graft viability (4). Early bile production, restoration of normal clotting function, and the absence of lactic acidosis are signs of good graft function. Profound hypoglycemia, progressive coagulopathy, metabolic acidosis, progressive encephalopathy, and hemodynamic instability clinically characterize graft failure. The only therapy for PNF is prompt retransplantation.

In the absence of complications, OLT recipients are transferred from the to a surgical ward for additional days. Close outpatient care at the transplant center continues for an additional 1 to 2 months, during which time patients undergo careful adjustments of their immunosuppressive regimens. Recipients are then followed up on a monthly basis for the remainder of the first year after transplantation. The progressive withdrawal of corticosteroids now begins during the first 3 months but may be delayed. The follow-up interval after 1 year is decided on a case-by-case basis.

CLINICAL PRESENTATION

OLT patients present to the ED with a wide variety of illnesses. Emergency physicians encounter vascular and biliary anastomotic complications, rejection, infections, and medication-related adverse effects in these patients.

Vascular Complications

Typically, there are one arterial and several venous anastomoses performed at the time of transplantation. However, up to 25% of transplant recipients have normal anatomic variants of their arterial circulation that require additional anastomoses (12). Each anastomosis is vulnerable to leakage, thrombosis, stenosis, and pseudoaneurysm. The most common vascular complications after liver transplantation are hepatic artery thrombosis (HAT), hepatic vein thrombosis (HVT), and portal vein thrombosis (PVT) (11,13). Together they account for about 10% of graft failure in adults and 40% of graft failure in children. The mortality of HAT ranges from 15% to 55% in adults, with death being more common if thrombosis occurs soon after transplantation. Fortunately, the incidence of HAT has been declining owing to improved surgical technique, from rates as high as 26% in the 1980s to $<10\%$ currently. Nevertheless, HAT continues to account for the majority of post-OLT vascular complications. The vascular supply to the donor common bile duct endothelium is entirely dependent on the newly reconstructed hepatic artery. The graft, in contrast to the native liver, has no collateral arterial blood supply, and any disruption to hepatic artery blood flow rapidly leads to bile duct necrosis, with resultant bile duct leaks, graft dysfunction, abscess formation, and sepsis. Although HAT tends to occur within the first month and most often within the first week after transplantation, it may occur months or even years later. The clinical presentation of HAT varies. Patients typically have fever and jaundice and may have right upper quadrant abdominal pain. Some present acutely ill with peritonitis or sepsis. Laboratory evidence of graft dysfunction (elevated transaminases and bilirubin levels) is present. Rapid deterioration of graft function is common, and patients often require retransplantation. Patients with HVT and PVT have similar presentations but are often less acutely ill and typically have better outcomes.

Biliary Complications

With an incidence of 17% to 28%, biliary complications—bile leaks and obstructions to bile flow from strictures, stones, or ampullary dysfunction—are the most common anastomotic complications of OLT (8,14–16). Biliary complications are typically the result of technical complications or ischemic injury to the bile ducts. Biliary leaks and strictures occur with both choledochocholedochostomy and Roux-en-Y choledochojejunostomy anastomoses. T-tubes are also associated with biliary leaks. Although biliary leaks tend to occur in the first month postoperatively and biliary obstructions are usually a later complication, the presentations are similar. Patients typically complain of abdominal pain, jaundice, or fever. In some cases evidence of cholangitis or peritonitis may be present. Unfortunately, some patients with biliary complications present with isolated fever, rigors, or elevated liver enzymes without jaundice or abdominal pain. The abdomen may even be soft and nontender. Emergency physicians should strongly consider the possibility of a biliary complication whenever faced with an OLT patient presenting with any combination of abdominal complaints, fever, or evidence of graft dysfunction.

Rejection

Immune-mediated disease in OLT recipients includes hyperacute, acute, and chronic forms of rejection, as well as graft-versus-host disease. Acute and chronic rejections are most clinically relevant to emergency physicians. The liver is relatively resistant to hyperacute rejection, and graft-versus-host disease is uncommon in liver transplantation (17). Acute and chronic rejections are classified on the basis of time of occurrence and histology. Between 60% and 80% of OLT patients in some published series have at least one episode of acute rejection (18). With current immunosuppressive regimens, the incidence of chronic allograft rejection has declined to approximately 5% of OLT recipients. Owing to the development of tolerance after liver transplantation, it is possible for some OLT recipients to be successfully weaned from immunosuppressive drug therapy (19–21).

Acute rejection commonly manifests as malaise, generalized weakness, progressive jaundice, right upper quadrant pain, and often fever. Alternately, acute rejection may be clinically asymptomatic, with elevation of liver enzymes as the only clue to the diagnosis. A pattern of early alkaline phosphatase and bilirubin elevation, followed shortly by a rise in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels, is typical of acute rejection. Although suggestive, this pattern is not specific for acute rejection and may occur with cholestasis, cholangitis, drug toxicity, and other states of hepatic dysfunction. Acute rejection occurs most commonly in the first 3 months after transplant and generally has a good prognosis (18). Most episodes respond to increased immunosuppression, commonly a corticosteroid pulse. Patients who are infected with hepatitis C may not be treated for mild episodes of acute rejection as treatment appears to worsen outcomes (22). Steroid-resistant episodes are often treated with antilymphocyte antibody preparations. Late acute rejection is more commonly associated with noncompliance, may be less responsive to steroids, and carries a higher risk of progression to chronic rejection.

The clinical presentation of chronic rejection is similar to that of acute rejection. Patients may report low-grade fever, fatigue, progressive jaundice, right upper quadrant pain, clay-colored stools, and dark urine. Patients with chronic rejection usually experience a more gradual clinical deterioration compared with patients suffering from acute rejection. Laboratory findings of chronic rejection are persistently elevated transaminase levels, increasing cholestasis, and declining hepatic synthetic function. Chronic rejection is resistant to therapy and often results in eventual graft loss.

Infection

Infection continues to be a major source of morbidity and mortality in OLT patients (23–25). Sepsis is the most common cause of death in the first year after transplantation, and up to 67% of recipients have at least one serious infection after OLT. Approximately 50% to 60% of these infections are bacterial, 15% are fungal, 5% to 15%

are viral, and <10% are caused by other organisms, such as *Pneumocystis jiroveci* or *Toxoplasma* species. Most infections occur during times of peak immunosuppression. Specifically, the risk of serious acute infection is greatest during the first month after transplantation but remains high throughout the first 6 to 12 months.

Infections occur during three distinct periods. In the month immediately after transplantation, patients are susceptible to the typical nosocomial pathogens. During the second through sixth month, the patients are susceptible to a variety of opportunistic infections, and after 6 months, the patients are susceptible to the typical community-acquired pathogens, although opportunistic infections may still occur if the patient has chronic viral infections or requires persistently elevated levels of immunosuppression. OLT recipients maintained on high levels of immunosuppressive medications after acute rejection episodes, recipients with indwelling central lines, and recipients with biliary complications (e.g., biliary strictures) also remain at high risk for serious acute infections irrespective of the duration of posttransplantation. Emergency physicians should bear in mind that OLT recipients are immunocompromised. They may present to the ED appearing well and complaining only of isolated fever, only to deteriorate rapidly during their subsequent hospital course.

Medication-Related Adverse Effects

The immunosuppressive regimens that make graft survival possible are a frequent source of adverse effects. In addition to promoting infection and malignancy, immunosuppressive medications may result in metabolic, renal, neurologic, hematologic, dermatologic, and bone disorders. Each agent has a characteristic pattern of adverse effects (Table 106.1), many of which are clinically important and may result in ED visits (18). Drug–drug interactions may precipitate these events, and the potential for adverse drug interactions should always be considered (Table 106.2).

TABLE 106.1
Immunosuppressive Medications and Associated Adverse Effects

Drug	Indications	Adverse Effects
Corticosteroids	Adjuvant prophylaxis for rejection Primary therapy for acute rejection	Hypertension, increased appetite, Cushing syndrome, acne, gastritis, hyperglycemia, delayed wound healing, osteoporosis
Cyclosporine (Gengraf, Neoral, Sandimmune)	Primary prophylaxis for rejection	Hypertension, infection, hyperglycemia, chronic renal failure, hirsutism, gingival hyperplasia, PTLD
Mycophenolate Mofetil (Cellcept)	Adjuvant prophylaxis for rejection Adjuvant therapy for acute and chronic rejection	Intestinal hypermotility, vomiting, cramping, diarrhea, infection, anemia, leukopenia, PTLD
Sirolimus (Rapamune)	Primary prophylaxis for rejection Primary therapy for chronic rejection	Hypercholesterolemia, infection, edema, PTLD
Tacrolimus (Prograf)	Primary prophylaxis for rejection Primary therapy for chronic rejection	Hypertension, headache, infection, hyperglycemia, tremor, chronic renal failure, PTLD

PTLD, posttransplant lymphoproliferative disorder.

TABLE 106.2
Significant Drug Interactions

Some substances that *lower* tacrolimus, cyclosporine, and sirolimus levels

Carbamazepine
Nafcillin
Phenobarbital
Phenytoin
Rifampin
Valproic acid
Garlic
St. John's wort

Some substances that *elevate* tacrolimus, cyclosporine, and sirolimus levels

Amiodarone
Bromocriptine
Cimetidine
Diltiazem, nicardipine, nifedipine, verapamil
Efavirenz
Erythromycin, clarithromycin
Fluconazole, itraconazole, ketoconazole
Imipenem
Metoclopramide
Methylprednisolone
Grapefruit juice

Avoid nonsteroidal anti-inflammatory drugs, as they may further compromise renal function in patients taking either tacrolimus or cyclosporine.

Oral contraceptives are contraindicated, due to the increased risk of a thrombotic event (e.g., hepatic artery thrombosis).

No live virus vaccinations should be administered to OLT recipients or any of their close household contacts.

Corticosteroids that OLT patients receive result in all of the typical complications of chronic steroid excess, including adrenal suppression, hypertension, insulin resistance, Cushing syndrome, delayed wound healing, and osteoporosis. Osteoporosis-related fractures, especially vertebral body compression fractures, are a common problem in OLT patients because of pre-existing hepatic osteodystrophies coupled with the osteopenic effects of corticosteroids and other immunosuppressives.

Dose-dependent TAC or cyclosporine nephrotoxicity is common (26). The initial presentation may be occult, with a rise in creatinine occurring with minimal, nonspecific symptoms. Corticosteroids, TAC, and cyclosporine all induce insulin resistance, and OLT recipients may develop diabetes mellitus with hyperglycemic symptoms (27). Additionally, the immunosuppressive regimens OLT patients require have been associated with a variety of neurologic (tremors, headaches, altered mental status, and seizures) and gastrointestinal symptoms (nausea, vomiting, and diarrhea) (28,29).

Late Complications

Late complications are defined as those that occur more than 1 year after transplantation. The most common causes of late deaths are chronic rejection and malignancies (2). Late complications can be categorized as related to the allograft itself or extrahepatic. The differential diagnosis of late graft dysfunction is broad. Noncompliance is an unfortunately common cause of chronic rejection. Biliary strictures may occur. Reactivation of hepatitis B and C, for which transplantation may have been performed, may occur and lead to graft failure. Although reactivation of hepatitis C remains common, advances in the use of antiviral agents have reduced the recurrence of hepatitis B to low levels. Autoimmune hepatitis, primary sclerosing cholangitis, and primary biliary cirrhosis may all recur in OLT recipients though autoimmune hepatitis is also increasingly being diagnosed in recipients without a history of autoimmune disease (30).

The extrahepatic late complications of liver transplantation are commonly due to the long-term use of immunosuppressive agents. Infections remain a concern. Nephrotoxicity is the most serious complication of the long-term use of TAC and cyclosporine. Dehydration may precipitate further deterioration in renal function, and any illness resulting in dehydration in patients on these agents should be taken seriously and be treated with intravenous fluids.

Malignancies are an important late complication of transplantation and chronic immunosuppressive therapy.

Recurrence is common among patients who have undergone transplantation for hepatocellular carcinomas. The most common new neoplasms are the Epstein–Barr virus-mediated posttransplantation lymphoproliferative disorders, including true lymphomas, which may occur within the first several months to many years after transplantation. Skin cancers and other solid organ malignancies are also increased in adult OLT recipients.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses for some of the more common presenting complaints are provided in Table 106.3. The frequently nonspecific presentations of the major complications usually preclude making a specific diagnosis on clinical findings alone (31). In addition, multiple diagnoses are common, owing to the interrelationship between many of the complications (e.g., HAT causing bile duct necrosis, leading to bile leakage, and abscess formation). A convenient mnemonic for the common problems in the OLT patient that may have unusual or vague presentations is ARID: *A*nastomoses, *R*ejection, *I*nfection, and *D*rug toxicity.

TABLE 106.3
Final Diagnoses for Common Presenting Complaints[a]

Complaint	Percentage
Fever	
Bacterial illness	38
Viral illness	21
Fever of unclear origin	16
Immune-mediated illness	8
Nausea/Vomiting	
Gastroenteritis	14
Nausea/vomiting of unclear etiology	13
Bacteremia	11
Gastroesophageal reflux/ gastritis	10
Biliary obstruction/leak	10
Medication effect	8
Immune-mediated illness	8
Pneumonia	6
Pancreatitis	5
Abdominal Pain	
Abdominal pain of unclear etiology	30
Biliary obstruction/leak	20
Gastroenteritis/colitis	9
Pancreatitis	9
Bowel obstruction	6
Lethargy	
Bacterial illness	31
Hepatic dysfunction	14
Medication effect	11
Jaundice	
Immune-mediated illness	36
Biliary obstruction	29
Altered Mental Status	
Medication effect	46
Hepatic encephalopathy	36

[a]Because only the most common final diagnoses are included in this table, the listed percentages for each presenting-complaint subset do not add up to 100%.

ED EVALUATION

ED evaluation of OLT patient begins with an extensive history and physical examination. Important historic factors include the etiology of liver failure, date of transplantation, history of postoperative complications, recent diagnostic studies, recent changes in medications, and current medications. A review of systems should determine the presence of fever, nausea, vomiting, abdominal pain, jaundice, acholic stools, and dark urine. Emergency physicians should bear in mind that serious OLT complications may present with deceptively nonspecific symptoms and normal initial physical examinations.

Because the presentations of many important complications of OLT are nonspecific, patients presenting to the ED generally require extensive laboratory testing. Laboratory tests should include a complete blood count and platelet count to screen for leukopenia or thrombocytopenia related to medications. Electrolytes and serum creatinine concentrations are useful to detect the nephrotoxic effects of TAC and cyclosporine. Total bilirubin, AST, ALT, alkaline phosphatase, and prothrombin time or international normalized ratio (INR) are used to evaluate graft function. Patients presenting with fever should have blood and urine cultures, chest radiography, and urinalysis (Table 106.4).

TABLE 106.4
Time of Occurrence and Management of Infections in OLT Recipients

Infectious Disease	Time of Presentation after OLT	Diagnostic Evaluation	Treatment[a]
Bacterial	Peak in months 1–2, progressive decline in incidence. Rare after 12 months, unless patient is still taking high-dose immunosuppressive regimen or has indwelling venous catheter	Blood, urine, and sputum cultures.[b] Culture all indwelling venous catheter and biliary tube fluid if T-tube present	Empiric broad-spectrum antibiotic coverage pending culture results (e.g., piperacillin/tazobactam 3.375 g IV q6h)
Fungal	Peak in months 1–2. Rare after 2 mos, unless patient is still taking high-dose immunosuppressive regimen	Blood, urine, and indwelling venous catheter cultures	Amphotericin B or fluconazole[c]
Viral	Most common in month 2 after OLT, rare after 2 mos. Cytomegalovirus is the most common infection	Blood, urine, and indwelling venous catheter cultures[d]	Ganciclovir or foscarnet
Protozoal	Rare, but occasionally occur months 1–6. *Pneumocystis jiroveci* pneumonia is the most common pathogen	Chest radiograph and sputum culture. Most require bronchoalveolar lavage; diagnosis is not usually made in ED	Trimethoprim-sulfamethoxazole, 20 mg/kg IV divided qid for 14–21 d

[a]Medication dosages must be adjusted on the basis of patient's renal function.
[b]Obtain sputum cultures and chest radiograph when clinically appropriate (e.g., patient with fever and cough). Consider stool cultures and Clostridium difficile toxin assay if infectious colitis is suspected.
[c]Antifungal and antiviral therapy are not routinely indicated in the emergency department. They are usually reserved for the hospital course of patients with orthotopic liver transplant when fungal infection has been documented or the patient's condition fails to improve with antibacterial therapy.
[d]Definitive diagnosis of clinically significant viral disease is difficult. Further diagnostic testing, such as polymerase chain reaction, serologic studies, and tissue histologic analysis, is performed later in the hospital course and is not an immediate priority during the emergency department visit.

When suspicion of vascular complications arises, several diagnostic modalities may be useful. Duplex ultrasonography has a reported sensitivity of more than 90% for detecting vascular complications and is often the initial imaging modality. Computed tomographic angiography (CTA) scanning has a similar sensitivity and may be used as the initial imaging study or employed to confirm or elucidate ultrasound findings. Angiography may be helpful diagnostically in equivocal cases or may be employed for a therapeutic intervention. Emergency physicians should have a low threshold for using ultrasonography or CT to evaluate OLT patients for vascular complications in the presence of abdominal complaints or laboratory evidence of graft dysfunction.

Although ultrasound or CT imaging may suggest biliary complications, definitive diagnosis is made by visualization of the biliary tract with T-tube cholangiography, endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography, or operative exploration.

Rejection is definitively diagnosed by liver biopsy. The histologic triad of portal tract inflammation and mononuclear cell involvement of portal vein branches and small bile ducts is diagnostic for acute rejection. Liver biopsy in chronic rejection reveals destruction and loss of interlobular bile ducts, mononuclear portal inflammation, arteriopathy, centrilobular cholestasis, and varying degrees of hepatocellular damage.

KEY TESTING

- Basic laboratory studies, plus liver function tests and INR
- Ultrasound or CT angiogram to assess vascular patency

ED MANAGEMENT

Emergency physicians should remember that rapid deterioration may occur in stable-appearing OLT patients with acute infections, particularly during times of peak immunosuppression. High-risk OLT patients presenting with fever, including recipients within 6

months of transplantation, should receive empiric broad-spectrum antibiotic therapy pending definitive culture results. Antibiotic coverage should include gram-positive organisms, gram-negative organisms (including *Pseudomonas aeruginosa*), and anaerobic organisms. Specific therapy against fungal, viral, and protozoal pathogens is rarely instituted in the ED.

A majority of OLT patients with vascular complications require surgical intervention for definitive therapy, and management of their cases should be done in concert with the liver transplantation team. Advances in nonsurgical techniques, including thrombectomy, thrombolysis, and angioplasty, have provided alternatives to open treatment of some of the less severe vascular complications. Utilization of these modalities is still center-specific.

Patients diagnosed with bile leaks require parenteral antibiotics, percutaneous drainage of any abscess, and, occasionally, surgical intervention for refractory cases. Bile leaks occurring earlier in the post-OLT period tend to be more severe and are often unresponsive to conventional therapy, probably because the higher initial level of immunosuppression renders patients incapable of eradicating infection. Infections tend to be polymicrobial and include the typical biliary tract bacterial pathogens (*Enterobacter, Enterococcus, Bacteroides,* and *Clostridium* species). Broad-spectrum gram-positive, gram-negative (including *P. aeruginosa*), and anaerobic coverage is recommended pending culture results. Many patients diagnosed with biliary strictures may be nonoperatively managed with stents or balloon dilation of their strictures.

Treatment of acute rejection involves the administration of high-dose intravenous methylprednisolone. Therapy is rarely initiated in the ED, because the definitive diagnosis of rejection is usually made later in the patient's hospital course by liver biopsy. Corticosteroids are effective in reversing 65% to 80% of acute rejection episodes. Patients who do not respond to glucocorticosteroids are treated with regimens using muromonab-CD3 (Orthoclone OKT3), with an 85% salvage rate. Chronic rejection does not respond to immunosuppressive regimens as uniformly as do acute rejection episodes. OLT recipients in whom chronic rejection is suspected

should be referred to a liver transplantation center for evaluation, because many patients with chronic rejection will suffer eventual graft failure and require retransplantation.

CRITICAL INTERVENTIONS

- Initiate broad spectrum antibiotic coverage for febrile, immunocompromised OLT patients
- Involve the liver transplantation team early in the care of OLT patients

DISPOSITION

Serious illness is common in OLT patients presenting to the ED. Not surprisingly, OLT recipients typically undergo extensive diagnostic evaluations and are frequently hospitalized. Much of the definitive diagnostic testing that patients with OLT require is beyond the scope of typical emergency medicine practice. Appropriate ED goals are assessing the severity and possible causes of an acute illness, stabilization, and transfer of care to the multidisciplinary liver transplantation team. Emergency physicians should involve the liver transplantation team early in the decision-making process to help coordinate the timing and location of the evaluation, especially if transfer to a tertiary care center is necessary.

New-onset graft failure mandates admission. The causes of graft failure are diverse, and their evaluation is best performed in the inpatient setting.

In general, febrile OLT patients who are $<$1-year posttransplantation and are without an obvious source of infection are admitted. Febrile patients who are $>$1-year posttransplantation but are still maintained at a high level of immunosuppression (e.g., chronic rejection patients) should also be hospitalized. Well-appearing, febrile patients who are $>$1-year posttransplant with an uncomplicated post-OLT course and whose immunosuppressives have been tapered may be managed as outpatients on an individual basis. Because maintaining a desired level of immunosuppression is vital in preventing rejection episodes, admission is mandatory if

compliance with the immunosuppressive regimen is in doubt (e.g., because of intractable vomiting).

Common Pitfalls

- Failure to consider the diagnoses that uniquely apply to the patient with OLT (ARID: *A*nastomoses, *R*ejection, *I*nfection, *D*rug toxicity) and that may have unusual or vague presentations.
- Failure to coordinate the ED evaluation and follow-up of OLT recipients with the multidisciplinary liver transplant team.
- Failure to manage infection aggressively in OLT recipients, especially early in the posttransplantation period when immunosuppression is at its peak.
- Using the leukocyte count as a marker for severity of infection. More than 50% of OLT patients with serious bacterial infections have a normal leukocyte count.
- Assuming that a soft and nontender abdomen excludes hepatobiliary complications.
- Prescribing *any* medication to OLT patients without carefully investigating potential drug interactions or adverse effects.

CHAPTER 107 Pancreatitis

Anuj A. Parikh and David C. Seaberg

Pancreatitis is a disease that is commonly encountered by the emergency physician and is challenging to diagnose and treat, as the symptoms can range from mild to potentially life-threatening. The pancreas is a retroperitoneal organ located in the epigastric region. It is divided histologically into two parts, endocrine and exocrine. The endocrine pancreas is housed in the Islets of Langerhans and its alpha, beta, and delta cells produce and are responsible for insulin, glucagon, and somatostatin homeostasis. The acinar, or exocrine, pancreas is responsible for production of lipase, amylase, and other proteolytic enzymes. The products of the exocrine pancreas are secreted into the pancreatic duct and ultimately into the duodenum. Insult to the pancreas that can occur for a variety of reasons or blockage of its duct causes leakage of pancreatic products into the pancreas and the surrounding tissue. This leakage can potentially cause damage to the pancreas and nearby organs. Pancreatic damage and the resulting pain and clinical manifestations can occur either acutely or chronically and thus, pancreatitis has been divided into two types, acute and chronic.

The incidence of pancreatitis varies with patient population and geographic location, but it has been estimated to affect up to 50 to 80 per 100,000 patients worldwide with the highest incidences in the United States and Finland (1). The overall mortality observed with acute pancreatitis has been estimated to be approximately 5% to 15% with approximately 20,000 patients dying annually from pancreatitis (2). Chronic pancreatitis, typically manifested by recurrent episodes of acute pancreatitis superimposed on a

chronically damaged pancreas, is rarely fatal. The incidence of pancreatitis has been noted to be on the rise and this coincides with increased incidence of alcohol abuse and cholecystitis (3). The incidence of pancreatitis in the pediatric population is rare, but should certainly be considered in patients with inheritable disorders like hereditary pancreatitis and cystic fibrosis. In fact, acute pancreatitis can be the first symptom of otherwise undiagnosed cystic fibrosis in a child (4).

The causes of acute pancreatitis are listed in Table 107.1. The most common cause is gallstone and biliary tract–related obstructive disease. As noted above, as the incidence of alcohol abuse is on the rise and so is the incidence of alcohol-related pancreatitis. Drugs, particularly in elderly patients or those on immunomodulating agents are also responsible for disease. Endoscopic retrograde cholangiopancreatography (ERCP) in the hands of an inexperienced endoscopist can be a potential cause of pancreatitis. Elevated triglyceride levels of greater than 1,000 mg/dL can trigger acute pancreatitis. In the setting of hyperparathyroidism or cancer, hypercalcemia can trigger the activation of trypsinogen thereby leading to trypsin-mediated pancreatic necrosis. Genetic mutations have been found more and more often to be associated with both acute and chronic pancreatitis. Autoimmune and tropical pancreatitis remain elusive in their mechanism of disease propagation. Multiple infectious causes have been identified including mumps, coxsackievirus, cytomegalovirus, varicella, herpes simplex virus, HIV, Mycoplasma, Legionella, Leptospira, Salmonella, Toxoplasma, Cryptosporidium, Ascaris, and Aspergillus. Idiopathic causes followed by the less common causes are also listed in Table 107.1 and account for the majority of causes of acute pancreatitis (5–7). Scorpion venom–induced pancreatitis is frequently cited as a cause of pancreatitis but it is, however, exceedingly rare and should be considered only in the face of an acute or subacute envenomation (2).

TABLE 107.1
Causes of Acute Pancreatitis

More Common	Less Common
Gallbladder disease	Cystic pancreatic lesions
Alcohol related	Cystic fibrosis
Drug related	Pancreas divisum
ERCP	Pancreatic cancer
Hyperlipidemia	Peptic ulcer
Hypercalcemia/hyperparathyroidism	Postsurgical
Genetic	Tropical pancreatitis
Autoimmune	Vasculitis
Infectious	
Idiopathic	
Abdominal trauma	
Hypotension	

Adapted from Taichman, Turner, Williams, Gupta, Wu. In the Clinic: Acute Pancreatitis. *Ann of Intern Med*. 2010;153(9):ITC51–ITC55 & Cappell, MS. Acute Pancreatitis: Etiology, Clinical Presentation, Diagnosis, and Therapy. *Med Clin N Am* 2008;92:889–923.

CLINICAL PRESENTATION

Acute Pancreatitis

Although no clinical finding is pathognomonic of acute pancreatitis, abdominal pain is the most striking clinical feature. The classic pain pattern is described as acute onset epigastric abdominal pain with radiation to the back though there is great variation to this presentation (5). The pain is usually severe and constant; it may be diffuse but is commonly localized to the epigastrium or left upper quadrant and often radiates through to the back. The pain is typically exacerbated by recumbency and relieved by sitting up and flexing forward. Nausea and vomiting are noted in the majority of cases. On physical examination, there is usually abdominal tenderness and guarding, often with signs of peritoneal irritation. Fever, hypotension, tachycardia, abdominal guarding, respiratory distress, and diaphoresis may also be noted, depending on the severity of the case (8).

Necrotizing acute pancreatitis is a potentially life-threatening disease. Pancreatic inflammation from necrosis results in shunting of blood from other organs causing hypovolemia, hypotension, vasospasm, and hemoconcentration (9). At worst, patients with acute necrotizing pancreatitis present with severe abdominal pain, in hypovolemic shock, with fever, renal failure, hypoxemia, and GI bleed (10). Cullen sign (periumbilical bruising) and Grey Turner sign (flank bruising) are exceedingly rare in pancreatitis and can arise in any instance of retroperitoneal hemorrhage (11).

Chronic Pancreatitis

Patients with chronic pancreatitis often present to the emergency department (ED) with recurrent attacks of abdominal pain, although in some patients pain is overshadowed by weight loss and the effects of pancreatic endocrine or exocrine dysfunction (i.e., diabetes mellitus or malabsorption and steatorrhea). The pain is described as midepigastric postprandial pain that radiates to the back, relieved by sitting upright and leaning forward (12). Pancreatic endocrine dysfunction, with deficient insulin and glucagon secretion, may result in diabetes mellitus that is occasionally brittle and associated with frequent episodes of hypoglycemia. The source of epigastric abdominal pain in chronic pancreatitis is thought to be due to acute inflammation, neural inflammation, or increased intrapancreatic pressure due to pancreatic ductal dilatation or pancreatic pseudocyst (10).

DIFFERENTIAL DIAGNOSIS

Acute Pancreatitis

The differential diagnosis is listed in Table 107.2. A perforated viscus may be identified by the detection of free air under the diaphragm on a chest radiograph. Acute cholecystitis and biliary disease can be identified by ordering liver function tests and right upper quadrant ultrasonography. Intestinal obstruction can be identified on abdominal radiographs or computed tomography (CT) scan. Mesenteric vascular occlusion can be diagnosed with serum

lactate levels as well as CT angiography. Ultrasound can play a role in the diagnosis of mesenteric ischemia as well. Abdominal aortic pathology can be rapidly identified with ultrasound and with CT. Renal colic can be diagnosed with urinalysis along with ultrasound or CT. Acute myocardial infarction (AMI) should be included in the differential diagnosis of every patient with midepigastric pain and risk factors for AMI. Acute appendicitis can be detected with CT scan or ultrasound. Ectopic pregnancy can be identified by presence of urine or serum HCG and ultrasound. Pneumonia or pulmonary embolism in the right lower segments can mimic gallbladder and pancreatic disease and plain film or CT should be done in cases where other causes of epigastric pain cannot be found. Finally connective tissue disorders with vasculitis should be considered in the absence of other obvious causes of upper abdominal pain but its diagnosis in the ED may be limited (7).

TABLE 107.2
Differential Diagnosis for Pancreatitis

Chronic Pancreatitis

The diagnosis of chronic pancreatitis is primarily a clinical one, but Table 107.3 lists the common conditions that should be considered when evaluating a patient with known chronic pancreatitis who

presents to the ED with an acute exacerbation of their chronic epigastric abdominal pain. Note that a careful social and family history should be obtained from the patient with particular regard to a history of chronic alcohol use, cigarette smoking, and family history of pancreatitis. New research indicates that there is a genetic link to alcoholic pancreatitis and that several genetic mutations can predispose patients to the development of pancreatitis for no known reason (13). There is emerging, but limited, data to suggest that environmental tobacco smoke from cigarettes have linked smoking with chronic pancreatitis (4).

TABLE 107.3
Differential Diagnosis of Chronic Pancreatitis

More Common	Less Common
Acute cholecystitis	Acute appendicitis
Acute pancreatitis	Acute salpingitis
Intestinal ischemia/infarction	Crohn disease
Common bile duct obstruction	Ectopic pregnancy
Pancreatic tumors	Gastroparesis
Peptic ulcer disease	Intestinal obstruction
Renal insufficiency	Irritable bowel syndrome
	Malabsorption
	Ovarian cysts
	Ovarian adenocarcinoma
	Thoracic radiculopathy

ED EVALUATION

The diagnosis of pancreatitis requires the emergency physician to combine the findings of a thorough history and physical examination along with appropriate laboratory work-up and imaging. The challenge of the ED evaluation of suspected pancreatitis is to make the diagnosis and to exclude other causes of abdominal distress, keeping in mind that other serious illness may occur in combination with pancreatitis. Once the diagnosis is made,

one must assess the severity of the pancreatitis to make an appropriate disposition. The gold standard of diagnosis is direct inspection or pathologic examination of the pancreas; all other diagnostic modalities are indirect. Therefore, it is often stated that pancreatitis should remain a working diagnosis that one should feel free to modify in the face of a changing clinical picture.

The amylase and lipase have historically been the initial laboratory tests for diagnosing pancreatitis. An elevation of the serum *amylase* is often incorrectly considered to be diagnostic of acute pancreatitis. Because amylase is found in a variety of extrapancreatic locations (including the salivary glands, the small intestine, and the female genital tract), reliance on the amylase level alone may be misleading, especially since the amylase level can normalize several days into an acute attack. In addition, acute-on-chronic pancreatitis from alcohol abuse may only cause a mild elevation in the amylase due to pre-existing pancreatic injury. Serum amylase level is a very sensitive but nonspecific test so it should not be relied upon alone for the diagnosis of pancreatitis (2). Because of its availability and high specificity, the serum *lipase* level is the confirmatory test of choice for pancreatitis (7). Because the pancreas is the only major source of lipase, an increased level, particularly more than three times the upper limit of normal, is very specific for acute pancreatic inflammation. It is important to note that serum lipase may not be elevated in patients with acute-on-chronic pancreatitis. The clinician must use clinical judgment in these cases. Liver function tests are important in ruling out an obstructive cause of pancreatitis. Determination of the WBC count, hemoglobin, and basic metabolic panel are often helpful. An ionized calcium level should be obtained to ensure that elevated serum calcium is not the cause of inappropriate release of proteolytic pancreatic enzymes that can ultimately lead to trypsin-mediated necrosis. Finally, a triglyceride level should be obtained as highly elevated triglyceride levels can precipitate acute pancreatitis (7).

Imaging can help differentiate pancreatitis from other diagnoses and help to evaluate the complications caused by pancreatitis, especially in acute pancreatitis. Plain radiographs of the chest and

abdomen can be considered to rule out other entities, such as pneumoperitoneum or small bowel obstruction, but are not generally helpful in the evaluation of pancreatitis. CT is of particular importance, however, especially in evaluating pancreatitis and its complications. Patients presenting with mild episodes, especially chronic, alcohol-induced pancreatitis, usually do not require imaging. Balthazar et al. developed the CT severity index that combines pancreatic necrosis and local complications of fluid collection to create a predictive score. CT with intravenous contrast is the imaging gold standard for evaluating the presence and extent of pancreatic necrosis and other local anatomic sequelae of acute pancreatitis, and has become a routine part of the diagnostic evaluation (8).

Ultrasonography can identify pancreatic edema as well as such complications as pancreatic pseudocyst or abscess. It is also useful in identifying the presence of gallstones or dilatation of the biliary tree, findings that have important diagnostic and therapeutic implications (14). The American College of Gastroenterology's current clinical practice guidelines suggest ultrasonography within the first 24 to 48 hours of admission to essentially rule out surgical causes of acute pancreatitis (15).

Magnetic resonance imaging (MRI) has an emerging role in the evaluation and ultimate management of patients with pancreatitis. While it is not superior to CT diagnostically, MRI avoids ionizing radiation and nephrotoxic iodinated contrast. This makes MRI the study of choice for pregnant patients with suspected acute pancreatitis. The other major advantage of MRI is the use of magnetic resonance cholangiopancreatography (MRCP) that allows for noninvasive evaluation of the biliary system. The disadvantages include the lack of availability of MRI, inability to monitor a critically ill patient, and the increased time that it takes to complete the test (16).

KEY TESTING

- Lipase, CBC, basic metabolic panel, calcium, liver function tests, triglyceride level
- Ultrasound and/or CT
- Serum lactate, arterial blood gas (in severe cases)

ED MANAGEMENT

After establishing the diagnosis of acute pancreatitis, the second priority is to determine its severity. Top priority for the emergency specialist is airway, breathing, and circulation, all of which can be compromised in a patient afflicted with severe acute pancreatitis. 10% to 15% of patients with acute pancreatitis develop systemic inflammatory response syndrome (SIRS) leading to organ failure (including shock, pulmonary insufficiency, and renal failure) and/or the presence of local complications (especially pancreatic necrosis) (11). Predictors of severity within the first 48 hours of hospitalization, including Ranson criteria and the Acute Physiology and Chronic Health Evaluation (APACHE-II) score, which serve as an early warning sign that an episode is likely to be severe (15). The practice guideline for acute pancreatitis recommends that a formalized system of scoring should be generated for each patient. The APACHE-II and Ranson criteria score should be generated on the day of admission to help identify patients with severe pancreatitis. Furthermore, the Atlanta classification was created at an international symposium in 1992 to create a clinically based classification system for acute pancreatitis. According to the Atlanta Symposium, acute pancreatitis is defined as an acute inflammatory pancreatic process that may also involve peripancreatic tissues and/or remote organ systems. Criteria for severity included organ failure (shock, pulmonary insufficiency, and renal failure) and/or local complications (such as pancreatic necrosis but also including pancreatic abscess and pancreatic pseudocyst).

The Ranson criteria are used to predict the severity and mortality of disease. They are listed in Table 107.4. The APACHE-II score, which can be quickly and efficiently scored online (www.sfar.org/scores2/apache22.html#calcul) is based on 12

physiologic variables, the patient's age, and any history of severe organ-system insufficiency, or immunocompromised state. The value of the APACHE-II system is that it allows measurement of severity at presentation and can be measured daily, whereas other systems (including Ranson criteria) require data at 48 hours. In general, when the APACHE-II score is less than 8 during the first 24 to 48 hours, the patient usually survives.

TABLE 107.4
Ranson Criteria for Predicting the Severity of Acute Pancreatitis

On admission
Age >55 yr
WBC >16,000/mm^3
Blood glucose >200 mg/dL
Lactate dehydrogenase >350 IU/L
Aspartate transaminase >250 U/L
Within 48 hrs
BUN >5 mg/dL
PaO_2 <60 mm Hg
Serum calcium <8 mg/dL
Hematocrit decrease >10%
Base deficit >4 mEq/L
Fluid sequestration >6 L

WBC, white blood cell; BUN, blood urea nitrogen.
Note: Mortality is based on the number of prognostic signs as follows: 0–2, 1%; 3–4, 15%, 5–6, 40%; >6, 100%.
Adapted from Ranson JH Etiologic and prognostic factors in human acute pancreatitis: A review. *Am J Gastroenterol*. 1982;77:663–63.

Historically, antibiotics such as ceftriaxone have played a role in treatment of patients with necrotizing pancreatitis. First studied in 1976 with a randomized, double-blind study, ampicillin was administered to those with acute pancreatitis. The conclusion was that the role of prophylactic antibiotics needed further study. Nearly 40 years later, researchers from the US and the UK reached no clear consensus on the role of antibiotics for severe pancreatitis. A meta-analysis done in the late 1990s showed that there may be some mortality benefit to prophylactic antibiotics but a double-blind

placebo-controlled trial published afterward showed no benefit (17,18). The American Gastroenterology Association has no formal recommendation for antibiotic prophylaxis but notes that it should be considered in cases with 30% or more pancreatic necrosis on CT scan (19).

CRITICAL INTERVENTIONS

- Aggressive fluid resuscitation in patients with acute pancreatitis, who often have substantial retroperitoneal sequestration of fluids
- Adequate analgesia for patients with severe pain

DISPOSITION

Patients with mild symptoms and without biliary tract disease may be managed on an outpatient basis if they are able to tolerate clear liquids in the ED and have no evidence of systemic complications. For these individuals, a clear liquid diet and oral analgesics should be prescribed and close follow-up should be arranged. Patients with alcohol-associated pancreatitis should be encouraged to stop drinking and if they smoke, to stop smoking. For patients with chronic pancreatitis, indications for hospital admission include uncontrollable pain, intractable vomiting, severe nutritional deficiencies, or complications requiring surgery. Any adjustments in the regimen for analgesia or pancreatic enzyme supplementation should be carried out in consultation with the patient's primary care physician.

All other patients must be admitted to the hospital. If severe or necrotizing acute pancreatitis is suspected, admission to an intensive care unit is mandatory for critical care monitoring of cardiac, pulmonary, and renal function. Surgical consultation is indicated for patients with clinically severe pancreatitis or evidence of large peripancreatic fluid collections, abscess, or pancreatic necrosis on CT.

Common Pitfalls

- No clinical or laboratory finding is pathognomonic of pancreatitis. The serum amylase is not a specific test, and an elevated serum amylase level is not diagnostic.
- Underestimating the severity of an attack. Measurements of APACHE-II and/or Ranson criteria should be made to estimate severity.

CHAPTER 108 Appendicitis

Brian K. Snyder

> "Acute appendicitis can mimic virtually any intra-abdominal process; therefore, to know acute appendicitis is to know well the diagnosis of acute abdominal pain."
>
> —Zachary Cope

Appendicitis is an acute inflammatory process of the appendix resulting from obstruction of the lumen with subsequent bacterial invasion, distention, ischemia, and ultimate rupture. As traditionally taught, appendicitis presents with initial periumbilical pain that later migrates to the right lower quadrant (RLQ). Anorexia, nausea, and vomiting are associated symptoms. Physical examination reveals a low-grade fever and RLQ tenderness, with guarding and rebound as the process progresses. Laboratory evaluation reveals a leukocytosis with neutrophilia. Unfortunately, this classic presentation occurs in only a minority of cases, and the diagnosis may be difficult to make. In one large series (before availability of CT), diagnostic accuracy averaged only 85%, with a 19% perforation rate. A percentage of the perforation rate surely results from delayed diagnosis. Incidence of perforation increases with the extremes of age, and perforation is associated with greater morbidity and mortality (1).

The lifetime risk of appendicitis is 8.6% for males and 6.7% for females, with an annual incidence of 1.1:1,000. The male-to-female ratio for appendicitis is 1.4:1, although females have a higher rate of negative appendectomies. The peak incidence for males is between 10 and 14 years and for females is between 14 and 19 years.

Appendicitis rates are 1.5 times higher for whites than for nonwhites and are higher in summer (1). The cause of these differences is unknown, but temporospatial clustering and outbreaks of appendicitis point to an infectious agent as a cause of some cases of appendicitis. A recent report found active infection with cytomegalovirus in a majority of examined appendicitis specimens from immunocompetent patients (2).

The normal, uninflamed appendix is a hollow visceral structure with a closed distal end arising from the cecum; on average, it is 9.5 to 10 cm in length. Although the density of immune cells in lymphoid follicles in the appendix suggests an immunologic role, the function of the appendix is unknown. Its anatomic position can be anterior (postilial, preilial, and pelvic) or posterior (retrocecal and subcecal), and many appendices are mobile or can be found outside the RLQ (Fig. 108.1). The traditional surface landmark for the location of the appendix is McBurney's point, which is located 1.5 to 2 in from the inferior aspect of a line drawn from the anterior superior iliac spine point to the umbilicus. However, barium and laparoscopic studies reveal that most appendices are pelvic and lie inferior to this point; therefore, making clinical decisions based on the presence or absence of pain or tenderness at exactly McBurney's point is unjustified (3).

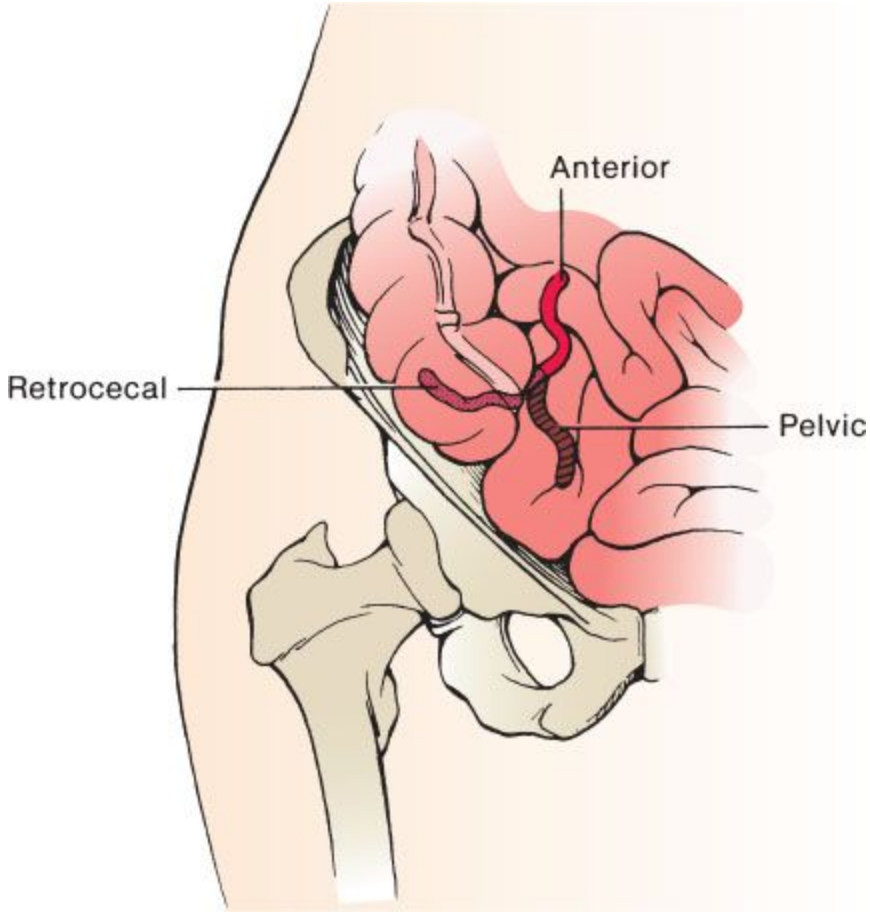

FIGURE 108.1 Various anatomic positions of acute appendix.

The common pathophysiologic event in appendicitis is obstruction of the lumen. Obstruction can be from lymphoid hyperplasia, intraluminal objects (fecaliths, foreign bodies, or parasites), or tumors (carcinoid, adenocarcinoma, or metastatic tumors). A variety of inflammatory conditions can result in hyperplasia of appendiceal lymphoid follicles that progresses until the appendiceal wall itself obstructs the lumen. Conditions noted for this process include respiratory infections, mumps, mononucleosis, amoebiasis, and bacterial gastroenteritis.

Crohn's disease can affect the appendix. Patients with the acquired immunodeficiency syndrome (AIDS) can have other processes of the appendix, including Kaposi sarcoma, lymphoma, or opportunistic infections (e.g., cytomegalovirus). Typhlitis can present similarly and occurs generally in neutropenic patients. Once

the appendiceal lumen is obstructed, secretion of mucus within the appendix raises intraluminal pressures until lymphatic and venous return is impaired. Ischemic injury to the mucosa results, followed by bacterial invasion of the appendiceal mucosa and submucosa. Continued inflammation and bacterial proliferation result in perforation of the appendix and spillage of inflammatory cells and bacteria into the peritoneum, resulting in peritonitis. At times, the peritoneal infection is contained by the omentum and a periappendiceal abscess forms.

CLINICAL PRESENTATION

History

The characteristic clinical presentation of acute appendicitis is abdominal pain in association with anorexia, nausea, and vomiting (see Table 108.1). Approximately 50% of patients present within 24 hours of the onset of symptoms, 33% between 24 and 48 hours, and the remainder thereafter. Abdominal pain occurs in nearly 100% of patients, is epigastric in onset in 74%, and migrates to the RLQ in 50%. Anorexia is present in 92% of patients, accompanied by nausea and vomiting in 78% and 54% of patients, respectively.

TABLE 108.1
Signs and Symptoms of Acute Appendicitis

	Nonperforated (%)	Perforated (%)	All Cases (%)
Symptoms			
Abdominal pain	99.6	99.3	99.6
Epigastric at onset	74.4	70.1	73.5
Constant RLQ	25.5	29.1	26
Anorexia		92	
Nausea	78	79.8	78.3
Vomiting	51.8	64.2	54.2
Migration of pain	52.3	38	49.6
Fever	16.3	39.6	20.8
Diarrhea	15	22.4	16.4
Constipation	8.3	14.2	9.4
Lucid interval[a]	3.2	11.2	4.8
Signs			
Abdominal tenderness			
Direct RLQ	99.6	99.3	99.6
Referred RLQ	26.3	18.6	24.9
Lower abdominal	7.8	21.6	10.6
Generalized	9.6	21.6	11.9
Right-sided rectal tenderness	48.7	41.8	47.4
Local rigidity over RLQ	26.3	45.5	30.1
Generalized rectal tenderness	11.4	19.4	12.9
Rebound tenderness	4.8	4.5	4.8
Positive psoas test	4.8	3.7	4.7
Generalized rigidity	0.7	12.7	3.1
Palpable mass in RLQ	0.5	3.7	1.2

RLQ, right lower quadrant.

[a]Lucid interval refers to a period after perforation in which pain is temporarily lessened; some authorities do not consider this a legitimate phenomenon.

Data from Lewis FH, Holcroft JW, Boey J, et al. Appendicitis: A critical review of diagnosis and treatment in 1,000 cases. *Arch Surg*. 1975;110:677; Pieper R, Kager L, Näsman P. Acute appendicitis: A clinical study of 1018 cases of emergency appendectomy. *Acta Chir Scand*. 1982;148:51.

Physical Examination

Although often regarded as a reliable clinical feature of appendicitis, fever is reported in only one-fifth of all cases and in only 16% of cases of appendicitis uncomplicated by perforation. The most

reliable sign of acute appendicitis is RLQ tenderness, present in nearly 100% of patients. Twenty-five percent of patients demonstrate referred RLQ tenderness under remote palpation (*Rovsing's sign*); rigidity in the RLQ is present in 30% of patients. Nearly one-half of patients demonstrate right-sided rectal tenderness.

The most significant complication of acute appendicitis is perforation, which either leads to generalized peritonitis and sepsis or is contained as an intra-abdominal abscess. The mortality rate of perforated appendicitis is 1.66%, seven times greater than that of patients undergoing appendectomy for simple, acute appendicitis (0.24%) and 12 times greater than that of appendectomy for a normal appendix (0.14%) (4). It is clear that the clinician must try to diagnose cases of simple acute appendicitis before perforation occurs.

There are few reliable clinical features that distinguish nonperforated from perforated appendicitis (Table 108.1). The duration of symptoms tends to be longer in patients with perforation (>48 hours). Signs that suggest perforation include lower or generalized abdominal tenderness, local or generalized rigidity over the RLQ, the presence of a palpable RLQ mass, and generalized rectal tenderness.

Pediatric, geriatric, and pregnant patients deserve special mention. Because diagnosis often is more difficult in these groups, their morbidity and mortality is greater.

Pediatric Patients

Appendices in children have a much thinner wall than those in the adult, allowing more rapid mucosal penetration and subsequent perforation. Besides higher perforation rates, the diagnosis can be more elusive given the inability of the very young to verbalize the symptoms, the difficulty sometimes encountered in examination, and the high prevalence of atypical features (e.g., diarrhea). See Chapter 269 covering pediatric appendicitis.

Geriatric Patients

Only 20% of patients older than age 60 years who are diagnosed with appendicitis present with the classic nausea, vomiting, RLQ tenderness, and elevated white blood cell count or shift. Consequently, the perforation rate is 67% to 90%. The mortality rate is 4.6%, 23 times greater than that of patients younger than age 60 years (1,5).

Pregnant Patients

The physiologic changes of pregnancy, especially during the second and third trimesters, impede the diagnosis and create a physiologic environment that suppresses the normal host response to inflammation. As the uterus enlarges, the appendix rotates in a counterclockwise direction out of the pelvis. In addition, as the expanding uterus lifts the abdominal wall away from the appendix, the omentum is less available to wall off the infectious process following perforation. Diffuse peritonitis develops preferentially over a periappendiceal abscess. The increase in serum steroids during pregnancy diminishes the inflammatory response and facilitates a more rapid and overwhelming peritonitis. These physiologic and anatomic processes result in a perforation rate of 43%. The maternal mortality rate remains low at 0.7%, but fetal mortality may approach 8.5% (6,7).

DIFFERENTIAL DIAGNOSIS

A variety of conditions mimic appendiceal inflammation (1) (see Table 108.2); the diagnostic accuracy of evaluation for suspected acute appendicitis may be as low as 85%. Disorders most commonly associated with removal of a normal appendix despite clinical suspicion of acute appendicitis include mesenteric lymphadenitis, other diseases of the appendix, and gynecologic processes. The greatest diagnostic difficulties are encountered in women of childbearing age. The overall diagnostic accuracy for females is 77%; in contrast, the diagnostic accuracy for males is 91% (1).

TABLE 108.2
Differential Diagnosis of Acute Appendicitis

Discharge Diagnoses Most Commonly Recorded after Negative Appendectomy	Percentage
Other diseases of the appendix (colic, concretion, Meckel diverticulum, fecalith, fistula, intussusception, mucocele)	19.4
Other appendicitis (chronic, recurrent, relapsing, or subacute)	16.5
Mesenteric lymphadenitis	22
Abdominal pain of unknown origin	12.2
Gastroenteritis, noninfectious	6.4
Cholelithiasis	4.1
Ovarian cyst	5.5
Uterine leiomyoma	4.3
Endometriosis	4
Lymphoid hyperplasia of the appendix	3.1
Cervicitis, endocervicitis	2.7

Other considerations in the differential diagnosis include regional enteritis, perforated peptic ulcer, diverticulitis, carcinoma of the bowel, ureteral calculi, pelvic inflammatory disease, and mittelschmerz.

Data from Addis DG, Shaffer N, Fowler S, et al. The epidemiology of appendicitis and appendectomy in the United States. *Am J Epidemiol*. 1990;132:910.

In addition, patients with previous appendectomy, especially if done by the laparoscopic approach, may present with symptoms and signs consistent with acute appendicitis from inflammation of residual appendiceal tissue, the so-called stump appendicitis (8).

ED EVALUATION

Despite the widespread use of radiologic studies and other diagnostic aides in the evaluation of appendicitis, the diagnosis can still remain elusive. Appendicitis should be suspected on the basis of history and physical examination. The emergency physician should be particularly aggressive in evaluating the very young, the elderly, and the pregnant patient, as the morbidity and mortality rates of acute appendicitis in these subpopulations exceed those of others. No laboratory or radiographic study is completely reliable for acute appendicitis, but several are commonly used for their supportive value.

Laboratory Studies

Acute appendicitis is classically associated with leukocytosis with a left shift. In one large study, 88% of adult patients with acute appendicitis had a white blood cell count of >10,000 cells/μL, and 94% had a leukocytosis *or* a neutrophilia of >75%. Specificity was only 76% and 62%, respectively. Approximately 10% of patients with acute appendicitis have normal leukocyte and neutrophil counts (9,10). Unfortunately, an elevated leukocyte count is nonspecific, with the specificity being reported as low as 38%. Further complicating matters, the normal range for the leukocyte count changes with age. By calculating likelihood ratios, one finds that the leukocyte count has minimal effect on the probability of disease, except at extreme values that are very uncommon (11). Some authors advocate serial leukocyte counts. Studies regarding the clinical utility of sequential leukocyte counts are inconclusive, and it appears that utility, if any, is limited to a small percentage of the total patient population.

Other serum markers of inflammation, such as the C-reactive protein, have also been evaluated as an aid in diagnosis of acute appendicitis but generally demonstrate the same limitations as the leukocyte count.

Urinalysis, often obtained in the evaluation of abdominal pain, cannot be relied on to distinguish disease of the urinary tract from that of the appendix. In one study of patients with histologically confirmed acute appendicitis, 30% had an abnormal urinalysis regardless of the position of the appendix. In those patients with either a ruptured or an inflamed appendix in the retrocecal or pelvic position, abnormal urinalysis was detected in 50%. Diagnostic decisions should not be based solely on the presence of blood, pyuria, or bacteriuria (12).

Imaging Studies

Radiologic studies should be reserved for those with equivocal symptoms and physical findings. In cases of strongly suspected appendicitis, time-consuming diagnostic procedures should not be

ordered. Because the incidence of perforation is related to the interval between symptom onset and surgery, tests that may delay definitive therapy should be used cautiously.

The expanded use of helical computed tomographic (CT) scanning of the abdomen in the evaluation of appendicitis has changed practice in equivocal and low probability cases. Other radiologic modalities including plain radiographs, barium enema, and labeled WBC scan have little utility and are no longer commonly used (13).

Abdominal ultrasonography is often used in the evaluation of appendicitis, especially in pediatric and pregnant patients. When obstructed, the appendix appears as a blind-ended, immobile, noncompressible structure that cannot be displaced under direct pressure from the ultrasound probe. An appendix that is visualized on ultrasound examination is considered diagnostic of appendicitis. The test is negative if the appendix cannot be visualized. Unfortunately, ultrasonography is nondiagnostic in 3% to 11% of cases because of pain, guarding, obesity, or overlying gas. Sensitivity ranges from 75% to 89%, and specificity ranges from 86% to 100%. Worse results are obtained in early appendicitis, perforation, and retrocecal appendicitis. Ultrasound is the preferred initial modality in pregnant patients, because it does not involve contrast or radiation exposure (13). However, because of the risk of fetal wastage in cases of delayed diagnosis or negative appendectomy, magnetic resonance imaging (MRI) and CT (despite the radiation exposure) are being increasingly used in pregnant women for the evaluation of possible appendicitis (14). Factors that should be considered in this decision include the clinical suspicion, follow-up, test availability, and the radiation risk that must be balanced against the need to make a diagnosis.

Helical CT of the abdomen is fast and highly accurate in the evaluation of acute appendicitis. The sensitivity of unenhanced helical CT is approximately 90%; with the addition of oral, rectal, or intravenous contrast, the sensitivity increases up to 97% to 98% with low-dose CT having similar performance (15,16). Specificity is equally high at 94% to 97%. Findings include a fecalith, an inflamed appendix, stranding in the surrounding fat or periappendicular fluid,

phlegmon, or abscess (Fig. 108.2). Helical CT in the evaluation of appendicitis appears to be cost-effective, and its use may decrease the negative laparotomy and perforation rates (15). It is highly accurate, whether or not oral contrast is used (17). Furthermore, CT often provides an alternative diagnosis and may decrease the time to operative intervention for female patients (18). In addition, it is useful in the assessment of cases of suspected perforated appendicitis with periappendiceal abscess formation, which may be treated conservatively or with percutaneous drainage and interval appendectomy (19). Diagnostic laparoscopy has advocates, especially for women of childbearing age, and is highly accurate and safe (20).

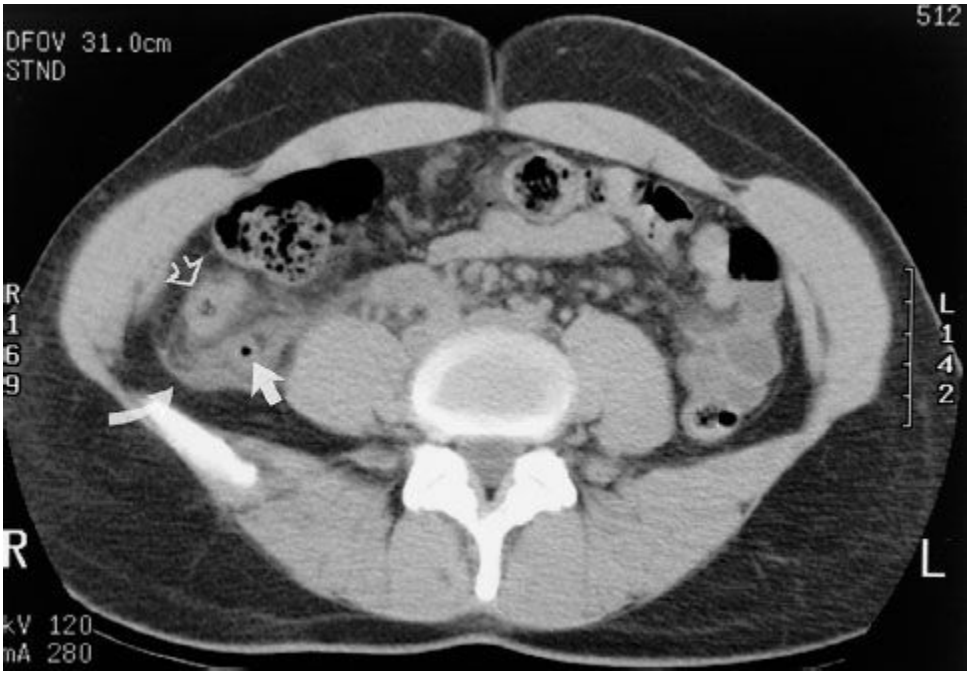

FIGURE 108.2 Computed tomographic appearance of appendicitis. Note the enlarged, thickened appendix (*open arrow*), surrounding fat stranding and inflammation (*curved arrow*), and extraluminal air, implying perforation (*closed arrow*).

KEY TESTING

- No laboratory or radiologic test is perfectly sensitive nor specific.

- Urinalysis, although urinary symptoms do not exclude appendicitis.
- Pregnancy test in women of child bearing age.
- Consider ultrasound in pregnancy and pediatric patients.
- Order CT scan when the diagnosis is uncertain.

ED MANAGEMENT

The patient suspected of having acute appendicitis should be given nothing by mouth except, perhaps, oral contrast. Intravenous fluid is indicated to ensure hydration. Surgical consultation should be obtained promptly, as timely appendectomy of an inflamed but nonperforated appendix is of paramount importance. If acute appendicitis is suspected but in doubt, radiologic study, ED observation, or admission for inpatient observation with serial examination are reasonable alternatives. Observation is a safe and effective way to distinguish patients with appendicitis from those without (21).

Although traditional teaching was that analgesia could obscure the diagnosis in acute abdominal pain, the use of narcotics has not been shown to increase the number of delayed or missed diagnoses (22). The judicious use of short-acting narcotics is reasonable in patients with acute abdominal pain while evaluation is in progress, especially those in which a radiologic procedure is to be performed or surgical consultation is delayed.

When perforation is highly suspected, intravenous antibiotics should be administered. Antibiotics that cover typical intestinal flora such as “triple antibiotics” (ampicillin 2 g, gentamicin 2 mg/kg, and metronidazole 500 mg), piperacillin/tazopactam, or a second-generation cephalosporin (cefotetan 1 to 2 g) or a quinolone (ciprofloxacin 500 mg or levofloxacin 500 mg) with metronidazole are appropriate.

There is increasing interest in treating uncomplicated appendicitis with antibiotics with or without later appendectomy (23).

CRITICAL INTERVENTIONS

- Obtain immediate surgical consultation for patients with a high likelihood of appendicitis, to reduce delay to the operating room and therefore the perforation rate.
- When in doubt, admit the patient to an observation area or surgical service for serial physical examinations.
- Administer intravenous antibiotics when perforation is highly suspected.

DISPOSITION

Patients in whom the clinical suspicion of appendicitis is moderate or high and those with a positive imaging study should be admitted to the hospital for further evaluation or surgery. For patients being discharged without a definitive diagnosis, who have low likelihood of appendicitis or other significant intra-abdominal process, it is important to provide clear, legible instructions explicitly detailing conditions meriting a return visit for further evaluation (e.g., continued or worsening pain, new symptoms). Advising a scheduled return visit in 12 to 24 hours for reassessment is good practice. In addition, when the diagnosis is uncertain, refrain from documenting a definitive diagnosis (e.g., gastroenteritis); rather refer to the process as “abdominal pain of undetermined origin.”

Common Pitfalls

- Caution is advised in evaluating the young, the elderly, pregnant women, and women of childbearing age. The diagnosis is often difficult, and many patients in these groups proceed to perforation.
- Reliance on the leukocyte count is unwarranted and usually leads to false reassurance.
- Overreliance on imaging studies may lead to a missed or delayed diagnosis. Imaging is most appropriate in patients with equivocal findings and moderate clinical suspicion.
- Failure to provide appropriate instructions and close follow-up for patients with abdominal pain without a clear diagnosis.

CHAPTER 109

Bowel Obstruction

Philip L. Henneman and Susan P. Torrey

Intestinal obstruction is a common disorder that has been recognized by physicians for centuries. It accounts for approximately 4% of patients presenting to an emergency department (ED) with nontraumatic abdominal pain of <7 days' duration. The challenge for the emergency physician is to promptly identify the patients with bowel obstruction from many patients presenting to an ED with abdominal pain and vomiting, without excessive testing or delays in diagnosis, treatment, surgical consultation, and admission (1,2).

Intestinal obstruction was associated with a 60% mortality in 1900. This has decreased to approximately 5% owing to early recognition, aggressive stabilization with fluid resuscitation, simple nasogastric decompression and, in many cases, surgical intervention. Mortality can still result from strangulation leading to bowel infarction and subsequent sepsis. Early recognition and initiation of treatment are the only ways for the emergency physician to minimize major morbidity or mortality.

Intestinal obstruction accounts for about 20% of all acute surgical admissions. The obstruction most commonly affects the small intestine but involves the colon in up to 20% of patients. The vast majority of bowel obstructions are caused by postoperative adhesions, accounting for 50% of small-bowel obstructions. Other common causes include inflammatory bowel disease (especially Crohn disease), hernias and neoplasm in adults, and intussusception, hernias, and congenital abnormalities in children. Fecal impaction,

foreign bodies, strictures, abscesses, trauma, and volvulus are other less common causes (2,3).

The stomach, small bowel, biliary tract, and pancreas secrete 8 to 10 L of fluid daily. Almost all of this volume is reabsorbed in the large bowel. Obstruction prevents the flow of fluid and intraluminal contents to the colon, resulting in accumulation in the more proximal sections of the bowel. This causes a gradual distention of the bowel proximal to the obstruction and increasing intraluminal pressure. As pressure increases within the bowel, hypersecretion of fluid into the bowel develops, and absorption from the bowel is retarded. Volume losses into the intraluminal space are variable but can be up to 9 L in 24 hours, causing significant depletion of intravascular volume. Further increases in intraluminal pressure result in capillary and lymphatic obstruction and then edema of the bowel wall. Retrograde peristalsis eventually develops, resulting in emesis. If allowed to progress, venous and finally arterial obstruction will occur. Bacterial overgrowth occurs in the stagnant bowel contents. Hemorrhagic necrosis, gangrene of the bowel, and leakage of contaminated contents ensue, resulting in bacterial peritonitis and sepsis. It is the goal of therapy to prevent these life-threatening complications (1–3).

CLINICAL PRESENTATION

Bowel obstruction should be considered in all patients with abdominal pain and vomiting, especially if they have a history of previous abdominal surgery or colorectal cancer. Pain is the initial and primary complaint, although it may be poorly appreciated or communicated in some patients. The pain is usually intermittent and colicky, with cramps occurring every 3 to 10 minutes, depending on the location of obstruction. Vomiting generally follows the development of abdominal pain, and the more proximal the obstruction, the earlier the vomiting begins. In obstruction of the colon, vomiting may not develop for 24 to 48 hours. Although obstipation (i.e., no passage of feces or flatus) is the rule once obstruction is complete, the passage of stool and flatus may

continue until the distal bowel is evacuated. Diarrhea may even occur when there is partial obstruction. Late in the course, abdominal distention may develop.

The patient's vital signs, including postural changes, may reflect the degree of volume depletion and in general are only modestly altered until late in the disease process. Hypotension and tachycardia imply advanced disease. Gangrenous bowel, however, may be present without fever or tachycardia. A helpful sign in diagnosing early small-bowel obstruction is the auscultatory finding of crescendo–decrescendo rushes of high-pitched peristalsis sounds coincident with the patient's crampy abdominal pain. Bowel sounds eventually decrease and disappear with overdistention and infarction of the bowel.

Abdominal tenderness is present in most patients. The determination of rebound tenderness is often complicated by the presence of distended bowel, which may give a false-positive result of increased pain with rapid decompression of the abdominal wall. The absence of percussion tenderness (tapping on the abdomen) or pain with jostling of the patient's gurney or bed implies that peritoneal signs are not present. The absence of local tenderness or rebound, however, does not exclude the possibility of vascular compromise or infarction. It is important to evaluate for the presence of an external hernia. An incarcerated hernia may be easily reducible, with immediate relief of the intestinal obstruction.

DIFFERENTIAL DIAGNOSIS

There are multiple reasons for abdominal pain and vomiting, including cholecystitis, hepatitis, pancreatitis, peptic ulcer disease, appendicitis, myocardial infarction, nonspecific abdominal pain, and pregnancy, to name a few. The presence of right upper quadrant tenderness should help to differentiate hepatobiliary disease. Elevated lipase or amylase will identify pancreatitis. Patients with peptic ulcer disease may have heme-positive stool. Appendicitis usually presents with right lower quadrant tenderness. The absence of abdominal tenderness may imply cardiac etiology in an elderly

patient with risk factors. Patients with kidney stones may complain of abdominal pain but do not usually have abdominal tenderness. An electrocardiogram may help diagnose myocardial ischemia, and patients with kidney stones usually have hematuria. A pelvic examination and pregnancy test will identify the pregnant patient. Colicky pain can be associated with appendicitis, cholelithiasis, kidney stones, or gastroenteritis. Diarrhea occurs in all patients with gastroenteritis but is an uncommon complaint in patients with bowel obstruction. Uremia and hepatitis can be associated with abdominal distention (ascites) and vomiting. Ascites and peripheral edema do not occur with bowel obstruction. The presence of jaundice should direct the emergency physician to the diagnosis of liver disease. Finally, air–fluid levels on abdominal x-rays are a common finding in patients with gastroenteritis, but frequent diarrhea, lack of distended loops of bowel, or fecal leukocytes will help in making the correct diagnosis.

ED EVALUATION

The patient's general appearance often helps to determine the severity of illness. A complete history and physical examination are critical in making the diagnosis of bowel obstruction. Ill-appearing patients require supportive treatment (e.g., monitor, intravenous fluid) before a complete history can be obtained. Inspection of the patient's vital signs is critical to determine the patient's volume status and risk of infection. Tachycardia and hypotension should prompt the emergency physician to provide immediate fluid resuscitation. The presence of fever indicates an infectious etiology for the patient's symptoms and implies bowel infarction if bowel obstruction is diagnosed. Evaluation of the skin will help to identify jaundice in the patient with hepatobiliary disease or poor capillary refill in a patient in shock. Auscultation of the lungs may reveal a pulmonary cause of the patient's symptoms. Inspection of the abdomen may reveal distention or surgical scars. Auscultation of the abdomen may reveal crescendo–decrescendo, decreased, or absent bowel sounds. Gentle palpation of the abdomen demonstrates areas

of tenderness, the presence of ascites or a mass, and the presence of guarding or rebound tenderness. Gentle tapping of the patient's costovertebral angle should be undertaken to determine the presence or absence of tenderness, which would imply renal disease.

Pelvic examination is appropriate in women with abdominal pain, looking for discharge, cervical motion or adnexal tenderness, or masses—none of which are usually present in patients with bowel obstruction. Rectal examination and testing of stool for occult blood, although important in the evaluation of patients with abdominal pain, should be delayed until an upright abdominal x-ray is obtained in patients for whom there is a high clinical suspicion of bowel obstruction. Digital examination may introduce air into the rectum, confusing the determination of complete bowel obstruction. Inspection and examination for an external hernia may identify the cause of a patient's complaints and lead to early reduction and relief of an obstruction.

Traditionally, the most important diagnostic test for bowel obstruction has been the upright abdominal x-ray (4). Patients who are too ill to stand can undergo a left lateral decubitus abdominal x-ray, which will reveal the same findings. X-ray findings in bowel obstruction include dilated loops of bowel, air–fluid levels, and strings of air pockets called the "string of beads" sign (Figs. 109.1 and 109.2). In approximately 15% of patients with bowel obstruction, the abdominal x-ray is normal or nondiagnostic, and the experience of the reviewer affects the accuracy of plain film interpretation (5). In one study, looking at discordance between radiology and emergency physicians' interpretation of abdominal x-rays, the most common missed abnormality by emergency physicians was bowel obstruction (6). If the bowel lumen is completely filled with fluid, it will not show the characteristic interface of air and fluid. Absence of air in the rectum may be a sign of obstruction unless the rectal examination was performed before the abdominal x-ray. Air within more distal portions of the bowel may be seen if the obstruction is only partial, and air–fluid levels may not develop in early and partial obstruction.

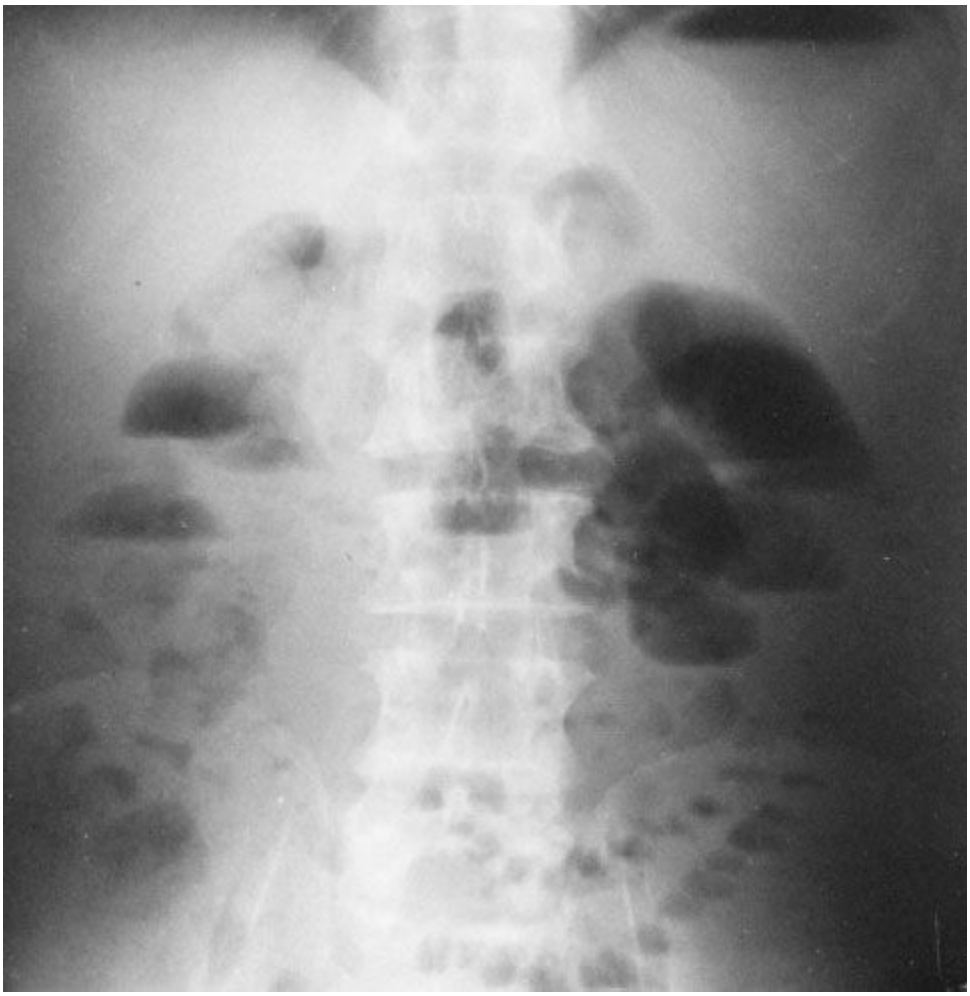

FIGURE 109.1 “Stepladder” pattern of air–fluid levels on upright view in patient with small bowel obstruction.

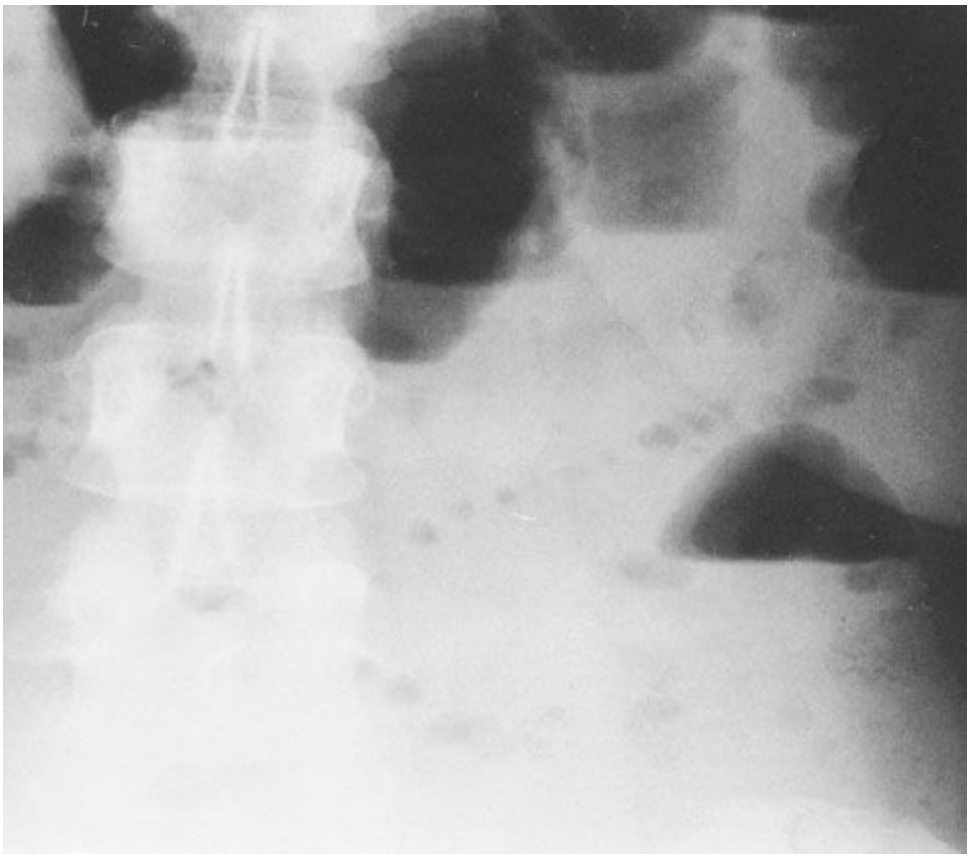

FIGURE 109.2 "String of pearls" sign on upright view in patient with small bowel obstruction.

Computed tomography (CT) has become an important tool in the diagnosis of bowel obstruction. Abdominal CT with water soluble contrast is superior to ultrasound and plain films in determining the presence, the level, and the cause of obstruction (1,4,7,8). Increasingly, the use of abdominal CT is advocated in determining the need for urgent surgery because of ischemic bowel or complete obstruction (1).

Patients with bowel obstruction may have metabolic abnormalities from profuse vomiting, third spacing of fluid into the lumen of the bowel, and resulting dehydration. Serum electrolytes, blood urea nitrogen, creatinine and glucose results should be obtained and abnormalities corrected. A lipase should be obtained if pancreatitis is being considered. An elevated lactate level may indicate bowel ischemia or a more toxic patient (9). A complete

blood count may reveal an elevated white blood cell count in an elderly patient without other signs of early sepsis, but this finding is nonspecific. A hemoglobin or hematocrit may be elevated from hemoconcentration or decreased from hemorrhagic complications of bowel necrosis or chronic blood loss from a malignancy. Clinical findings always trump laboratory results, which are nonspecific for bowel obstruction.

KEY TESTING

- Upright abdominal x-ray
- CT of the abdomen using water-soluble contrast.
- Complete blood count, electrolytes, BUN, creatinine, glucose, and lactic acid.

ED MANAGEMENT

An intravenous line should be started, and signs of hypovolemia should initiate prompt fluid resuscitation with normal saline. Several liters may be required for adults. Patients who are vomiting or nauseated should be treated with an antiemetic. Intravenous narcotic analgesia should be given early for relief of abdominal discomfort. Febrile patients or those with evidence of peritonitis should receive antibiotics active against bowel flora (2,7,10).

On confirmation of the diagnosis and after discussing the planned clinical course with the patient, a nasogastric tube should be inserted, after anesthetizing the nasal passage and posterior pharynx, and attached to intermittent suction. The gastric contents should be visualized to determine the presence or absence of blood. Surgical consultation should be obtained as soon as the diagnosis is made or immediately in patients with signs of peritonitis (2).

CRITICAL INTERVENTIONS

- Initiate fluid resuscitation, as many patients with bowel obstruction are hypovolemic.
- Administer antiemetics and narcotic analgesics for patient comfort.

- Place a nasogastric tube to allow decompression and reduce pain and distention.
- Facilitate surgical consultation and hospital admission.

DISPOSITION

Patients with bowel obstruction should be admitted to the hospital. Determining the appropriate hospital bed depends on the patient's condition and comorbid illnesses. Surgical consultation should be obtained promptly, with direct communication by the emergency physician. The challenge for the surgeon is to determine whether strangulation has occurred and whether the patient requires acute operative management or a 12- to 48-hour trial of observation and bowel rest (3,4,7,10).

Common Pitfalls

- Delay in promptly and aggressively treating hypovolemia.
- Delay or failure to treat a patient's symptoms with antiemetics and opioid analgesics.
- Extensive laboratory and radiographic testing that delays diagnosis and early consultation with a surgeon.
- Delay or failure to place a nasogastric tube after making the diagnosis of bowel obstruction.

CHAPTER 110
Hernias

Sharon E. Mace

A hernia is the protrusion of a structure or organ through the tissues that normally contain it. External or abdominal wall hernias are far more common than internal hernias and are the focus of this chapter (Fig. 110.1). Herniorrhaphy is the most common general surgical procedure in the United States and worldwide, accounting for 10% to 15% of all general surgery operations (1–3). Inguinal hernias account for about 75% of herniorrhaphies (4). Inguinal hernia repair is also the most commonly performed pediatric surgical operation (5). It is estimated that 5% of the adult male population has a groin hernia (6), but the actual prevalence may be higher since many hernias are asymptomatic or have only mild symptoms and may be undiagnosed. Abdominal hernias are the second most common cause of small bowel obstruction (6,7).

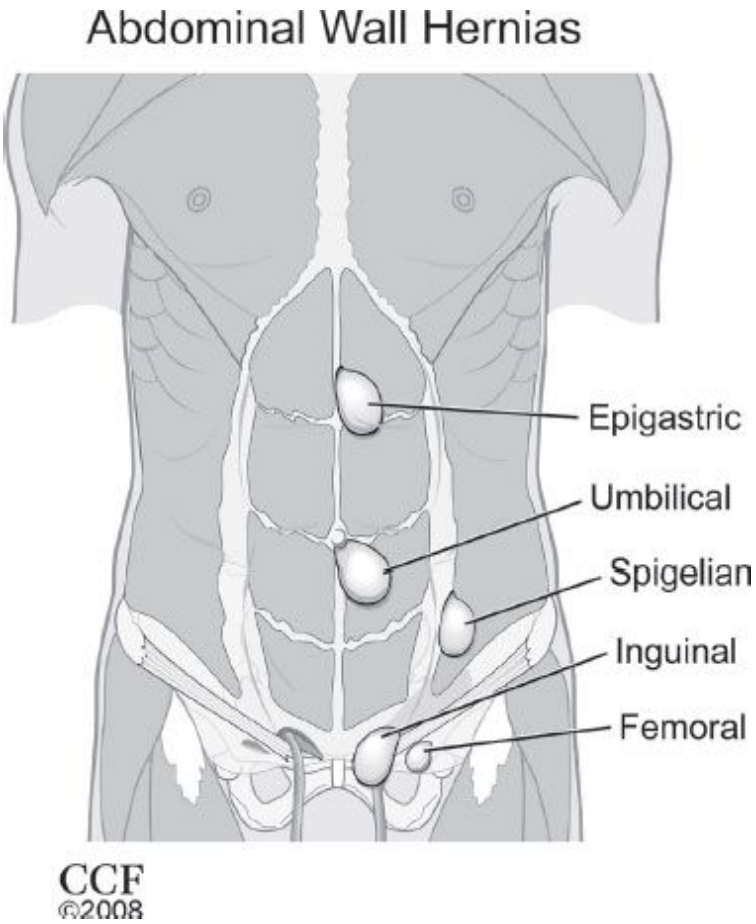

FIGURE 110.1 Abdominal wall hernias. (Reproduced with permission from Sharon E. Mace, MD, and Dave Schumick of the Cleveland Clinic Center for Art and Photography.)

Males are nine times more likely to have a groin hernia than females, while there is a marked female predilection (10:1) for femoral hernias. Femoral hernias are rare in men and direct hernias are rare in women. The most common hernia in either gender is an indirect inguinal hernia (Table 110.1).

TABLE 110.1
Relative Distribution of Hernias in Men and Women

Hernia Type	Men (%)	Women (%)
Indirect inguinal	53.6	32.9
Direct inguinal	27.4	1.5
Combination (direct and indirect)	7.6	3.1
Incisional	3.5	17.5
Femoral	2.8	11.1
Umbilical	2.3	16.6
Hiatal	2.2	14.8
Epigastric	0.66	2.5
Total	100	100

Percentages reproduced with permission from Ponka JL. *Hernias of the Abdominal Wall*. Philadelphia, PA: Saunders; 1980:85.

Age is also a factor affecting the incidence of hernia. For inguinal hernias, there is a bimodal distribution by age—those younger than 1 year and those older than 40 to 55, especially geriatric patients (7).

The cause of hernias is probably multifactorial: weak connective tissue with cellular and extracellular matrix defects, aging, and congenital defects; incisional and recurrent inguinal hernias may be due to surgical wound failure or technical limitations (8). Smoking and malnutrition can impair collagen structure (8). There is also a high prevalence of hernias in patients with connective tissue disorders such as Marfan syndrome, Ehlers–Danlos syndrome, Hurley–Hunter syndrome, and Down syndrome (8–10).

The “shutter mechanism” is a reflex contraction of the internal oblique and transversus abdominis muscles in response to increased abdominal pressure. It causes the inguinal ring to close like a sphincter around the spermatic cord, which protects against herniation. When the abdominal musculature is weakened (e.g., age, malnutrition, wasting, neuropathy), the protective shutter mechanism does not function optimally, and the risk of herniation is increased (11).

Increased intra-abdominal pressure (e.g., ascites, pregnancy, peritoneal dialysis) may also contribute to the development of a hernia. If the transversalis fascia is weakened or thinned or a patent processus vaginalis is present, a hernia may develop. Physical exertion precipitates the development of an inguinal hernia in $<10\%$

of patients, except when worker's compensation is a consideration (12). The fact that athletes such as weightlifters do not have a higher incidence of inguinal hernias supports the current view that a specific episode of physical exertion is not a major risk factor for a hernia.

A *reducible hernia* is defined as one in which the herniated structures can be returned through the abdominal wall defect back into the abdominal cavity. An *irreducible hernia* cannot be returned through the abdominal wall defect back into the abdominal cavity. Another term for an irreducible hernia is an *incarcerated hernia,* which is sometimes mistakenly used to imply an irreducible hernia about to become strangulated.

A *strangulated hernia* is one in which the blood supply to the herniated structures is compromised. Gangrene may occur if the vascular compromise is not relieved. A strangulated hernia is a life-threatening situation requiring emergency treatment and surgical intervention. Hernias with a small neck or opening and a large sac have a tendency to strangulate. All strangulated hernias are irreducible or incarcerated, but not all irreducible or incarcerated hernias are strangulated.

Hernias can be classified as an external, internal, or interparietal. An *external* hernia protrudes completely through the abdominal wall to the outside and, thus, can be seen and palpated. Examples include incisional, umbilical, inguinal, and femoral hernias. An *interparietal* hernia is a rare hernia in which the hernial sac is contained within the abdominal wall. An *internal* hernia is one in which the herniated part occurs within the confines of a body cavity. Internal hernias include diaphragmatic hernias, hernias through a tear in the mesentery or omentum, and hernias through the foramen of Winslow into the lesser sac. Internal hernias are much less common than external hernias and can be very difficult to diagnose.

Hernias occur where there is a weakness in the abdominal wall so that peritoneum and other internal abdominal structures or organs can protrude through the abdominal wall defect. Thus, hernias represent a failure of the abdominal wall to contain the abdominal structures or viscera. The intestines are the most common structure

undergoing herniation, but all intraperitoneal structures can herniate, from a tiny piece of omentum to an entire organ.

Groin hernias, which include *inguinal hernias* (both direct and indirect) and *femoral hernias,* are the most common, accounting for 85% of all hernias (80% groin, 5% femoral). Adding umbilical and incisional hernias to groin hernias would raise the total to 95% to 98% of all hernias.

Inguinal hernias are superior to the inguinal ligament, whereas the femoral hernia is inferior to the inguinal ligament (Fig. 110.2). The indirect inguinal hernia passes through the internal (or deep) inguinal ring and into the inguinal canal and lies lateral to the inferior epigastric vessels. The direct hernia lies medial to the inferior epigastric vessels and protrudes through Hesselbach triangle, which is bounded by the inferior epigastric artery, the lateral border of the rectus abdominis muscle, and the inguinal ligament. Of all inguinal hernias, about two-thirds are indirect.

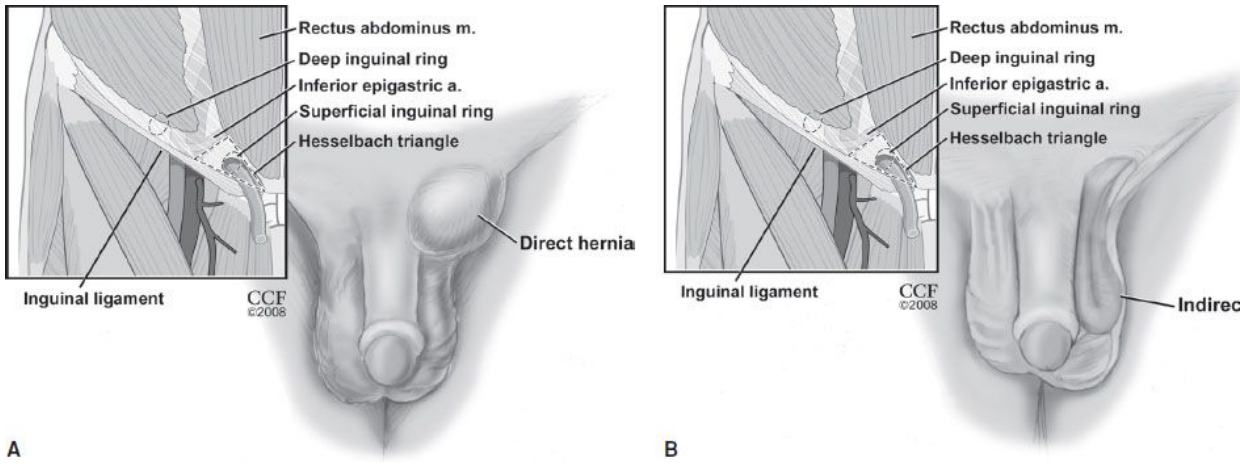

FIGURE 110.2 Inguinal hernias. **A:** Direct inguinal hernia. **B:** Indirect inguinal hernia. (Reproduced with permission from Sharon E. Mace, MD, and Dave Schumick of the Cleveland Clinic Center for Art and Photography.)

An indirect inguinal hernia follows the path of a patent processus vaginalis. The processus vaginalis is formed during fetal development to allow the descent of the testes in the male from their original retroperitoneal site into the scrotum (Fig. 110.3). If the processus

vaginalis fails to close off after birth, an indirect hernia may occur, allowing abdominal contents to progress down the inguinal canal into the scrotum.

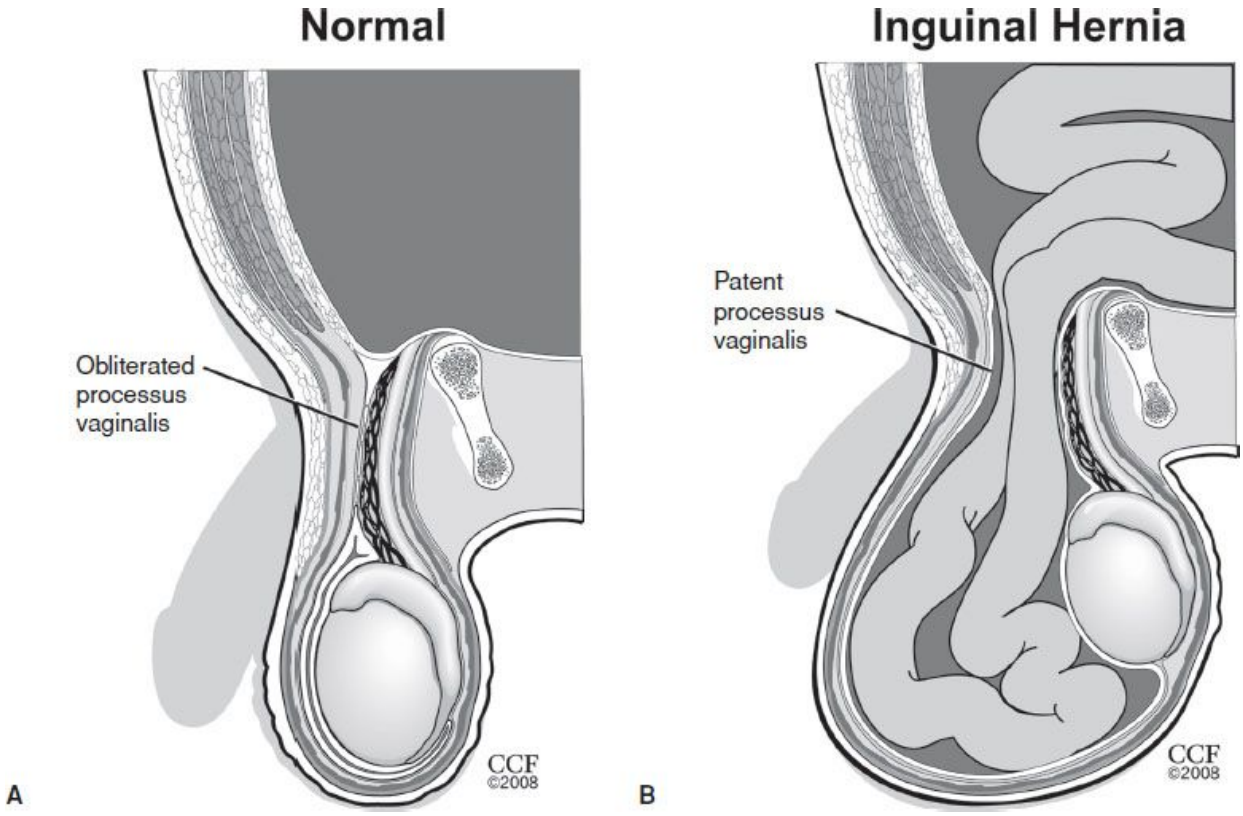

FIGURE 110.3 Processus vaginalis. **A:** Normal, fusion of processus vaginalis. **B:** Inguinal hernia, complete failure of fusion of processus vaginalis. (Reproduced with permission from Sharon E. Mace, MD, and Dave Schumick of the Cleveland Clinic Center for Art and Photography.)

A femoral hernia is the protrusion of abdominal contents between the femoral vessels (artery and vein) and the lacunar ligament in the femoral canal. Femoral hernias occur almost exclusively in women and, because of the narrow neck or opening, they frequently incarcerate.

Less common types of abdominal wall hernias include epigastric, pelvic, lumbar, and spigelian hernias. *Epigastric hernias* are hernias that occur in the midline of the abdominal wall between the umbilicus and the xiphoid. *Pelvic hernias* involve the protrusion of

abdominal contents through areas in the floor of the abdominal cavity. The *obturator hernia* involves herniation through the obturator foramen and generally occurs in elderly women. *Lumbar hernias* occur in the superior and inferior lumbar triangles, which are two naturally weak regions of the posterior abdominal wall. *Spigelian hernias* are protrusions of abdominal contents lateral to the rectus abdominis muscle through the external oblique fascia (Fig. 110.1).

Ventral hernias include umbilical, epigastric, and spigelian hernias. *Incisional hernias* constitute about 10% of all hernias and result from postincisional weakness of the anterior abdominal wall. Incisional hernias of the abdominal wall occur in up to 20% of postoperative patients and up to 35% to 50% of those with a postoperative wound infection or dehiscence. There is a 6% incidence of trocar site hernias following laparoscopic surgery. Parastomal hernias are reported in nearly half (50%) of ostomies (6).

Umbilical hernias in adults, unlike those in pediatric patients, result from an acquired rather than a congenital defect and are usually due to increased intra-abdominal pressure. Patients with increased intra-abdominal pressure, such as peritoneal dialysis, ascites, pregnancy, or obesity, have a higher incidence of umbilical hernias. Umbilical hernias occur in about 20% of patients with cirrhosis and ascites. Elective repair is often recommended for umbilical hernias in adults since there is a greater incidence of complications, including incarceration and spontaneous rupture than in children and infants (7). Ulceration and perforation are complications that are associated with high morbidity and mortality, especially in cirrhotic patients. Skin changes with maceration and ulceration usually occur before frank rupture occurs and so patients with these findings need referral for urgent repair (6). Strangulation of an umbilical hernia precipitated by rapid fluid removal during paracentesis has been reported. Therefore, before paracentesis is performed, an umbilical hernia should be reduced (6).

PEDIATRIC CONSIDERATIONS

In pediatric patients, the incidence of inguinal hernias is greatest in infancy (age 0 to 12 months) with a peak in the first month of life.

The overall incidence of pediatric inguinal hernia is 4%. There is an increased incidence in premature infants, with 30% of infants weighing <1,000 g having an inguinal hernia (9,13).

Inguinal hernia repair is the most common surgical procedure in children (5). As with adults, hernias are much more common in males than females, with a ratio of about 10:1 (5). Most children with an inguinal hernia are asymptomatic; the hernia is discovered by the parent changing the infant's diaper or by a physician during a routine examination. However, incarceration and strangulation can occur. It has been estimated that 70% of incarcerated hernias occur in infants younger than 1 year (14) and the rate of incarceration in premature infants with an inguinal hernia is as high as 31% (5). Most incarcerated hernias (90%) can be reduced outside the operating room (15). As with adults, if the hernia cannot be reduced, immediate surgery is warranted owing to the risk of subsequent strangulation (5).

Umbilical hernias are very common in infants, occurring in 10% of infants, with a higher incidence in African American infants (20%) versus white infants (3%) and in premature infants occurring in up to 75% of infants <1,500 g (10). The majority of umbilical hernias in infants close spontaneously by 2 years of age, and rarely incarcerate or strangulate. "Strapping" is not an effective treatment. Surgery is generally not recommended unless the hernia becomes strangulated, persists to age 5 years, becomes progressively larger after 1 to 2 years of age, or is symptomatic (9).

CLINICAL PRESENTATION

The most common presenting complaints of a symptomatic hernia are swelling and pain. If there is an acute incarceration, there may be the sudden onset of severe pain with nausea and vomiting. The pain occurring with an acute incarcerated hernia is caused by edema and inflammation of the herniated structures and the surrounding tissues. Incarcerated hernias are the second most common cause of bowel obstruction in the United States, with postoperative adhesions being first. If strangulation is present, the patient may present with pain, distention, peritonitis, vomiting, fever, or sepsis.

Occasionally, the initial symptoms may be somewhat misleading. In some patients, the pain from an incarcerated groin hernia may be located in the epigastrium because of traction on the abdominal contents from the hernia. In other patients, strangulation can occur without any symptoms and signs of bowel obstruction when only part of the bowel wall is herniated. This occurs with a *Richter hernia,* in which only one side of the intestinal wall is within the hernia sac.

Pain and/or hypesthesia located along the medial aspect of the thigh radiating to the knee owing to irritation of the obturator nerve (Howship–Romberg sign) occurs in half of patients with an obturator hernia.

DIFFERENTIAL DIAGNOSIS

The most common diagnoses to consider in a patient presenting with a groin mass are an inguinal hernia, enlarged inguinal lymph node(s), abscess, hydrocele, and testicular pathology such as torsion of an undescended testicle in an infant (Table 110.2).

TABLE 110.2
Differential Diagnosis of Groin and Scrotal Masses

- Groin hernias
  - Indirect inguinal (most common groin hernia in men and women)
  - Direct inguinal
  - Femoral
- Urologic
  - Hydrocele
  - Varicocele
  - Spermatocele
  - Testicular torsion
  - Torsion of appendix testis ("appendix epididymis")
  - Urologic tumors
    - Testicular tumor
    - Spermatic cord tumor
  - Undescended testes (especially in pediatric patients)
  - Retractile tests (especially in pediatric patients)
  - Epididymitis (also listed under infections)
  - Epididymal cyst
- Infectious
  - Lymph nodes (may be from infection or malignancy)
  - Epididymitis
  - Cellulitis of groin
  - Sexually transmitted disease (such as lymphogranuloma venereum)
  - Psoas abscess
- Vascular (involvement of femoral vein or artery)
  - Femoral artery aneurysm
  - Femoral thrombophlebitis
  - Femoral saphenous vein varices

ED EVALUATION

History should include questions about previous operations or hernia. Also noteworthy is whether the patient has noted variability in the size of the hernia related to activity or lying flat. Physical examination should include inspection and gentle palpation for any bulges or masses. Cooperative patients may be asked to cough or strain, which increases intra-abdominal pressure, in an attempt to demonstrate the hernia. Palpation of the external inguinal ring in a standing male patient may also be helpful in detecting an inguinal hernia.

Laboratory tests are generally not helpful unless the patient has developed an incarcerated or strangulated hernia. In such cases, leukocytosis with a left shift may be present, although these findings are not sensitive or specific. Dehydration with electrolyte abnormalities and an elevated BUN also occurs frequently in patients with incarceration or strangulation.

Acute abdominal series radiographs may be helpful if bowel obstruction is suspected. The upright chest roentgenogram can rule out free air under the diaphragm resulting from perforation or dead bowel. Computed tomography scan and ultrasound are also useful in demonstrating a hernia and whether it contains bowel, when the diagnosis is in doubt, or an acute complication is suspected. One study reported 100% sensitivity and specificity for the diagnosis of groin hernia by bedside emergency ultrasound (16).

KEY TESTING

- History and physical examination alone are adequate in most cases.
- CT scan and ultrasound are useful in equivocal cases or to evaluate for complications.

ED MANAGEMENT

Patients with hernias can be grouped into three categories: (a) asymptomatic or minimal symptoms (swelling or mild discomfort) with a reducible hernia, (b) irreducible but not strangulated hernia, and (c) strangulated hernia.

Although surgery is indicated for the majority of patients with complications or significant symptoms related to their hernia, a recent clinical trial comparing routine surgical repair versus observation for asymptomatic patients with inguinal hernias concluded that “watchful waiting” is an acceptable option for men with minimally symptomatic inguinal hernias (17). Although used in the past, trusses are generally not recommended (18) and may actually be harmful in some cases (19). If the irreducible hernia is acute (and there is no evidence for strangulation), nonsurgical

reduction should be performed. Cool compresses may be placed over the hernia site to diminish pain, edema, local blood flow, and decrease intraluminal gas pressure. Appropriate sedation should be given. If the patient has a groin hernia, he or she may be placed in the Trendelenburg position. The hernia may spontaneously reduce. If not, gentle manipulation (or taxis) may be attempted. Slow, steady compression should be used, not forceful attempts.

If the acute, incarcerated hernia cannot be reduced, emergency surgery should be performed as soon as fluid and electrolyte abnormalities are corrected. Complications of manual hernia reduction include partial reduction and hernia reduction en masse. Hernia reduction en masse is a rare complication in which the hernia sac is manipulated into the preperitoneal space. This gives the false impression that the hernia has been reduced although it is still incarcerated and at risk for strangulation.

The patient with a strangulated hernia requires aggressive resuscitation with fluids and blood as needed and emergent surgical consultation for operative intervention. Gastric decompression with a nasogastric tube is appropriate if bowel obstruction is present. Broad-spectrum antibiotics are also advised in the acutely ill or potentially septic patient.

CRITICAL INTERVENTIONS

- Reduction of an incarcerated hernia
- Aggressive resuscitation and early surgical consult for patients with a strangulated hernia

DISPOSITION

Patients with an asymptomatic or a reducible hernia should be given discharge instructions, which include the warning signs of incarceration and strangulation. They need referral to general surgery for evaluation for possible elective herniorrhaphy.

For patients with a hernia that has been reduced in the emergency department, urgent surgical referral for herniorrhaphy is recommended, as the incidence of recurrence is high.

Admission for surgical management is mandatory for acute, incarcerated hernias that cannot be reduced and for all strangulated hernias.

Common Pitfalls

- Failure to identify an incarcerated or strangulated hernia.
- Failure to diagnose a small hernia.
- Failure to make an appropriate referral to a surgeon.
- Failure to aggressively resuscitate a patient with a strangulated hernia.

CHAPTER 111

Inflammatory Bowel Disease

Howard A. Werman, Sarah M. Greenberger, and Nicholas E. Kman

Inflammatory bowel disease (IBD) comprises two chronic intestinal disorders: *ulcerative colitis* (UC) and regional enteritis or *Crohn disease.* Both are characterized by recurrent episodes of gastrointestinal symptoms separated by periods of remission, and both are associated with a variety of systemic manifestations. Approximately 10% to 15% of patients with IBD have clinical features and endoscopic findings that do not allow clear classification. Emergency physicians must be familiar with IBD for two reasons. First, these disorders must be considered in the differential diagnosis of patients with chronic recurrent gastrointestinal complaints. Second, patients with established diagnoses of IBD may present to the emergency department (ED) for management of exacerbations and complications of their disease.

The cause of both disorders remains unknown. Immunologic, infectious, genetic, dietary, environmental, and psychological factors have been implicated. An abnormal immune response to enteric bacteria in genetically susceptible hosts appears to be the underlying disease mechanism (1). The role of steroids and immunosuppressive agents in treatment of UC and the efficacy of agents such as antitumor necrosis factor in treatment of Crohn disease further suggest that immunologic factors play a prominent role in IBD.

IBD affects approximately 1.4 million Americans (2). For both diseases, there is a bimodal age distribution at onset, with peaks at 15 to 25 years and at 55 to 60 years (3); 25% to 30% of patients with Crohn disease and 20% of patients with UC are younger than 20 years old. 10% to 15% of patients with IBD, particularly those with early onset of disease, have relatives who are also affected. The incidence and prevalence of Crohn disease is increasing in the United States for reasons that are unclear (4).

UC tends to remain localized to the colon; in the majority of patients, the disease is found in the rectum and left colon only. The entire colon is affected (pancolitis) in the most severe cases. UC usually is limited to the intestinal mucosa and submucosa and occurs in an uninterrupted pattern.
